It is well known that anomalous phenomena of absorption take place at the Laue-Bragg reflecting position in a single crystal for X-rays[1]. In electron diffraction, too, similar phenomena take place. Honjo et al[2] found the difference in the absorption coefficients of two wave fields and the present authors[3] observed the anomalous transmission corresponding to the Borrmann effect[4]. On the other hand, it was theoretically explained by Yoshioka[5] that the effect of inelastic scattering in electron diffraction can be represented by the imaginary potential in the same way as in the case of X-ray diffraction. But there has been no quantitative study of the anomalous absorption coefficient for electrons.** We have measured the mean and anomalous absorption coefficients of electrons for MgO crystals by the use of electron micrographs.

Fig. 1 is an example of bright field electron micrographs of MgO crystals, where the equal thickness fringes due to the (200) reflection are seen. Fig. 2 gives the intensity curve along the line indicated by the arrow in Fig. 1. Taking into account the effect of absorption in the dynamical theory, the transmitted intensity is given by the following equation which is analogous to the one in the case of X-ray diffraction[7]:

$$I_t=\frac{1}{2}I_0\left\{\frac{\cos(\sqrt{1+w)}\,|v_h|\lambda t/2\pi)}{\sqrt{1+w^2}}e^{-\mu_0 t}\right.$$
$$+\frac{1}{2}\left(1+\frac{w}{\sqrt{1+w^2}}\right)^2 e^{-(\mu_0-\varDelta\mu)t}$$
$$\left.+\frac{1}{2}\left(1-\frac{w}{\sqrt{1+w^2}}\right)^2 e^{-(\mu_0+\varDelta\mu)t}\right\}, \qquad (1)$$

where

$$\mu_0=\frac{v_{oi}\lambda}{2\pi\sqrt{1+w^2}}, \qquad (1a)$$

$$\varDelta\mu=\frac{|v_{hi}|\lambda}{2\pi\sqrt{1+w_2}}. \qquad (1b)$$

I_0 is the intensity of the incident wave, t the thickness, w a parameter indicating the deviation from the Laue-Bragg condition, v_h the h-th Fourier coefficient, and v_{oi} and v_{hj} the o-th and h-th coefficients of the imaginary potential, respectively. t is known from the magnification of the electron micrograph and w is determined from the period of the fringe. For v_h the calculated value used by Honjo et al[2] is here also used. The first term in (1) corresponds to the fringe pattern indicated by **a** in Fig. 2, and the sum of second and third terms to the background indicated by **b**. From the curve **a** the mean absorption coefficient is determined, and from the curve **b** the anomalous absorption coefficients of the two wave fields.

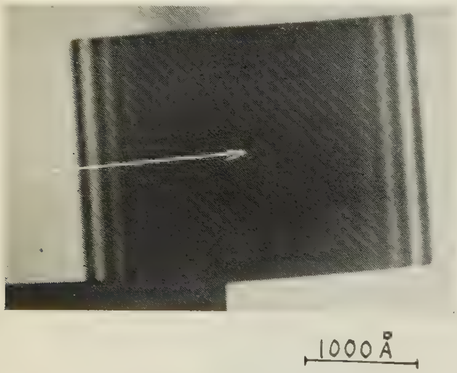

Fig. 1. A bright field electron micrograph of MgO crystal.

Table I.

Accelerating voltage (kV)	$l_0=\mu_0^{-1}$ (A)	$l'=(\mu_0-\varDelta\mu)^{-1}$ (A)	$l''=(\mu_0+\varDelta\mu)^{-1}$ (A)	w	v_{oi} (ev)	$\|v_{hi}\|$ (ev)
40 (theory)	—	—	—	—	1.47	0.068
50	230 260	1840 1460	140 130	0.19 0.14	1.85	1.54
75	670 625	2500 1790	260 490	~0 ~0	0.84	0.62

It is to be noted that the observed intensity involves contributions from not only elastic but also inelastic scatterings, whereas the theory is concerned only with the former. In the present paper, however, neglecting the contribution from inelastic scattering, the values for the (200) reflection at 50 and 75 kV were determined as shown in Table I, where theoretical values at 40 kV[5] are also given for comparison. Measurements are being extended to 100 kV, and similar procedures are applied to the

On the Ferrimagnetic Resonance of Europium Iron Garnet

By W. P. WOLF

J. Phys. Soc. Japan **15** (1960) 2104

The following footnote was omitted at the end of the above communication:

(7) Measurements on single crystals have recently been reported by T. Miydai, H. Takata, Y. Shichijo and N. Tsuya, J. Phys. Soc. Japan **15** (1960), 1354. The results are essentially similar to the polycrystalline values, but the agreement with our theory is even closer, especially at low temperatures. It may be noted that the theoretical curve shown by Miydai et al. is identical to our calculated line although it is derived from a basically different assumption: see footnote (6).

Angular Distributions of Protons from the Alpha Particle Bombardment of B^{10}, N^{14}, O^{16} and Ne^{20}

By Hisashi YAMAGUCHI

Institute for Nuclear Study, University of Tokyo,
Tanashi-Machi, Kitatama-Gun, Tokyo

(Received December 26, 1960)

Angular distributions of protons from the alpha particle bombardment have been obtained for the following transitions, corresponding to discrete states of the residual nuclei: $B^{10}(\alpha, p)C^{13}$ ground at bombarding energies 27.5 and 33.1 MeV; $N^{14}(\alpha, p)O^{17}$ ground, first, second, third at bombarding energies 26.8, 28.1 and 33.3 MeV; $O^{16}(\alpha, p)F^{19}$ ground to second (unresolved), third to fifth (unresolved), sixth at bombarding energies 26.7 and 33.1 MeV; and $Ne^{20}(\alpha, p)Na^{23}$ ground and first (unresolved), second to sixth (unresolved) at bombarding energy 26.9 MeV. These angular distributions show the so-called diffraction patterns and some of them are interpreted with the aid of predictions of the direct interaction theory. However, some deviations from the predictions of the direct interaction theory exist and suggest the effect of other nuclear reaction processes.

§ 1. Introduction

In the past few years a few experimental studies of angular distributions of (α, p) reaction have been reported. Eisberg, Igo and Wegner[1] studied the spectra of protons from heavy elements at 40 MeV alpha particle energy and they suggested noncompound nucleus processes in the region of small excitation energy in the residual nucleus.

On the lighter elements, several angular distributions of protons from B^{10}, C^{12}, F^{19}, Na^{23}, Al^{27} and P^{31} have been measured at low and intermediate alpha particle energies[2)-5)]*. On the reaction mechanism of (α, p) reaction in intermediate energy region, a few theoretical treatments exist so far.[6)-9)] Generally, the treatment analogous to the knock-on process (surface) for the (p, n) or (p, p'), and to the stripping process for the deuteron induced reaction are used. Neglecting the detailed discussion, the differential cross sections for such direct interaction theories are shown to be in proportion to the square of the spherical Bessel function of appropriate order. Some experimental results have been interpreted with the aid of predictions of such direct interaction theories. S. T. Butler[6] compared his formula (surface) to the results for $C^{12}(\alpha, p)N^{15}$ ground at 30.5 MeV alpha particle energy obtained by C. E. Hunting and N. S. Wall. Also C. E. Hunting and N. S. Wall[2] compared their results for $B^{10}(\alpha, p)C^{13}$ ground, $Al^{27}(\alpha, p)Si^{30}$ ground and $P^{31}(\alpha, p)S^{34}$ ground at 30.4 MeV alpha particle energy to the Butler formula. In these comparisons the theoretical curves were fitted well to the experimental ones, but for the case of B^{10} the interaction radius was rather small and for the case of Al^{27} the agreement was not so good. P. von Hermann and G. F. Pieper[3] compared their results for $B^{10}(\alpha, p)C^{13}$ ground at 4.9, 7.0 and 8.1 MeV alpha particle energies and $P^{31}(\alpha, p)S^{34}$ ground at 7.0 and 8.1 MeV alpha particle energies to $|j_l(QR)|^2$ (surface) and got partial fits in these comparisons. G. F. Pieper and N. P. Heydenburg[4] also compared their results for $F^{19}(\alpha, p)Ne^{22}$ ground at 6.25 and 6.40 MeV alpha particle energies to $|j_l(QR)|^2$ (surface) and showed good fits. In the experiment above mentioned[4] Pieper and Heydenburg have measured angular correlations of gamma ray from the first excited state of Ne^{22} with the alpha particle and proton directions at 6.10 and 6.40 MeV alpha particle energies. The results at 6.40 MeV bombarding energy agree with predictions based on simple direct interaction mechanism, but the results at 6.10 MeV do not show the same agreements as that for the 6.40 MeV.

In a previous paper[5] we have showed the angular distributions for the reaction $C^{12}(\alpha,$

---

* In the reference 5), other references of the reaction $C^{12}(\alpha, p)N^{15}$ were listed.

$p)N^{15}$ ground for twelve bombarding energies in the region of 25 to 39 MeV. These angular distributions changed remarkably with the variation of the bombarding energies, particularly in large angles.

To study the mechanism of the (α, p) reaction, such energy dependence of angular distribution is very interesting. In this paper we wish to show the results of the measurements of the angular distributions for the (α, p) reactions of B^{10}, N^{14}, O^{16} and Ne^{20} at 27, 28 and 33 MeV alpha particle energies.

§ 2. Experimental Methods

The external alpha particle beam from the I.N.S. (Tokyo) variable energy cyclotron[10] was brought into a scattering chamber of 100 cm in diameter. The beam focusing system and the scattering chamber used in this experiments are the same as our previous experiment[5] except for the case of gas target bombardment such as nitrogen, oxygen, and neon. In the bombardment of gas target, we used a gas chamber which was made of a brass cylinder of 9 cm in diameter and of 6 cm in height and had two windows extending over the angular range of more than 90° corresponding to "forward counter" and "backward counter," each including the beam entrance (backward) and the beam exit (forward). Each window was covered with a sheet of aluminum foil of 20μ in thickness. The slit front of the scintillation counter which was used in the case of solid target was replaced by a set of slits by which the solid angle and the target thickness were defined.

As the targets we used N_2 of 39 cm Hg, O_2 of 40 cm Hg, Ne of 43 cm Hg at room temperature respectively, and the film of natural boron suspended in polystyrene of about 6.0 mg/cm² thickness. N_2 and O_2 were the commercial gases guranted 99% in purity by the dealer and Ne was a reagent graded gas guranted 98% in purity by the dealer. The boron target was prepared by the method described by N. S. Wall[11].

The beam energy was determined by the measurement of its range in aluminium. For the calculation of alpha particle energy from the measured range in aluminum we used the range-energy curve of protons in aluminum of W. A. Aron et al.[12]. The absolute value of the beam energy is in accuracy of a few %. The incident beam energy spread was estimated to be within about 0.5%.

For identification of the levels[13),14] involved in these reactions, the energies of the detected proton groups were calculated from the kinetics and the incident alpha particle energy, and compared to the energy of the recoil protons produced by the scattering of the alpha particles from the hydrogen atoms contained in the target.

In order to obtain an absolute differential cross section, we used following formula for the gas target

$$\sigma(\Theta)=N\frac{1}{nI}\frac{1}{G}\sin\Theta \qquad (1)$$

where N is the number of protons entering the detector, n is the number of target nuclei in a unit volume, I is the number of alpha particles that traversed the target, and $G=(b\pi r^2)/(hR_0)$ is the geometrical factor of the slit system which is shown in Table I. For the B^{10} case, we could not estimate the absolute differential cross section owing to unknown boron content of the target.

Table I. Slit dimensions (in millimeters).

	Foreward counter	Backward counter
In the case of Boron;		
Diameter of slit, $2r$	8.0	8.0
Distance from the target center to slit, R_0	250	218
In the case of gas target;		
Width of front slit, b	5.0	5.0
Diameter of rear slit, $2r$	8.0	8.0
Distance from the target center to rear slit, R_0	260	223
Distance between slits, h	143	131
Geometrical factor, G	6.76×10^{-3}	8.60×10^{-3}

The errors indicated in the figures of angular distributions include those from two sources, one being the error in the estimation of background subtraction and the other being the statistical errors. These errors were generally small, but in the larger angles increasing background and decreasing energy of detected proton group made these errors serious, particularly in the weak proton groups, such as $N^{14}(\alpha, p)O^{17}$ first and second, estimated errors reached a few tens percent.

§ 3. Results and Discussions

The observed angular distributions for the (α, p) reactions are listed in Table II and shown in Fig. 1. In Fig. 2 the differential

* In the case of B^{10} the relative values of the total cross section to the 27.5 MeV's are shown.

cross sections for the case of nitrogen and oxygen at fixed angles are shown as functions of bombarding energies. In Table II and Fig. 3 the total cross sections σ_t are also shown. For the B^{10} case, the relative values of σ_t compared to the value at $E_\alpha=27.5$ MeV are shown in Table II. Tabulated data for all the results are given in Ref. 15).

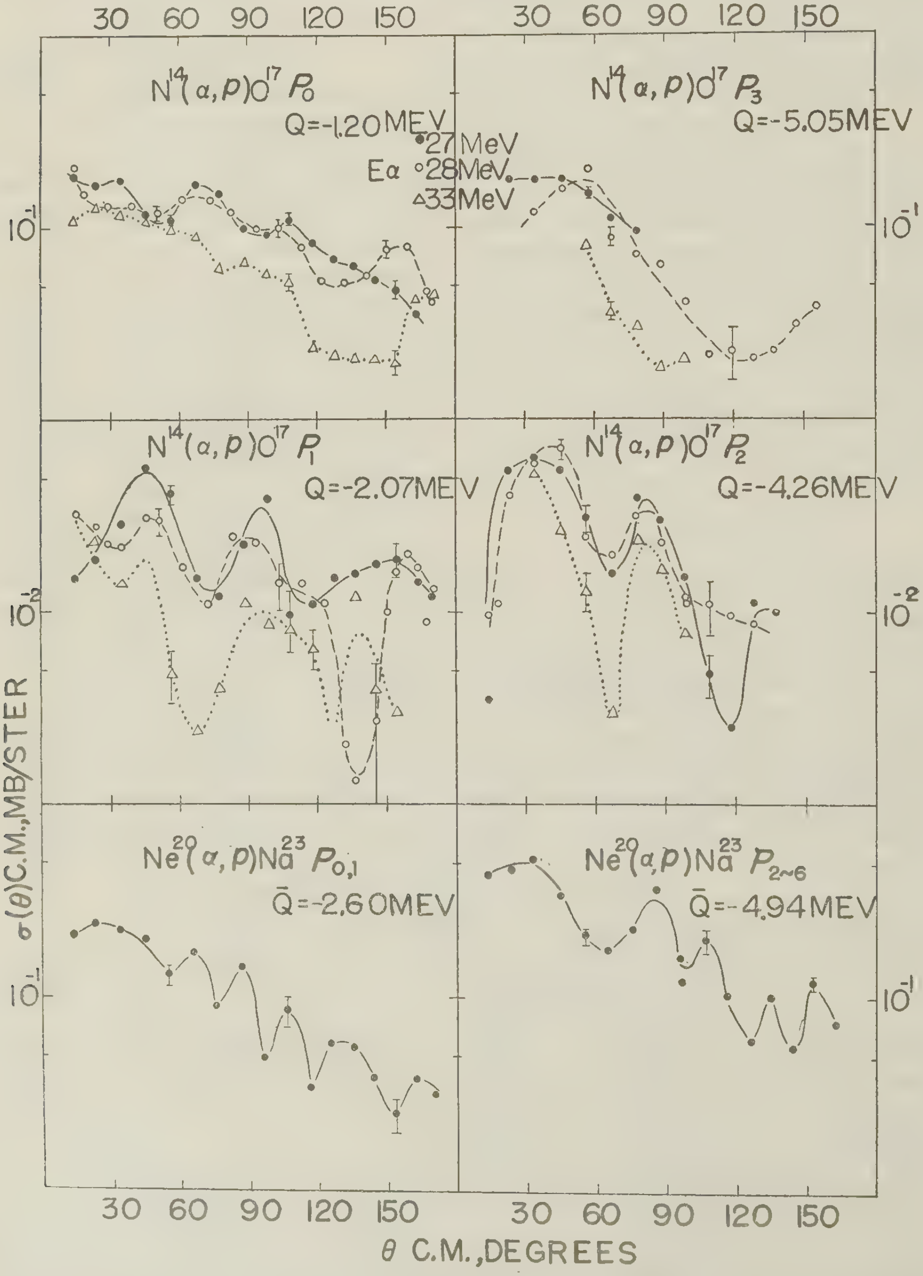
(1) *Angular distribution*

As mentioned in the Introduction, the angular distributions of the (α, p) reaction are compared to the predictions of the direct interaction theories.

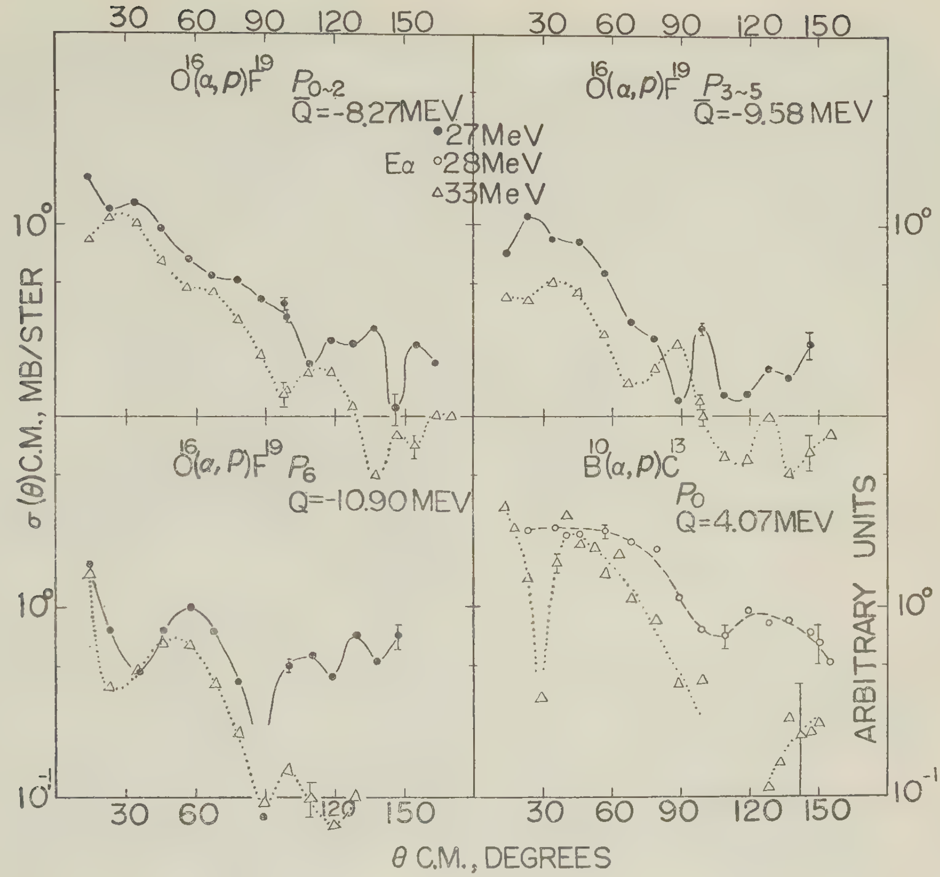
Under the assumption of a knockout process, the differential cross section has the following form

$$\sigma(\theta) \propto |f(\theta) j_l(QR)|^2 \tag{2}$$

where $f(\theta)$ is a form factor, j_l is the spherical Bessel function of order l, Q is the momentum transfer vector defined by the form

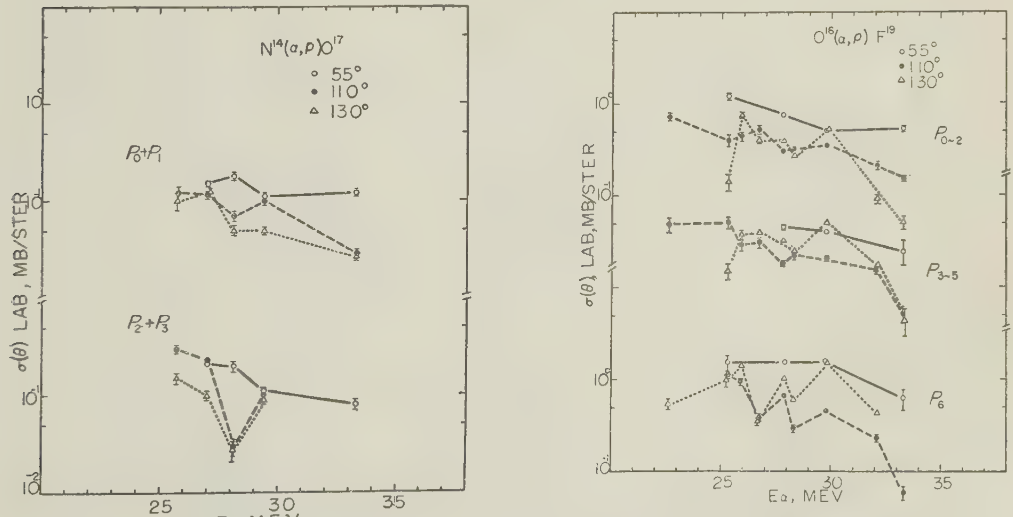


(a)



(b)

Fig. 1. Angular distribution of protons from the alpha particle bombardment of B^{10}, N^{14}, O^{16} and Ne^{20} at $E_\alpha=27$(●), 28(○) and 33(△) MeV. Representative errors are shown.



(a)

(b)

Fig. 2. Differential cross sections for the reactions $N^{14}(\alpha, p)O^{17}$ ground and first, second andthird; and $O^{16}(\alpha, p)F^{19}$ ground to second, third to fifth, sixth as functions of alpha particle energies at laboratory angles 55°, 110°, and 130°.

$$Q=\left(\frac{M_x-M_p}{M_x}\right)\left(K_\alpha-\frac{M_x}{M_y}K_p\right) \qquad (3)$$

where M_x, M_y, and M_p is the mass of the target, the residual nucleus and the proton respectively, and the K's are the wave vector of the alpha particle, and proton. R is the interaction radius, and l is the change of angular momentum, which is limited by the selection rule

$$|J_x+J_y+i|_{\min}\leqslant l\leqslant J_x+J_y+i \qquad (4)$$

where J_x is the spin of the target nucleus, J_y is the spin of the residual nucleus, and i is the vector sum of the spins of the entering and emerging particles. l must be odd if the parity of the residual nucleus differs from that of the target nucleus, and must be even if the parities are the same. Under the assumption of a stripping process, the differential cross section, also, has the form of Eq. (2). In this case, Q is defined by the form

$$Q=K_\alpha-\frac{M_x}{M_y}K_p\,. \qquad (5)$$

The differential cross sections of these two processes have similar expressions and we are not able to distinguish these two processes from the results of the angular distribution measurements.

Other mechanisms for the (α, p) reaction are heavy particle stripping and triple or double stripping. In heavy particle stripping, the differential cross section is of the same form of Eq. (2) but Q as defined as $Q=K_\alpha+(M_\alpha/M_y)K_p$ and this process interfers with ordinary stripping. This assumption was originally used by G. E. Owen and L. Madansky[16] for the analysis of the $B^{11}(d, n)C^{12}$ reaction, and in the alpha induced reaction B.

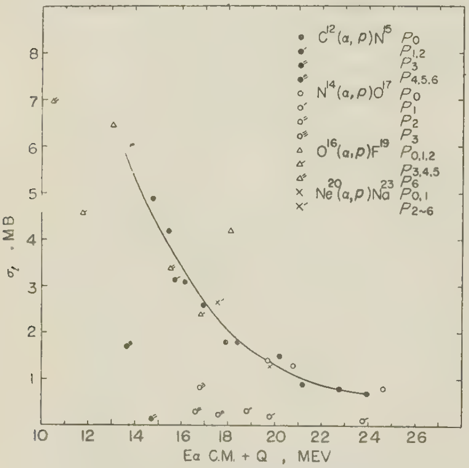


Fig. 3. Total cross sections σ_t as a function of $(E_{\text{c.m.}}+Q)$ in MeV. The data of carbon are replotted from I. Nonaka et al.[5]. A solid curve is of the case of the reaction $C^{12}(\alpha, p)N^{15}$ ground.

			33.1	7.2, 8.1, 9.0	

* Interaction radius expected from the elastic alpha-particle scattering analysis in reference 19): $(1.017A^{1/3}+2.94)$ in 10^{-13} cm.

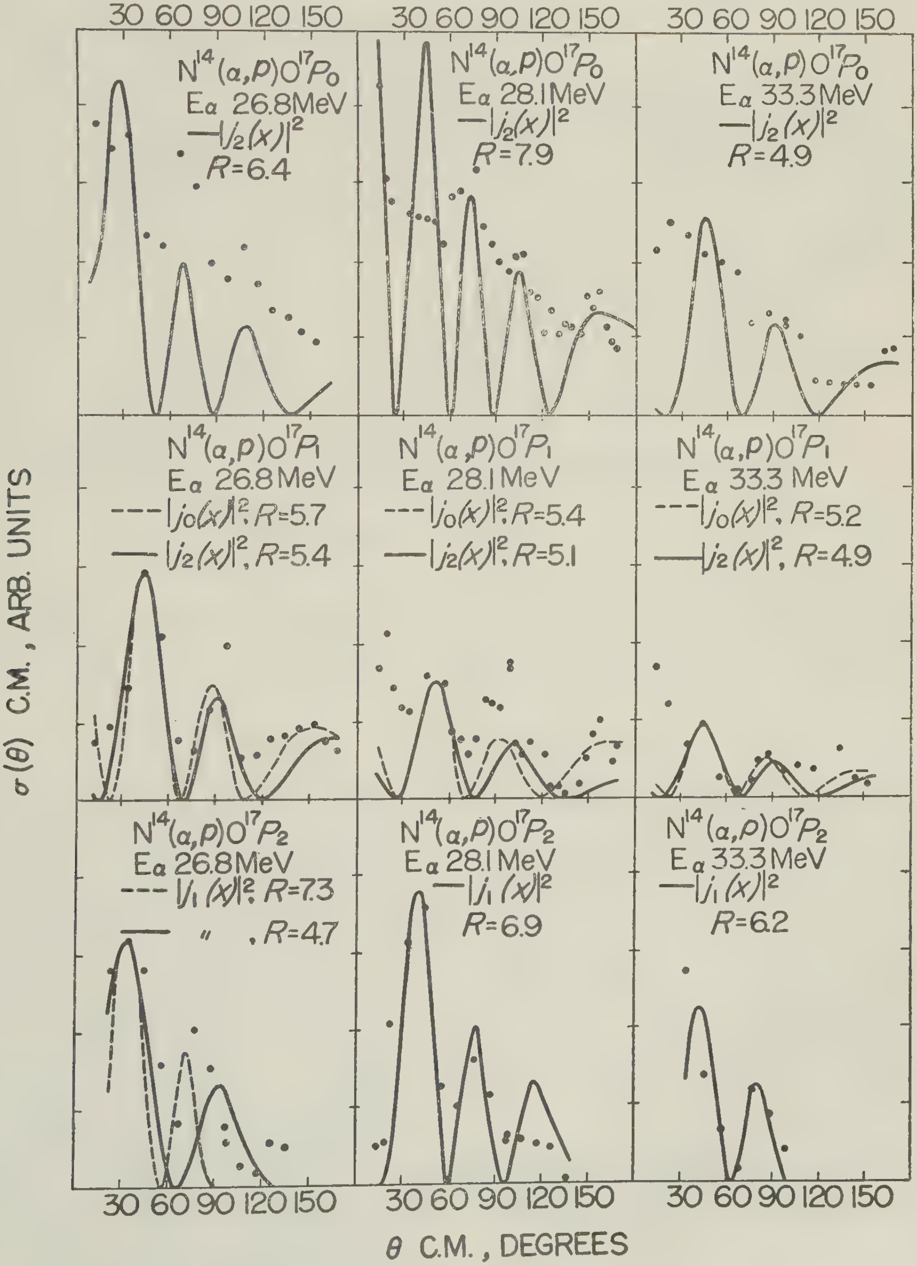
Zeidman and J. L. Yntema[17)] applied it to the results for the (α, d) reactions on N^{14} and Li^6 at bombarding energy 43 MeV.

S. Hinds and R. Middleton[18)] have compared their results for the (He^3, p) reaction to the double stripping process derived by H. C. Newns. The differential cross section has the form

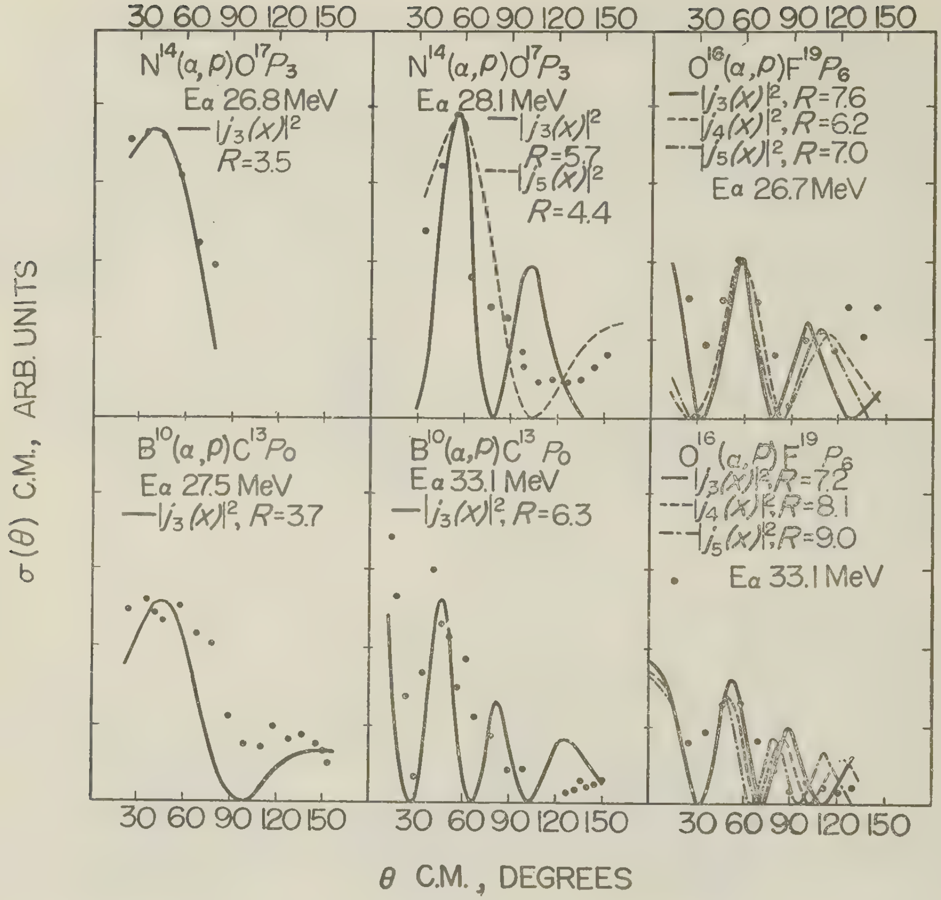
$$\sigma(\theta) \propto \sum_L |A(L) j_L(QR)|^2 \qquad (6)$$

where j_L is a spherical Bessel function and $A(L)$ is a constant analogous to the capture probability occurring in the Born approximation deuteron stripping theory, and $L = l_n + l_p$. This assumption may be used in the case of the (α, p) reaction in which the nucleons in the incident alpha particle interact with the target nucleus, individually or in a pair.

In order to compare our results to the direct interaction theory, the stripping process is



(a)



(b)

Fig. 4. Comparisons between the experimental angular distributions and $|j_l(x)|^2$ based on a stripping process. Where $x=QR$, Q is the momentum transfer, and R is the interaction radius in unit of 10^{-13} cm.

assumed, and owing to our capacities of calculation we are limited in these comparison to fit $|j_l(QR)|^2$, where $Q=K_\alpha-(M_x/M_y)K_p$, to each resolved proton group. The results of these fits are shown in Fig. 4 and Table III.

(i) $B^{10}(\alpha, p)C^{13}$ ground $l=3$ (uniquely); For the case of $E_\alpha=27.5$ MeV, we have had to choose a small interaction radius $R=3.7\times 10^{-13}$ cm to explain the broad peaks. This circumstance was seen for the case of $B^{10}(\alpha, p)C^{13}$ ground at $E_\alpha=30.4$ MeV obtained by C. E. Hunting and N. S. Wall[2], choosing the interaction radius $R=3.3\times10^{-13}$ cm in the comparison to the Butler formula. We had to choose, however, the larger interaction radius $R=6.3\times10^{-13}$ cm for the case of $E_\alpha=33.1$ MeV to explain the sharp rise in the small angles.

(ii) $N^{14}(\alpha, p)O^{17}$ ground $l=2$*; For the case of $E_\alpha=26.8$ MeV, we have failed to explain the rise in the small angles by the choice $R=6.4\times10^{-13}$ cm in spite of the success of the reappearance of following maxima and minima. For the case of $E_\alpha=28.1$ MeV, we have failed to explain the first shallow valley by the choice $R=7.9\times10^{-13}$ cm in spite of the success of the reappearance of following maxima and minima too. For the case of $E_\alpha=33.3$ MeV, we have had to choose a smaller radius, $R=4.9\times10^{-13}$ cm than the ones for the case of two lower bombarding energies.

(iii) $N^{14}(\alpha, p)O^{17}$ first, $l=0$ or 2; For the case of $E_\alpha=26.8$ MeV we get the almost same result for $|j_0|^2$ with $R=5.7\times10^{-13}$ cm, or $|j_2|^2$ with $R=5.4\times10^{-13}$ cm to be fitted the experimental results. For the higher two energies, $E_\alpha=28.1$ and 33.3 MeV, where the sharp rises exist in the region smaller than 30 degrees, we have failed to explain these rises. In the larger angle region, $|j_l|^2$ with $l=0$ is preferable to $|j_l|^2$ with $l=2$.

---

* In this case $l=2$ or 4 from the selection rule Eq. 3. We have chosen $l=2$ according to the results of preliminary fit. The situations are the same in the case of other reactions.

(iv) $N^{14}(\alpha, p)O^{17}$ second, $l=1$ (uniquely); For the case of $E_\alpha=26.8$ MeV the first maximum is fitted only, and the first and second maxima are fitted for $E_\alpha=28.1$ MeV.

(v) $N^{14}(\alpha, p)O^{17}$ third, $l=3$; For this proton group, we failed to get the full angular distribution owing to the strong proton group leaving the O^{17} in the fourth excited state. Nevertheless, we are able to see the situation of these proton groups, by comparison with other proton groups.

(vi) $O^{16}(\alpha, p)F^{19}$ sixth, $l=3$ or 4 if the spin of F^{19} sixth is 7/2; $l=4$ or 5 if the spin of F^{19} sixth is 9/2. The spin of the F^{19} sixth is 7/2 or 9/2.[13] In each case, the allowable l-values are 3 or 4 and 4 or 5 depending on whether the parity of F^{19} sixth is odd or even. In our results, the fits of $|j_l|^2$ to the experimental results in the small angles (first maximum) are obtained equally well for $l=3$, 4 and 5 for the case of $E_\alpha=26.7$ and 33.1 MeV. In the calculation of the energy level of F^{19}, by the intermediate $j-j$ coupling shell model[20] or by the collective model[21], this state is assigned to 9/2+. However, we could not affirm this prediction by $|j_l|^2$ fit.

(2) *The cross section*

In Fig. 3, the total cross sections σ_t for all transitions measured are plotted against (E_α in c.m.$+Q$)[*]. The data for $C^{12}(\alpha, p)N^{15}$ ground are plotted from I. Nonaka et al.[5]. The σ_t decrease generally as (E_α in c.m.$+Q$) increase, and they are same order in this energy region. On the other hand, in Fig. 2 we show the strong energy dependence of the differential cross sections at fixed angles for the reaction $N^{14}(\alpha, p)O^{17}$ and $O^{16}(\alpha, p)F^{19}$.

Table IV. $N^{14}(\alpha, p)O^{17}$.

(1) Proton group	(2) Energy level in MeV[13]	(3) l value by shell model	(4) Spin and parity[13]	(5) σ_t relative to P_0		
				$E_\alpha=26.8$ MeV	28.1 MeV	33.3 MeV
P_0	0	2	5/2+	1.0	1.0	1.0
P_1	0.871	0	1/2+	0.21	0.16	0.12
P_2	3.058	(1)	(1/2−)	0.21	0.21	—
P_3	3.846	(3)	(7/2−)	—	0.63	—

For the case of the $N^{14}(\alpha, p)O^{17}$ reaction, we obtained the cross sections for four transitions leaving O^{17} in ground, first, second, and third (only at $E_\alpha=28.1$ MeV) state. In Table IV the result for N^{14} are shown. The transitions to first and second state of O^{17} have relatively small cross sections. It is interesting to compare these results to the ones for the $O^{16}(d, p)O^{17}$ reaction. T. S. Green and R. Middleton[22] measured this (d, p) reaction at $E_d=9$ MeV. In their results, the ground and excited states at 0.87 and 3.85 MeV had large capture probabilities and reduced widths, and the level at 3.06 MeV which exhibited an isotropic angular distribution had small yield. Then, they concluded that the former two were the single particle states formed by the addition of $1d$, $2s$, and $1f$ neutrons to the O^{16} core respectively, and that the latter involved core excitation. Such a situation are not true for our results.

(3) *Reaction mechanism*

The simple calculation based on direct interaction theory are not sufficient to explain the present experimental results. Modifications of the theory are expected to make these comparison better. As we show in Fig. 2, however, the angular distribution have a strong energy dependence. Accordingly we must expect an energy dependence of the reaction mechanism. Such an energy dependence is also seen in the reaction $F^{19}(p,\alpha)O^{16}$ ground[23] in almost the same excitation energy as our reaction $O^{16}(\alpha,p)F^{19}$. As mentioned in the Introduction we showed[5] the backward peaking in the reaction $C^{12}(\alpha,p)N^{15}$ ground at excitation energies of compound nucleus 26.0–30.1 MeV.[*],[**] In this excitation region, a resonance at 26.6 MeV was found by J. P. Schiffer et al.[24] in the reaction $C^{13}(He^{3},p)N^{15}$ ground.

---

[*] (E_α in c.m.$+Q$) means the kinetic energy of the system for the final state of the reaction.

In our experimental results for the elastic and inelastic scattering of alpha particles by carbon[25], nitrogen[26], and oxygen[26] in the region of $E_{\alpha}=25-40$ MeV, we have found a strong energy dependence of the angular distributions for the reactions.

From these experimental results it may be reasonable to think that there are some effects of the compound process for the (α,p) reaction of light nuclei in intermediate energy region.

At any rate more experimental and theoretical work is needed to study the reaction mechanism of the (α,p) reaction.

Acknowledgement

The author wishes to express his thanks to Professor I. Nonaka for his valuable suggestions and encouragement, and Drs. J. Sanada, T. Mikumo, and S. Okai for their valuable suggestions and discussions. He also thanks the cyclotron crew and members of the electronic division for their constant cooperation, and Miss. A. Adati for calculations of theoretical angular distributions. His thanks are also due to Messrs. I. Umeda, T. Tabata and S. Hitaka for their cooperative efforts throughout this work.

[*] Recently J. R. Priest et al.[27] measured the angular distributions for $C^{12}(\alpha,p)N^{15}$ at 16.1-19.0 MeV and $F^{19}(\alpha,p)Ne^{22}$ at 18.9 MeV and also showed results similar to ours for the reaction $C^{12}(\alpha,p)N^{15}$. They found a resonance of $C^{12}(\alpha,p)N^{15}$ ground at about $E_{\alpha}=17.5$ MeV in excitation curve at 31.8° (lab), and at this energy (corresponding to 20.3 MeV excitation of O^{16}) there is a peak[28] of the total γ-absorption in O^{16}.

[**] P. R. Klein et al.[29] reported the angular distributions for $Li^{6}(\alpha,p)Be^{9}$ and $Li^{7}(\alpha,p)Be^{10}$ at $E_{\alpha}=30$ MeV and also showed backward peaking there.

Resonance Levels in the Reactions ^{28}Si(p, γ)^{29}P, ^{29}Si(p, γ)^{30}P and ^{30}Si(p, γ)^{31}P

By Haruko OHMURA[*], Hiroyasu EJIRI, Yutaka NAKAJIMA, Kinuko HORIE[†], Kiichi ETOH[**], Akiji OHUCHI[***] and Yozo NOGAMI

Department of Physics, Faculty of Science, University of Tokyo, Tokyo, Japan

(Received December 27, 1960)

The reactions ^{28}Si(p, γ)^{29}P, ^{29}Si(p, γ)^{30}P and ^{30}Si(p, γ)^{31}P have been studied in the region of proton energy from 300 kev to 1700 kev. We have found in the reaction ^{29}Si(p, γ)^{30}P two new resonances at proton energies 1307.5±3 kev and 1331.5±3 kev, and in the reaction ^{30}Si(p, γ)^{31}P nine new resonances at proton energies 1094, 1179.5, 1209-5, 1290.5, 1300, 1302.5, 1324.5, 1394.5 and 1403 kev with the errors of ±3 kev. No definite resonant level has been observed in the reaction ^{28}Si(p, γ)^{29}P in the range of proton energy between 570 kev and 1400 kev.

§1. Introduction

The reactions ^{28}Si(p, γ)^{29}P, ^{29}Si(p, γ)^{30}P and ^{30}Si(p, γ)^{31}P have been investigated by a number of authors[1-12] using natural and enriched silicon targets measuring gamma rays and positron activities produced in the target.

For the reaction ^{28}Si(p, γ)^{29}P, no resonant level was found by Tsytko et al.[3] from 500 kev to 1000 kev of proton energy. Olness et al.[12] also reported that the capture cross section for ^{28}Si(p, γ)^{29}P had shown no evidence for a level reported on the basis of (d, n) and (p, p) reactions at excitation energy of about 3.7 Mev.[13,14,15] Considering the correspondence between excited states in mirror nuclei, ^{29}P and ^{29}Si, based on the charge symmetry hypothesis of the nuclear force, several resonant levels should be expected for proton capture by ^{28}Si in the region of proton energy below 1650 kev. In Fig. 1 the known level schemes of ^{29}P and ^{29}Si are shown.

Detailed studies on the resonant levels in the reaction ^{30}Si(p, γ)^{31}P have been reported by many authors, especially by Broude et al.[7] and Antuf'ev et al.[10] in the range of proton energy from 500 kev to 1000 kev, while for the proton energy between 1000 kev and 1400 keV, no resonance has been reported.

We have investigated the reactions ^{28}Si(p, γ)^{29}P, ^{29}Si(p, γ)^{30}P and ^{30}Si(p, γ)^{31}P in the region of proton energy between 300 kev and 1700 kev using isotopically enriched thin targets. This paper presents the results of the studies on the excitation functions of those reactions and on the resonant levels in each phosphor isotopes.

§2. Experimental Procedures and Results

The University of Tokyo electrostatic generator provided a proton beam of up to 4 μa in the range of proton energy from 300 kev to 1410 kev. For higher energy protons, J.A.E.R.I. electrostatic generator was used. Above 570 kev in proton energy the H^+ beam was used, while for below energies the H_2^+ beam was also employed. The proton beam energy was analyzed with a magnetic analyzer. Its magnetic field was measured by nuclear magnetic resonance method and was calibrated by referring to the 990.8 keV resonance in the reaction ^{27}Al(p, γ)^{28}Si. The errors in proton energies are estimated to be less than 3 kev.

Thin targets enriched in each stable silicon isotope ^{28}Si, ^{29}Si and ^{30}Si, deposited on Ta plates, were obtained by electromagnetic separation at the University of Kyoto. The target chamber is made of 1 mm thick brass wall equipped with two windows of thin mica foils (0.7 mm and 0.14 mm of thickness) for positron detection.

Gamma rays from the target were detected by sodium iodide crystal scintillation counters and analyzed with a twenty-channel pulse height analyzer. To measure positron activities, a Geiger-Müller counter with a mica window of 1.9 mg/cm^2 thick was used.

A. Reaction ^{28}Si(p, γ)^{29}P

The excitation function of the reaction ^{28}Si(p, γ)^{29}P was obtained for the proton energy from 1300 kev to 1700 kev with a proton beam from J.A.E.R.I. electrostatic accelerator. As gamma ray detectors, use was made of 2″ dia.×2″ and 1½″ dia.×1″ sodium iodide crystals, each coupled to 6292 photomultiplier tube. A broad resonance was observed at proton energy 1650 kev, in agreement with the reports by Newton[6] and Olness et al.[12]

The excitation function in the range of proton energy from 570 kev to 1400 kev was observed using a proton beam obtained from the University of Tokyo electrostatic accelerator, and no definite resonant level was found. In this case, a 5″ dia.×4″ sodium iodide crystal attached to a 6099 (B) photomultiplier tube was also used to detect the high energy gamma rays as well as a 2″ dia.×2″ sodium iodide crystal.

There are some evidences for existence of excited levels in ^{29}P in the region of excitation energy 3.4∼3.7 Mev. Calvert et al.[14] and Macefield and Towle[15] reported a level at 3.5 MeV of excitation energy in ^{29}P in the reaction ^{28}Si(d, n)^{29}P. In the elastic scattering of protons by silicon, a resonance may have been observed at proton energy of 1 Mev[13] (3.7 Mev in ^{29}P excitation energy). Corresponding to such excited levels, some resonances might be anticipated in the reaction ^{28}Si(p, γ)^{29}P for the proton energy from 700 kev to 1200 kev. We tried more precise experiment on the excitation function using another type of target chamber. For the detection of gamma rays, we used 4″×4″ and 3″×3″ cylindrical sodium iodide crystals attached to a 6099 (B) photomultiplier tube and a 6363 photomultiplier tube respectively. The target chamber and scintillation counter arrangement is illustrated in Fig. 2. The result of this experiment showed no distinct resonance. Assuming total width Γ_t of the resonant level to be much smaller than the target thickness (about 3 kev for protons of 1 Mev), an upper limit of 5 $\times 10^{-3}$ ev may be set to the value $(2J+1)\Gamma_p\Gamma_\gamma/\Gamma_t$ for the resonant levels in the range of proton energy from 700 kev to 1200 kev.

B. Reaction ^{29}Si(p, γ)^{30}P

The excitation function of the reaction ^{29}Si(p, γ)^{30}P was measured for the proton energy from 300 kev to 1410 kev, recording low energy gamma rays with a 2″ dia.×2″ sodium iodide crystal and higher energy gamma rays with a 5″ dia.×4″ sodium iodide crystal. Resonances were observed at proton energies 326, 415, 698, 730, 917.5 and 958.5 kev with the errors of ±3 kev, and they agree well with the results reported by previous investigators.[4,5,8,11] In addition to these, new resonances were found at proton energies 1307.5±3 kev and 1331.5±3 kev. The excitation function of the $^{29}Si(p,\gamma)^{30}P(\beta^+)^{30}Si$ was also observed by an activation method in the region of proton energy from 900 kev to 970 kev with a Geiger-Müller counter detecting 2.5 min. positron activities produced in the target. Yield curves of gamma rays above 1.2 Mev detected in the 2″ dia.×2″ sodium iodide crystal scintillation counter and positrons from the reaction $^{29}Si(p,\gamma)^{30}P$ are shown in Fig. 3 and Fig. 4.

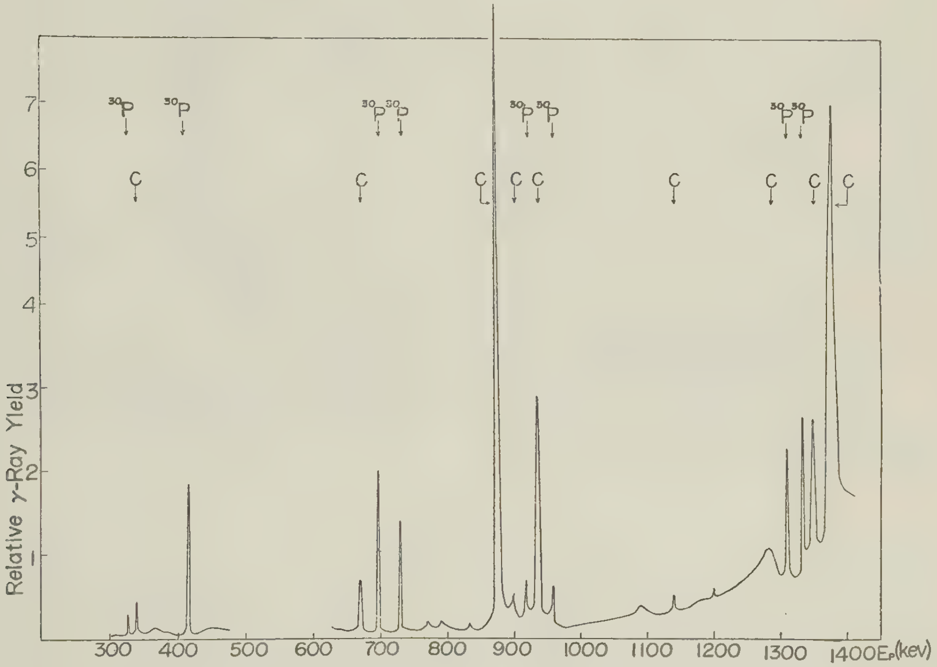

Fig. 3. Excitation function for gamma rays above 1.2 MeV from $^{29}Si(p,\gamma)^{30}P$. Background has been subtracted.
C: γ rays from ^{19}F contamination.

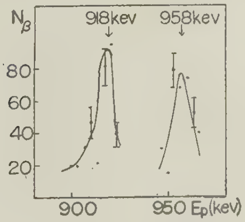

Fig. 4. Yield curve for positrons in the reaction $^{29}Si(p,\gamma)^{30}P$. Background has been subtracted.

At each resonant energy the gamma ray spectrum was measured with a 2″ dia.×2″ sodium iodide scintillation counter and the results, together with the relative yield of the gamma rays in the targets of different isotopic abundances, were used to assign the resonance to proper isotope. We also observed the decays of positron and annihilation gamma activities with a Geiger-Müller counter at several resonant level for the identification of the reaction.

C. Reaction $^{30}Si(p,\gamma)^{31}P$

The reaction $^{30}Si(p,\gamma)^{31}P$ was investigated with the same detector arrangement as in the case of the reaction $^{29}Si(p,\gamma)^{30}P$ for the range of proton energy, 500 kev to 1410 kev. Resonances were observed at 501, 620, 670, 759, 776, 835.5, 945, 961.5, 982 and 986.5 kev in proton energy with the errors of ±3 kev, showing good correspondences with previous reports.[3,7,9,10] Above 1000 kev nine unreported resonances were observed at proton energies 1094, 1179.5, 1209.5, 1290.5, 1300, 1302.5, 1324.5, 1394.5 and 1403 kev with the errors of ±3 kev, which are considered as resonances in the reaction $^{30}Si(p,\gamma)^{31}P$ from the observed

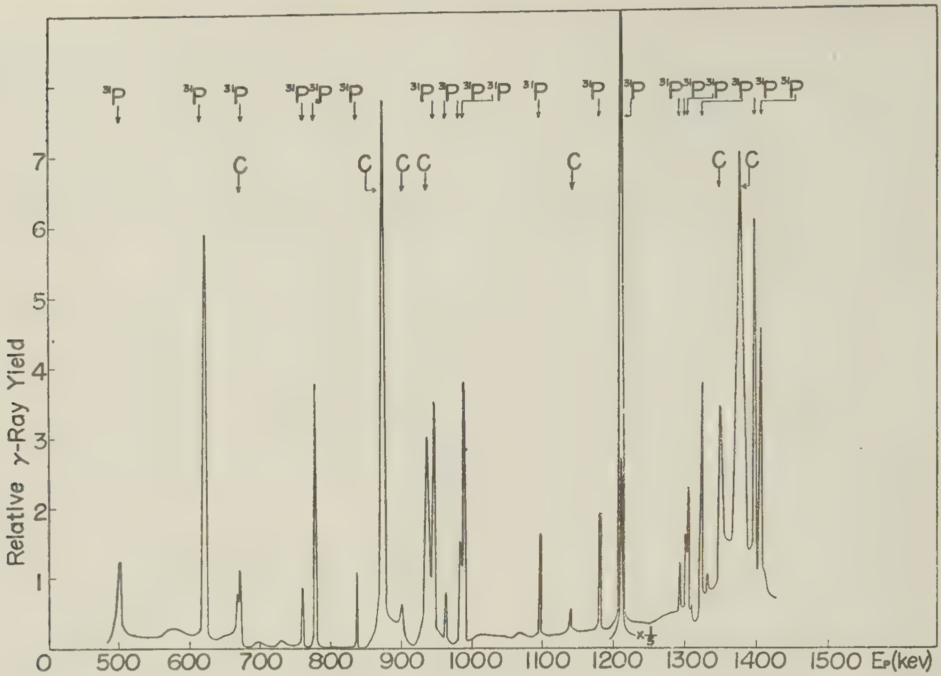

Fig. 5. Excitation function for gamma rays above 1.2 MeV from ^{30}Si(p, γ)^{31}P. Background has been subtracted.
C: γ ray from ^{19}F contamination.

gamma ray spectra and by comparing the relative yield of gamma rays from the targets with different isotopic abundances. In Fig. 5 is shown the excitation function obtained by measuring gamma rays above 1.2 Mev in a 2″ dia. × 2″ sodium iodide scintillation counter.

§ 3. Discussions

The broad resonance observed at the proton energy 1650 kev in the reaction ^{28}Si(p, γ)^{29}P may be considered to be the analog state of 4.93 Mev excited state in the mirror nucleus ^{29}Si. This 1650 kev resonant level was suggested to be a $2p\frac{3}{2}$ single particle-like state from the result of elastic scattering experiments[16]. Studies on the gamma rays emitted from this resonant level would be of interest as to the properties of this level and low lying excited levels in ^{29}P.

Any other resonances corresponding to the excited states in ^{29}Si were not observed in the present experiment on the reaction ^{28}Si(p, γ)^{29}P for the proton energy between 570 kev and 1400 kev, while in this region of proton energy, some excited levels in ^{29}P were observed in the reaction ^{28}Si(d, n)^{29}P.[14,15] Supposing that the excited state at 3.49 Mev observed in the reaction ^{28}Si(d, n)^{29}P[15] is the single particle-like $1f\frac{7}{2}$ level corresponding to the 3.62 Mev excited level in ^{29}Si and that the low lying $\frac{5}{2}^{+}$ excited state has the character of collective excitation, the gamma ray transition probability between these two levels would be highly reduced from that of the electric dipole transition between single particle excited states, and the value $(2J+1)\Gamma_{\gamma}\Gamma_{p}/\Gamma_{t}$ might be very small.

For the levels in ^{29}Si between 3.62 Mev and 4.93 Mev, the characters of the excited levels are not well known, therefore it seems to be difficult to deduce a conclusion on the existence of the corresponding excited levels in ^{29}P from the present (p, γ) experiments. Studies on the reaction ^{32}S(p, α)^{29}P are under progress as well as the experiments on gamma rays from 1650 kev resonant level in order to investigate the structure of the excited states in ^{29}P.

As for the newly observed levels in the reaction ^{29}Si(p, γ)^{30}P, the gamma ray spectra show that from the 1307.5 kev resonant level a strong transition occurs to the first excited state (T=1) of ^{30}P and the 1331.5 kev resonant level decays mainly to the ground state (T=0).

In order to study the characters of the

resonant levels and low lying excited levels in ^{30}P and ^{31}P, we are now undertaking the experiments on the gamma rays emitted from new resonant levels found in the reaction ^{29}Si$(p, \gamma)^{30}$P and ^{30}Si$(p, \gamma)^{31}$P.

Acknowledgements

The authors would like to express their cordial thanks to the staffs of Van de Graff group of the Japan atomic Energy Research Institute for their cooperation. They are also very grateful to the isotope separator group of the University of Kyoto for their kind assistance.

The Reaction $Mg^{25}(d, p)Mg^{26}$ in the Energy Range of Deuterons from 1.5 MeV to 3.0 MeV

By Naoyuki Takano

Department of Physics, Kyusyu University, Fukuoka, Japan

(Received, January 6, 1961)

Angular distributions and excitation functions of protons from the reaction $Mg^{25}(d, p)Mg^{26}$ leading to the 1.83- and 2.97-MeV state of Mg^{26}, have been investigated in the deuteron energy range from 1.55- to 3.00-MeV. The yield of the protons leading to the ground state were so small that this group was not measured. The results of angular distributions were compared with the deuteron stripping theory, and a qualitative agreement for the second excited state group at the deuteron energies above 2.5 MeV, was obtained in the forward directions, but not for the first excited state group and also in the backward directions for each groups.

The angular distributions of the first excited state group at the deuteron energies above 2.44 MeV, could be fitted to Bhatia's formula with two l_n-values of 0 and 2. Both angular distributions include considerably isotropic part, and show a competition between the deuteron stripping process and the compound nucleus formation. Also, the results of excitation functions for total cross section were compared with the statistical theory and a fairly good agreement was obtained with the interaction radius of $(1.21+1.3\cdot A^{1/3})\times10^{-13}$ cm. Furthermore, a considerably small yield of this reaction seems to show that Coulomb effects play an important role in this lower energy range.

§1. Introduction

An investigation of the reaction $Mg^{25}(d, p)$-Mg^{26} leading to the low-lying state of Mg^{26} had been made by a few authors[1,2,3]. Nevertheless, angular distributions of these proton groups were measured only at the deuteron energy of 8.0 MeV in the forward directions[1]. These results were compared with Butler's theory for the deuteron stripping reaction and a good agreement, in general, was obtained with Bhatia's formula with the interaction radius of $(1.7+1.22\cdot A^{1/3})\times10^{-13}$ cm.

For the first excited state group, a considerably better agreement was obtained with the superposition of two angular distributions corresponding to two l_n-values of 0 and 2. This state also had been investigated using a magnetic analyser and nuclear emulsion[2], and found to be not a doublet but a single state.

Furthermore, theoretical analysis for this group had been made by a few authors[4,5]. They explained this angular distribution with a configuration mixing of $s_{1/2}$ and $d_{3/2}$ level of Mg^{26} in nuclear shell model, and also estimated the mixing ratio of $s_{1/2}$ to $d_{3/2}$ level of Mg^{26}, and deformation parameter using the data at the deuteron energy of 8.0 MeV[1]. In the case where the bombarding energies are higher than the Coulomb potential, angular distributions of the protons from (d, p) reaction in the forward direction, can usually be fitted to the deuteron stripping theory[6] which is based on the Born approximation. But in such a low energy range as in this experiment, the Born approximation may not be applicable. Although it may be difficult to obtain a good agreement between theoretical results and experimental, we carried out the present experiment in order to investigate how the anomalous angular distribution of the 1.83 MeV state proton group would behave in the lower energy range of deuteron, and to obtain some information for the reaction mechanism and the structure of the nucleide Mg^{26}, from angular distributions and excitation functions.

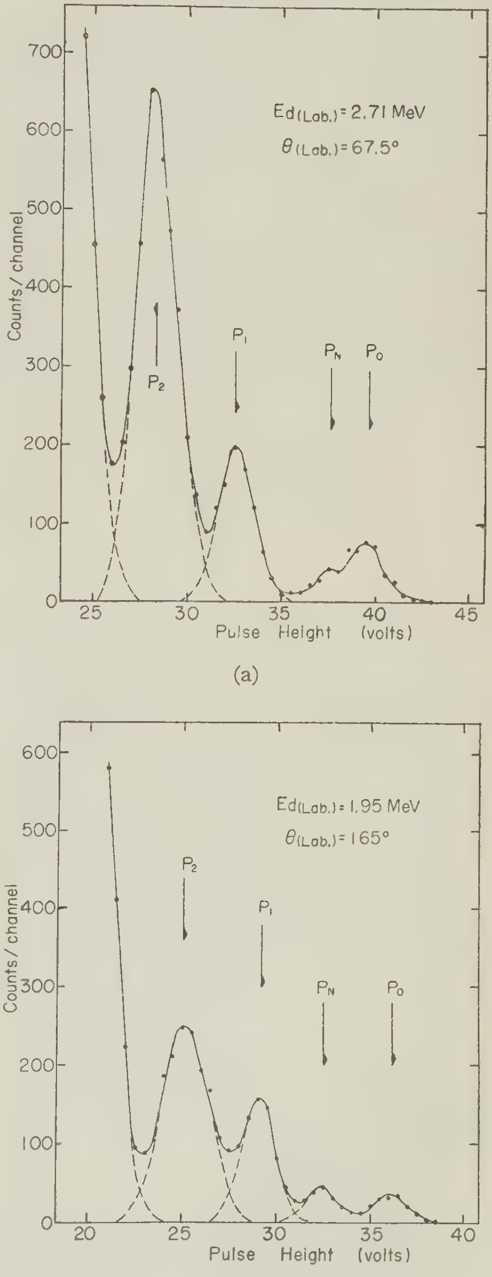
§2. Apparatus and Experimental Procedures

The deuteron beam used in this experiment, was produced by the Van de Graff accelerator of Kyusyu University, whose accelerating voltage was calibrated with resonances of the gamma-ray from the reaction $F^{19}(p, \alpha\gamma)O^{16*}$. The deuteron beam deflected by 45° with a beam analyzing magnet, after passing through a tantalium slit of 1 mm in width located at a distance of 47 cm from the target and another silver slit of 4 mm in diameter located at a distance of 20 cm from the target, entered into the scattering chamber. The enriched $Mg^{25}O$ target was set in such a way that the target plane made 45° with respect to the deuteron beam at the center of the scattering chamber. And then the beam was collected in the Faraday cup located at a distance of 12 cm from the center of the scattering chamber.

The target was prepared by depositing a suspension of MgO powder in alcohol on the silver backing foil of 2.0 mg/cm² and evaporating the alcohol in vacuum. A sample of MgO enriched in Mg^{25} was supplied by the mass separator at the I.N.S. of University of Tokyo. Isotopic content of Mg^{25} was estimated to be about 90%, by comparing the proton yield with that of natural MgO target. A considerably uniform target of about 1.2 mg/cm² in thickness was prepared by this method. This target thickness corresponds to the energy loss of about 150 kev at the deuteron energy of 2.5 MeV⁷⁾.

Scattering chamber, scintillation counter and other electronic circuits used in this experiment, were quite similar to those used in the study of other (d, p) reactions in our laboratory⁸⁾ and are described here briefly. Scattering chamber has an inner diameter of 23 cm and height of 10 cm, having 20 ports in its side wall. The side ports of 6 mm in aperture, bored at intervals of 15°, from 15° to 165° on one half of the side wall of the scattering chamber and from 22.5° to 157.5° on the other half. These ports also play a role as the defining slit to scintillation detector. The solid angle, subtended by these defining slits for the target was estimated to be 2.17 $\times 10^{-3}$ steradian in the average. Angular resolution of these slits was estimated to be ±1.5°.

The beam current, collected by a Faraday cup, was measured by a current integrator of Higinbotham type. But in the case of the measurement of excitation curve, this Farady cup was replaced by another one, which has an inner diameter of 3 cm and length of 5 cm, and located at a distance of 5 cm from the target surface, in order to avoid the effect of scattering of deuteron beam by the target and its backing foil. Furthermore, for the



(a)

(b)

Fig. 1. Pulse height spectra from the scintillation counter of the protons emitted by the $Mg^{25}(d, p)Mg^{26}$ reaction, obtained at 67.5° (Lab. system) with $E_d = 2.71$ MeV (a) and at 165° (Lab. system) with $E_d = 1.95$ MeV (b).

measurement of the yield at 0° to the deuteron beam, this Faraday cup was taken away and the same defining slit as that used at another side ports of the scattering chamber was set at the direction of 0°.

The protons emitted by this reaction were measured with a scintillation counter which consisted of CsI(T*l*) of 1 mm in thickness and E.M.I. 6097 photomultiplier. Furthermore, another CsI(T*l*) scintillation counter was fixed to the side port of the scattering chamber making an angle of 82.5° to the deuteron beam in the opposite side to the proton detector, and was used as a monitor counter. The bias of the monitor counter was set to count only the pulse due to the protons of higher energies than those leading to the second excited state of Mg^{26}. The signal pulses, after passing through a cathode follower and an A-1 type linear amplifier, were fed to a 20 channel differential pulse height analyser. The typical pulse height spectra from the scintillation counter obtained in this experiment are shown in Fig. 1.

Assignment of the peaks in these spectra was carried out by reaction kinematics. The first, third and fourth peaks correspond to the protons from the reaction $Mg^{25}(d, p)Mg^{26}$ leading to the ground, the first excited and the second excited state of Mg^{26}, respectively. The second peak corresponds to the protons from the $N^{14}(d, p)N^{15}$ ground state reaction, produced by the nitrogen contamination in the MgO target. Aluminium absorber of $20\,\mu$ in thickness was inserted in front of the scintillation counter in the forward directions, preventing the alpha particles emitted by the reaction $N^{14}(d, \alpha)C^{12}$ from entering the proton detector. And also, in measuring the yields at 0° direction to the deuteron beam, another silver absorber of 40 mg/cm² in thickness was inserted in front of the defining slit at 0° direction, in order to stop the direct deuteron beam.

Background runs were carried out at the several deuteron energies with a silver foil of 2.0 mg/cm² in place of the target. Although the background from the other element was so small that the subtraction of the background was easy, the resolution of each proton groups was not complete, and then the area of each peaks in pulse height spectrum was obtained from the estimated peak, as is shown by dotted curves in Fig. 1.

An uncertainty arising from the group separation was estimated to be 5% at maximum. Excitation curves of the protons from this reaction leading to the 1.83-, and 2.97-MeV state of Mg^{26} were also measured with the CsI(T*l*) scintillation counter, fixed at the 75° side port of the scattering chamber and with the aforementioned Faraday cup and are shown in Fig. 6.

§ 3. Results and Discussions

Angular distributions of the protons from the reaction $Mg^{25}(d, p)Mg^{26}$ leading to the first and second excited state of Mg^{26} at the deuteron energies of 1.65-, 1.95-, 2.20-, 2.44-, 2.71-, and 2.99-MeV are shown in Figs. 2 to 5. Indicated errors at each points include the

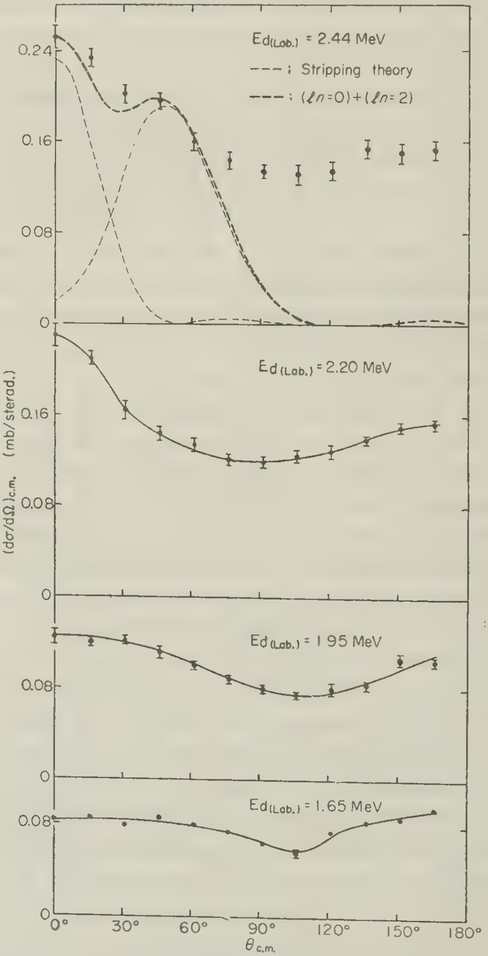


Fig. 2. Angular distribution of the proton from the $Mg^{25}(d, p)Mg^{26}$ first excited state reaction at the deuteron energies of 2.44-, 2.20-, 1.95-, and 1.65-MeV.

over all uncertainty due to the experimental procedures described above. Statistical error amounts to 3% at maximum. Absolute cross section was estimated from the results obtained by measurement of excitation curves at 75° direction. The scale of the ordinate in these figures has an uncertainty of about 40%, which is mainly due to the non-uniformity of the thickness of target.

Although the shape of angular distributions for the first excited state group varies gradually with the deuteron energy, it shows nearly isotropic pattern for the deuteron energies below 2 MeV and shows a characteristic forward peak of the deuteron stripping reaction above this energy, and also two peaks corresponding to the orbital angular momentum $l_n=0$ and $l_n=2$, above the deuteron energies of 2.44 MeV. The second peak at about 50°, in the center-of-mass system, becomes predominant with the increasing deuteron energy.

The dotted curve indicated in Figs. 2 and 3 are theoretical curves calculated from Bhatia's formula[6] with interaction radius of 5.0×10^{-13} cm and $l_n=0$ and 2. Each theoretical curve is normalized to the peak value of experimental curve. The fat dotted curves in these figures indicate the superposition of these two theoretical curves. A qualitative agreement was obtained with Bhatia's formula in the forward direction at the deuteron energy of 2.99 MeV, but not in the backward directions. The shape of the angular distribution for the deuteron energy of 2.99 MeV is similar to that obtained by Holt *et al.*[1] at 8.0 MeV. Furthermore, it must be noted that the ratio of these two peaks is in agreement

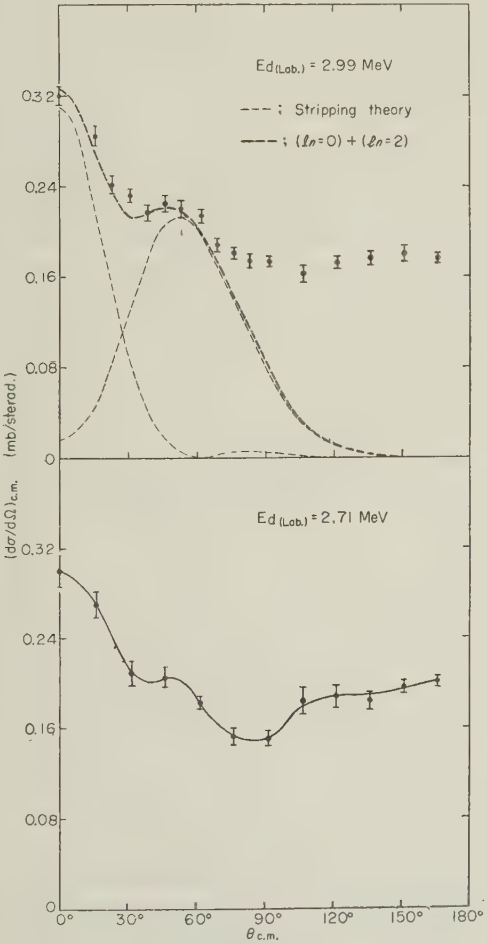

Fig. 3. Angular distribution of the proton from the $Mg^{25}(d, p)Mg^{26}$ first excited state reaction at the deuteron energies of 2.71-, and 2.99- MeV.

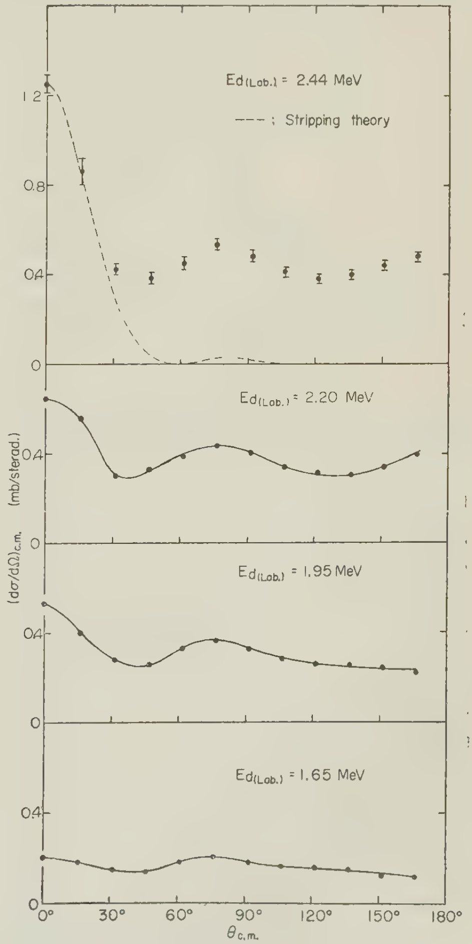

Fig. 4. Angular distribution of the proton from the $Mg^{25}(d, p)Mg^{26}$ second excited state reaction at the deuteron energies of 2.44-, 2.20-, 1.95-, and 1.65- MeV.

with their result within the experimental error. Although these evidences may not be incompatible with those predicted by the nuclear shell model and spheroidal model[4,5] a remarkably small absolute cross section and a feature at the backward directions will not be explained by a direct interaction theory. It seems probable that the compound nucleus formation contributes mainly to this group at these lower deuteron energies.

Angular distributions of the protons from the reaction leading to the second excited state of Mg^{26} are shown in Figs. 4 and 5.

The dotted curve indicated in Figs. 4 and 5 are theoretical curves calculated from Bhatia's formula with interaction radius of 6.0×10^{-13} cm and $l_n=0$. Theoretical curves is normalized to the experimental curves at 0° direction.

A qualitative agreement is obtained with Bhatia's formula in the forward directions, but not in the backward directions and in the energy range of deuteron below 2.2 MeV. The characteristic forward peak of the deuteron stripping reaction, in general, becomes remarkable with the increasing deuteron energy, but angular distributions have rather large isotropic part.

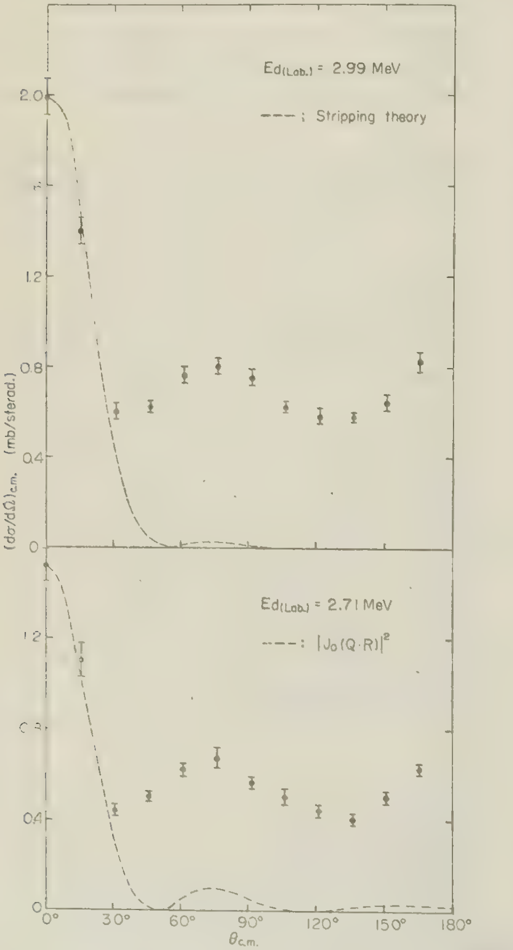

Fig. 5. Angular distribution of the proton from the $Mg^{25}(d, p)Mg^{26}$ second excited state reaction at the deuteron energies of 2.71-, and 2.99- MeV.

The shape of the angular distribution for the second excited state group, in general, shows the oscillatory pattern, as is expressed by

$$|J_0(Q\cdot R)|^2$$

where J_0 is the spherical Bessel function of order 0. R is interaction radius and Q is the magnitude of the momentum transfer, given by

$$Q=\left|K_p-\frac{1}{2}K_d\right|$$

K_p and K_d are the wave vectors for the outgoing proton and the incident deuteron, respectively.

The dotted curve at the deuteron energy of 2.71 MeV is theoretical curve calculated from the above described formula with interaction radius of 7.0×10^{-13} cm. The rise in the backward direction also may be affected by other direct process, such as heavy particle stripping reaction.

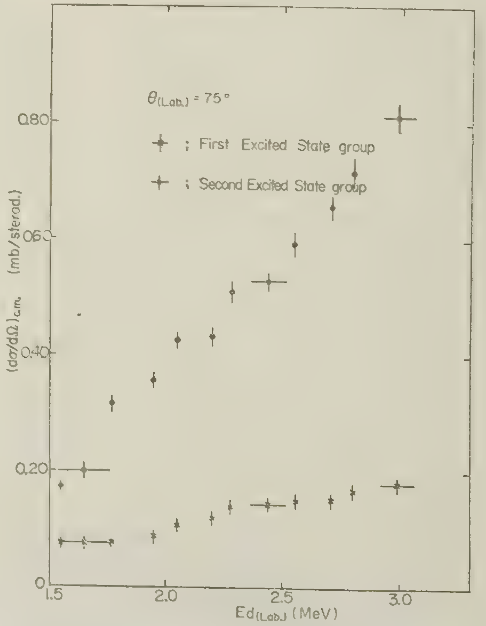

Fig. 6. Excitation curve for the $Mg^{25}(d, p)Mg^{26}$ reaction at $\theta_{(Lab.)}=75°$.

Excitation curves of the protons from the reaction leading to the first and second excited state of Mg^{26} were measured at 75° to the deuteron beam in the energy range of deuteron from 1.55- to 3.00-MeV, and are shown in Fig. 6.

Furthermore, the total cross sections for the first and second excited state groups, obtained from the angular distributions in Figs. 2 to 5 and the excitation curves shown in Fig. 6, were plotted against deuteron energy in the center-of-mass system and are shown in Fig. 7.

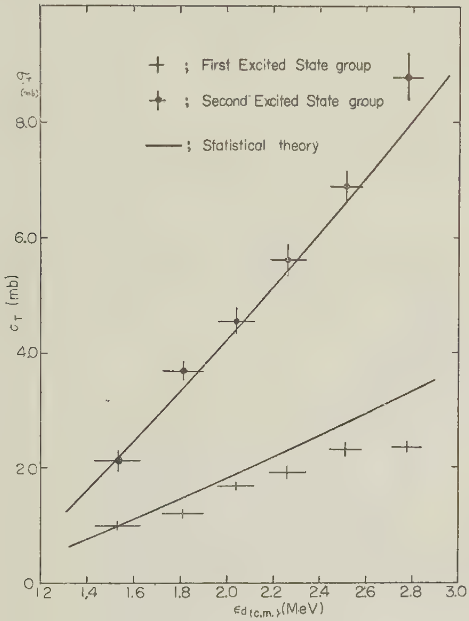

Fig. 7. Excitation function for the $Mg^{25}(d, p)Mg^{26}$ reaction. The full curves show theoretical excitation curve calculated by statistical theory.

From the shape of angular distribution described above, it seems probable that the cross section of the compound nucleus formation considerably contributes to the excitation curve in lower energy range. Therefore, the general this behavior of the total cross section will be shown by the formula of Blatt and Weisskopf for the statistical theory. The full curves are theoretical curves calculated by the formula of Blatt and Weisskopf[9], and are normalized at the deuteron energy of 1.53 MeV (center-of-mass system) to the experimental point of each group. A qualitative agreement for the second excited state group was obtained with the interaction radius of $(1.21+1.3\cdot A^{1/3})$ 10^{-13} cm, but not for the first excited state group. These two excitation functions vary monotonously with the increasing deuteron energy and show no resonance like feature owing to the statistical assumption for the level of compound nucleus.

Furthermore, the ratios of a total cross section for the second excited state group to that for the first excited state group were plotted against the incident energies in the center-of-mass system and are shown in Fig. 8.

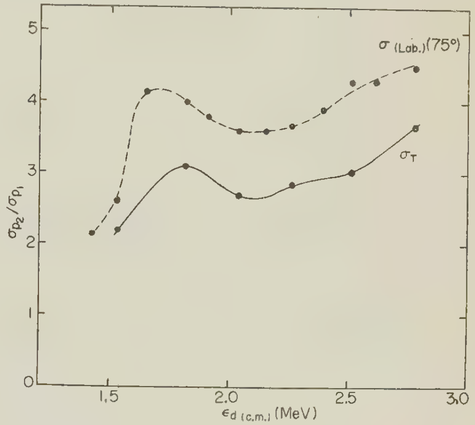

Fig. 8. The ratios of a total cross section for the second excited state group to that for the first excited state group. The dotted curve shown in figure, is the result obtained at 75° direction.

A peak which is unexpected from the statistical theory appears at the deuteron energy of 1.8 MeV in the center-of-mass system. This phenomenon will not be explained by the competition of the branching to these two states of residual nucleus, because the spin and parity of these two states of Mg^{26} both have been found to be $2+$[10]. Taking account of the evidence that the angular distributions of the second excited state group have rather simple form but those of the first excited state group have a complicated form, the first excited state of Mg^{26} seems to have a complex structure, probably of two or more particles excitation. In the case where the incident deuteron are considerably affected by Coulomb potential, direct process may not be a predominant process, but plays only a part of the nuclear reaction.

The author wishes to express his cordial thanks to Prof. S. Morita for his constant encouragement and valuable discussion, and to all other staffs of nuclear laboratory of Kyusyu University for their helpful discussion throughout the present work. He also wishes to express his thanks to the mass separator crew of I.N.S. of University of Tokyo for the preparation of target.

The Structure of Extensive Air Showers Near the Axes

By Shūji FUKUI

Physical Institute, Nagoya University, Nagoya, Japan

(Received August 23, 1960)

The lateral distribution of electrons and also of the mean energy of extensive air showers (EAS) were observed with a detector array composed of 14 scintillation detectors, 15 Čerenkov detectors, an arrival direction detector and a neon hodoscope. In particular the precise structure near the axes could be detected by the neon hodoscope. Each EAS was specified by various parameters, that is, the lateral distributions of electrons and energy flow, μ-mesons, and nuclear active component, and it was found that the structure of the EAS thus observed are different from case to case.

Near the axis the lateral distributions of electrons are rather flat and varied gradually from $r^{-0.4}$ to $r^{-1.0}$ according to the distance from the axis, up to a few meters. The slope of the distribution between 5 m–50 m distance from the shower axis is well fitted by the predicted one from the Nishimura-Kamata theory, adjusting the value of the s-parameter. The observed lateral distribution of mean energy of electrons is expressed by $E=7.5\times10^8\times r^{-0.7\pm0.1}$ ev in the region from the axis to 7 m.

The probable influences on the structure near the axis are discussed.

§1. Introduction

An extensive air shower, abbreviated as EAS, is a phenomenon which is caused by the interaction of a primary cosmic ray particle of ultra-high energy at high altitude in the atmosphere and in which a larger number of particles are accumulated by many successive interactions of the particles in the atmosphere. Numerous experimental studies of EAS carried out up to the present have dealt with the average structure of EAS. The results thus far obtained have been summarlized in several review articles.[1]

It has recently been noticed that the structure of individual EAS fluctuating about the average structure exhibits very important information about the development of EAS. As has been pointed out by several authors,[2] the fluctuation of the depth in the atmosphere of the very early stages of the development may be significant. Besides this, the fluctuation of the development of the nuclear cascade which is caused by the inelasticity of the interaction and the nature of the secondary particles may also play an important role.[3] Therefore, EAS observed at any altitude, even assuming a constant primary energy, show a different structure from case to case owing to the effects of these fluctuations. It is necessary to measure all the characteristics, i.e. the various parameters, of EAS in as much detail and as comprehensively as possible for the purpose of studying ultra-high energy interactions. In this manner the Moscow group has been studying EAS vigorously. Also an air shower project has been founded at the Institute for Nuclear Study, University of Tokyo.

In this report the structures of EAS near their axes are discussed. The lateral distributions of particles were measured by the array of 14 plastic scintillation detectors and the neon hodoscope.* The latter instrument is the same device as the one known as the Conversi counter.[4] The neon hodoscope covers an area of 7 m² and can give precise information about the particle distributions and the position of the shower axis. The energies of the shower particles were measured by Čerenkov detectors. The lateral distributions of electrons and also of mean energies of particles were well determined by means of these detectors and compared with the theoretical ones predicted by the Nishimura-Kamata function.[5] It is noticeable that the observed structure of EAS near the axis is different from case to case and that the variety is not caused by statistical fluctuation but is due to the essential character of EAS. It is emphasized that the individual character of EAS presents information about the development of EAS and the nuclear interactions. The results on the nuclear active and μ-meson components and the interpretations of EAS concerning all of the components will be discussed elsewhere.[6]

§ 2. Experimental

A. General

Observations of EAS were performed with two arrangements. The general features of EAS were examined with Arrangement A and then the fine structure of EAS, especially near the axes, was studied with Arrangement B. As the details of detectors used, with the exception of the neon hodoscope will be reported elsewhere,[7] they are only briefly described here.

a. *Arrangement A*

The experimental arrangement of detectors is schematically illustrated in Fig. 1 a. The n-detector is used to measure the particle density and is a plastic scintillator whose effective area and thickness are 1 m² and 4.5 cm, respectively. 14 detectors are used. The e-detector is used to measure the energy flow carried by particles in an unit area. 9 e-detectors are lead-glass Čerenkov detectors 53 cm in diameter and 30 cm thick (12 radiation length equivalent). 6 e-detectors are $Pb(NO_3)_2$ solution (30%) Čerenkov detectors. The container of the solution is 56 cm in diameter and 80 cm in thickness (6 r.l. equivalent).[8] Each e-detector is surrounded by barytes concrete of 30 cm width in order to compensate the number of particles which scatter out from the detector by those which scatter in from the concrete. Five 0.25 m² plastic scintillation detectors placed at the vertices of a pentahedron are used to determine the arrival direction of the shower by means of fast timing circuit.[9] 4 plastic scintillation detectors each of area 2 m² placed 30 m.w.e. underground and a hodoscope chamber of 1 m² under a concrete block of 20 r.l. are employed to detect μ-mesons of energies of >5 Bev and of >1 Bev, respectively.[10] 2 "transition chambers", which are five layer sandwiches of iron sheets and plastic scintillators give information concerning the nucleon components.[11] The neon hodoscope whose details are presented in the following section is used to observe the lateral distribution of electrons.

The apparatus was triggered by 4-fold coincidences of the n-detectors with the added requirement that more than 7 particles must traverse each detector. This was accomplished by suitable bias to give the proper triggering level. A coincidence between n_6, n_7, n_8, and n_9 was mainly employed, but other coincidences, that is, n_1–n_2–n_3–n_4 and n_8–n_9–n_{10}–n_{12} were used for short periods. The size (the total number of particles) of observed showers were in the range of 10^4 to 10^7.

---

* Prof. J. Nishimura proposed at the symposium held in February of 1956 the utility of this device as a density detector which would display the character of EAS by permitting observation of the precise particle distribution near the shower axis.

b. *Arrangement B*

To obtain the precise structure of EAS near their axes Arrangement B was used and is shown in Fig. 1 b. The locations of the n-detectors are the same as in Arrangement A, except that 4 detectors at the central part of the detector array were rearranged. 10 lead glass e-detectors without concrete compensators are placed in a group under the neon hodoscope. 3 fast timing detectors which detect the arrival direction of the shower are placed at vertices of a triangle. The other detectors, excepting the neon hodoscope, were not operated. 4-fold coincidences between n_6, n_7, n_8, and n_9 triggered the apparatus.

B. Neon Hodoscope

a. *Construction*

The neon hodoscope which covers an area of 7 m^2 is the same device as the hodoscope chamber originally developed by Conversi.[4] These instruments work on the following principles. Glass tubes filled with a mixture of neon and argon are placed between parallel conducting plates, and an intense pulsed

electric field is applied across the tube immediately after the passage of ionizing particles. Then the tubes which are traversed by particles become luminous, and the others do not.

Our purpose is to determine the particle density, not the trajectory, so tubes are placed on a horizontal plane. As shown in Fig. 2, tubes are arranged in a lattice, the total number being five thousand. Each tube, 5 cm long and 2 cm in a diameter, is filled with a mixture of (Ne+0.1%A) at a pressure of 30 cm Hg. The pre-treatment of tubes before filling with the gas followed the method described in a previous paper.[12] The operating circuit of the neon hodoscope is shown schematically in Fig. 3. The peak voltage gradient and the time constant of the voltage pulse are fixed at 13.5 kV/2.3 cm and 1 μsec, respectively. The time delay between the passage of the shower particles and the application of the voltage pulse is 1.5 μsec. Under this operating condition the efficiency of detecting particles is estimated to be almost 100%. Light from tubes which are lit is reflected by a mirror and photographed on 35 mm film. Pictures were taken on Fuji SSS film at f/1.8.

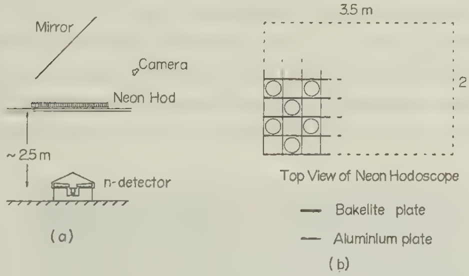

Fig. 2. Arrangement of the neon hodoscope shown schematically. Each tube, 5 cm long and 2 cm in diameter, is filled with a mixture of (Ne+0.1% A) at a pressure of 30 cm Hg. Tubes are set in the lattices and cover an area of 7 m². The instrument including its photographic system is placed in a dark room which serves as well for the electrical shielding. The hodoscope is placed 2.5 m above the level of the other detectors.

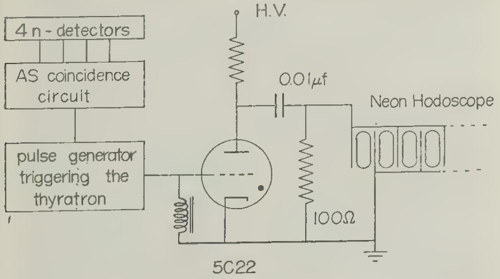

Fig. 3. High voltage pulse generator. The voltage of H. V. is fixed at 13.5 kV. The time constant of the voltage pulse is 1 μ sec. The time delay between the passage of the shower particles and the application of the voltage pulse is 1.5 μ sec.

This instrument can be easily constructed. It is very stable and also has a long operating life. Actually it was confirmed that the detection efficiency does not vary during a few tens of thousands of times of operation.

b. *Estimation of electron density*

The density of electrons is estimated from the number of lighted tubes by the following method. The total area of the neon hodoscope is divided into 28 sections, each of area of 50×50 cm². Assuming that all electrons pass through the tubes parallel to the shower axis and the particle density is uniform throughout the area of each section, the number of lighted tubes, m, is given by

$$m = T(1-\exp(-\Delta s)) + T(1-\exp(-\Delta s'))\exp(-\Delta(s-s')),$$

where T is the total number of tubes in the section, Δ the electron density per unit area in the section, s the effective area of each tube, and s' the effective area for one particle to cross two adjacent tubes. As each tube has a cylindrical shape and stands vertically, the effective area through which particles can pass varies with the inclination of the direction of the particle's path to the axis of the tube. From previous experiment[13] it is confirmed that the detection efficiency of tubes in the present arrangement is not dependent upon the region where a particle crosses. So the effective area, s, is a function only of the inclination of the shower axis and can be easily estimated. When the path of particle is inclined markedly, one particle can cross two adjacent tubes and then two tubes are lighted. The effective area, s', varies with the zenith and the azimuth angles of the shower axis. For the shower for which the axis is inclined at less than 25°, the values of s' are zero or negligibly small. The second term of the above expression has a significant value only when the particle density and the inclination of the axis are large.

From the present arrangement of tubes the details of the local concentration of particles can not be studied. That is, the special resolution is not sufficiently good to analyze the concentration of particles within an area of 10 cm × 10 cm. It is noted from the above expression that the number of lighted tubes is almost saturated when electrons with density of more than 5,000 particles per m^2 strike the neon hodoscope.

§ 3. Results

A. Lateral distribution of electrons

a. *The region from a few m to 80 m from the axis*

From the amplitude of the pulse from each scintillation detector (n-detector), which was recorded on film, the number of particles striking the detector was determined. Pulses from single pentrating cosmic ray particles were used for calibration. It should be noted that the pulse from a scintillation detector depends on the number of ionizing particles falling on it, their energies, and any secondary events produced in it. On the other hand, the neon hodoscope is expected to give a nearly true density of electrons, because the tubes are made of very thin glass and the process of discharges does not depend on the energy of the particles. In the first step of analyzing the data, we used the raw number determined as indicated above, not correcting for the effects of secondary processes and variation in particle energies. The location of the shower axis was determined by using a special-purpose computer whose operation is based on the assumption that the lateral distribution of densities given by the scintillation detectors can be smoothly fitted to some curve representing the function r^{-n}, where r is the distance from the axis. After determining the location of the axis, the distance of each detector from the axis was measured and then the distribution of particle densities was plotted against the distance.

In the region beyond a few m to 80 m from the axis, each lateral distribution of particle density thus obtained is in good agreement with that predicted by the N. K. theory[5], assigning a certain value of the s-parameter, which has an inaccuracy of ±0.2 due to the statistical fluctuation of the electron numbers fell in the detectors and due to the accuracy in determining the location of the shower axis. Each observed lateral distribution can be expressed by one value of s which denotes now only the slope of the distribution rather than its original meaning. Then the size of each EAS can be determined by comparing the observed distribution with that of the N.K. theory, assuming that the lateral distribution of particle density at far distances beyond the observed points can be also given by the N.K. theory with the same value of s and that the N.K. theory keeps its validity in that region.

The two values of observed density given by the scintillation detector and by the neon hodoscope can be compared for various distances from the axis. The ratio of these as a function of the distance from the axis is given in Fig. 4. It is found that the ratios do not depend on the shower sizes or the values of s within the present accuracy. The points in Fig. 4 represent the averaged values.

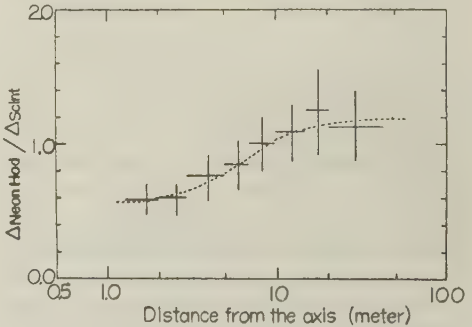

Fig. 4. Comparison between particle densities obtaided by scintillation detectors and by the neon hodoscope as a function of the distance from the shower axis.

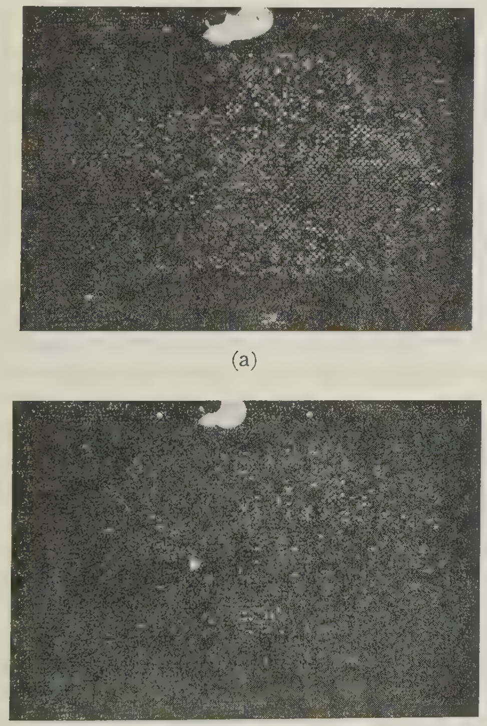
Assuming the neon hodoscope data to be correct, Fig. 4 can be used to correct the n-detector data, and thus arrive at corrected lateral distributions. If we use the N.K. function assigning a certain value of the s-parameter to express the lateral distribution of particle density, the corrected value of s for each EAS is about 0.2 greater than the value of s previously obtained. Hereafter in this report, the corrected values of s are used to express the slope of the lateral distribution of particle density.

b. *The region very close to the axis*

When the axis of EAS passed through or very close to the neon hodoscope, the location of the axis and the lateral distribution of electrons could be precisely determined by the spatial distribution of tubes discharged in the neon hodoscope. Two typical examples of photographs are illustrated in Fig. 5. Fig. 6 shows an example of analysis of an EAS derived with the aid of the neon hodoscope. As seen in the figure, the lateral distribution obtained by the neon hodoscope is smoothly connected with the corrected distribution given by the scintillation detectors and changes its slope gradually with the distance from its axis. When the axis of an EAS of size more than a few $\times 10^6$ strikes the neon hodoscope, the number of tubes discharged is almost saturated and it becomes impossible to determined the density of electrons. In most cases the lateral distributions were examined as closed to the axis as 30 cm.

For convenience to discuss the lateral distributions, most of the observed EAS are separated in two groups in terms of the value of s, which is determined as described in the previous section; that is, $s<1.2$ and $s\geq 1.2$. The composite distributions of these two groups, normalized to the shower size of 10^5, are plotted in Fig. 7 a and Fig. 7 b. It is remarkable that only four showers among eighty whose axes passed through the neon hodoscope present very steep distributions, characterized by $s=0.6$, as shown in Fig. 7 c, where the sizes are normalized to $N=10^5$. The averaged distributions of these three groups are illustrated together in Fig. 8.



(a)

(b)

Fig. 5 Two typical examples of photographs taken by the neon hydroscope. a) shower size $=1\times 10^5$ and $s=0.8$. b) shower size$=0.8\times 10^5$ and $s=1.2$.

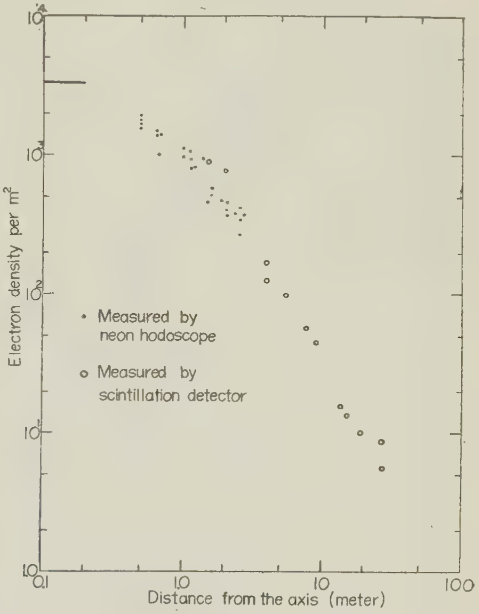


Fig. 6. A typical example of the lateral distribution of electrons, for the shower of Fig. 5. a.

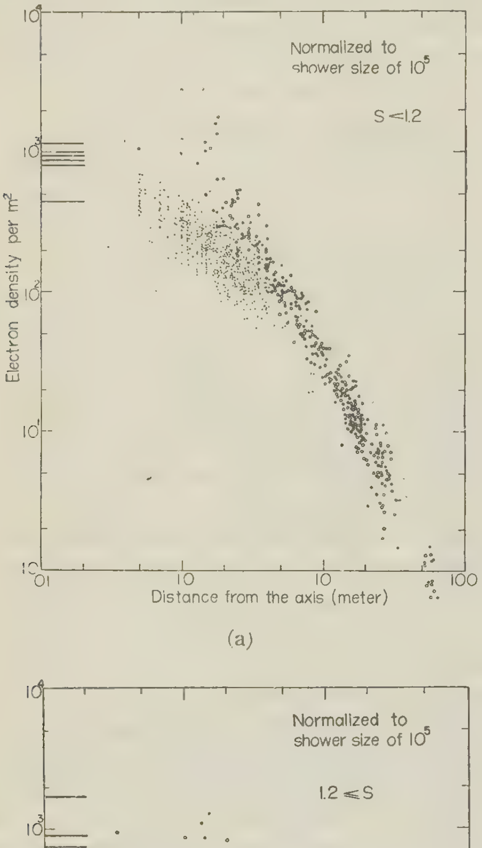
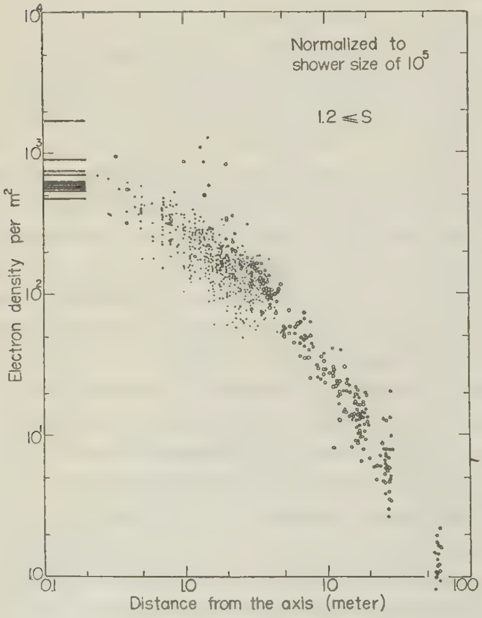
It is noted from the figure that i) the distributions near the axis are rather flat except in the case of the four showers of Fig. 7 c, ii) the character of the distribution for the showers with $s<1.2$ varies gradually from $r^{-0.6}$ to r^{-1} with the distance from the axis and the distribution is represented by $s=1.0\pm 0.2$ in the region beyond a few m from the axis, iii) the character of the distribution for the showers with $1.2\leq s$ varies from $r^{-0.4}$ to $r^{-0.7}$ near the axis and is fitted to $s=1.4\pm 0.2$ in the region beyond a few m from the axis, and iv) the character of distribution of the four showers with steep distributions is nearly equal to r^{-1} near the axis and is well represeted by $s=0.6\pm 0.1$.

B. The lateral distribution of the mean energy of shower particles

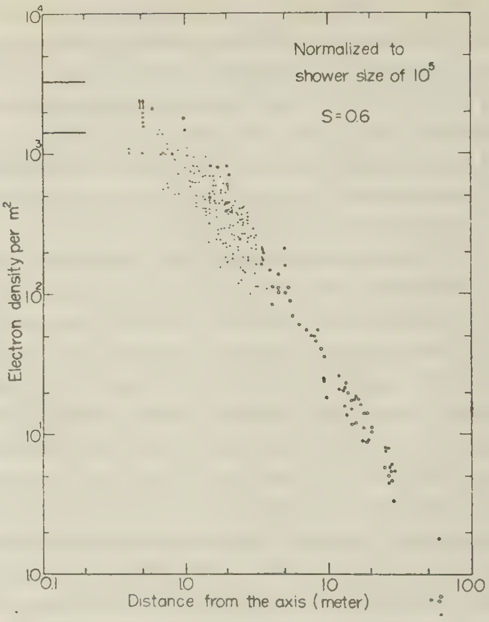
The pulses from e-detectors were recorded by photography of the oscilloscopes in the same way as in the case of the n-detectors. The almost of energy dissipated in the detector was calibrated by comparison with pulses from single penetrating μ-mesons. In order to obtain the mean energy of electrons near the shower axis the following procedures were carried out. As the location and the arrival direction of the axis are already determined, the lateral distribution of particles of each EAS given by the neon hodoscope can be traced on the places where the e-detectors are set. The spatial distribution of particles probably does not change from the level of the neon hodoscope to that of the e-detectors, because the only material between the two levels is wood of a few cm thickness. Correcting the effective area of the e-detector by the direction cosine of the shower axis, the dissipated energy divided by the number of particles gives the mean energy of electrons incident on each detector.



(a)



(b)



(c)

Fig. 7. The accumulated lateral distributions of electrons, normalized to a shower sizes of 10^5. a) is the case of showers with $s<1.2$, b) showers with $1.2 \leq s$ and c) the showers with $s=0.6$.

The values of the mean energies observed in individual EAS show large fluctuations. However, assuming that the density of particles in each EAS and also the process of the energy loss of particles in the Čerenkov detector show Poissonian fluctuation, the observed fluctuation of the mean energy shows no indication beyond what can be explained by the fluctuation of the Poissonian distributions. No dependence of the lateral distribution of the mean energy on the shower size or on the value of the *s*-parameter was found within the present accuracy. The composite lateral distributions are shown in Fig. 9. The theoretical curve from the N.K. lateral distribution function for mean energy and the experimental results of Dmitriev et al.[14] and Vernov et al.[15] are shown in the same figure. From the observed distributions the lateral distribution of mean energy in the region from the axis to 7 m is expressed by $E=7.5\times10^8\times r^{-0.7\pm0.1}$ ev, where r is measured in meters. The present distribution is in good agreement with the results of Vernov et al.

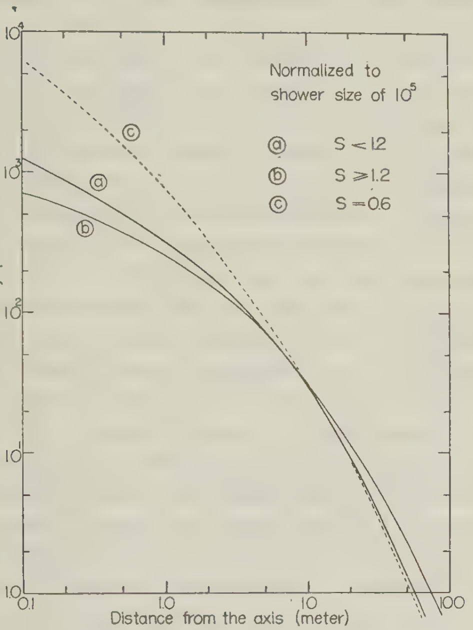


Fig. 8. The averaged lateral distributions of electrons which are shown in Fig. 7. Curve a is the lateral distribution corresponding to Fig. 7a. The r-dependency varies from $r^{-0.6}$ to $r^{-1.0}$ at distances from the axis up to a few meters, and s has the value 1.0 in the region beyond 5 m. Curve b corresponds to Fig. 7b. The r-dependency varies from $r^{-0.4}$ to $r^{-0.7}$ near the axis, and $s=1.4$ in the region beyond 5 m. Curve c is the one corresponding to Fig. 7c. The r-dependency is nearly equal to $r^{-1.0}$ near the axis, and $s=0.6$ in the region beyond 5 m.

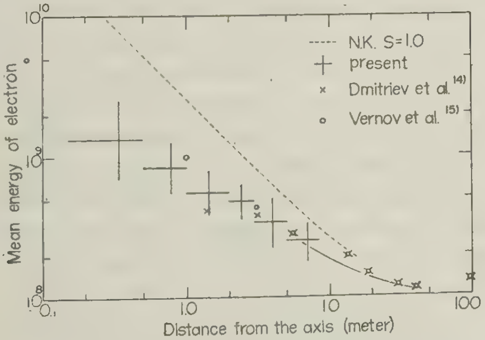

Fig. 9. The lateral distribution of the mean energy of electrons. It is well expressed by $E=7.5\times10^8\times r^{-0.7\pm0.1}$ ev in the region from the axis to 7 m.

§ 4. Discussion

A. Comparison between the density obtained by the scintillation detector and by the neon hodoscope

Concerning the particle density of EAS, the kind of detectors used must be considered. If scintillation detectors are used and the particle density is estimated by the method previously mentioned, the estimated density may not represent the correct electron density, especially near the axis, because of various phenomena caused by electrons of relatively high energy and other particles in scintillation detectors of finite thickness.[16] On the other hand, the neon hodoscope tube has a character similar to that of the G-M counter, and the accuracy of the estimation of the particle density depends only on its geometry and the trajectories of changed particles. At large distances from the axis, the paths of electrons are not strictly parallel to the axis owing to multiple scattering, and therefore the effective area of tubes may be larger than that assumed. In this case the estimated value of the particle density may be a little larger than the true value, but the correction is estimated to be not larger than 20% from the data on the lateral distribution of the mean energy.

The correction for the density observed with the scintillation detector can be made by comparison with the density obtained by the neon hodoscope as a function of the distance from the shower axis.

B. The lateral distribution of electrons

Many workers have observed EAS and discussed the lateral distribution of electrons, comparing the observed distribution with the predicted one from the theory with respect to the averaged features. It is shown from the N.K. theory that the lateral distribution of electrons can be expressed by one value of the *s*-parameter even when the electron components are initiated from many sources distributed in one dimention, namely the longitudinal direction. The lateral structure of electrons of EAS is the superposition of a large number of electron cascade showers which are produced by many sources in successive stages of the development of EAS. It is apt to be considered that the lateral distribution of electrons is expressed by some averaged structure. However, as has been pointed out by various authors[2),3)] the lateral distribution of electrons is influenced by the fluctuations in the development of EAS.

The individual lateral distribution of electrons in the region from a few meter to 80 m from the axis can be well fitted by the N.K. function, the value whose s-parameter is suitably adjusted for each EAS. Here, it must be noticed that the s-parameter is used only to express the slope of the lateral distribution of electrons observed and that the value of s has an error of ± 0.2 due to the statistical fluctuations of the particle numbers in the detectors and due to the accuracy in determining the position of the shower axis. As presented in § **3.A**, about half of the eighty showers whose axes passed through the neon hodoscope have N.K. age parameter in the range $s<1.2$ and about fourty percent of them have values in the range $1.2 \leq s$. Four of the observed showers have a steep slope, that is, $s=0.6$. The observed frequencies of EAS of different values of s may be changed by changing the triggering condition and the arrangement of the detector array.

It is remarkable that, for instance, an EAS of size 2×10^5 and its lateral distribution of electrons with $s<1.2$ can be well represented by the superposition of an EAS of size 1.5×10^5 and lateral distribution of electrons with $1.2\leq s$ and an EAS of size 4×10^4 and the lateral distribution of electrons with $s=0.6$. This example shows the possibility that, if a young shower, though its size is small, is superimposed on an old shower, it can change the apparent lateral distribution of electrons of the composite shower considerably. Taking into account this possibility, the lateral structure of EAS may be affected by the fluctuation of the survival of nuclear-active particles which have relatively high energy.

Direct measurements on the particle distribution very near the axis have been made by some workers. In the work of Hazen,[17)] performed experiments with a cloud chamber at 3000 m altitude, the density gradients within 0.5 m from axes were found to be much smaller than those predicted by the Molière theory. From observations with a large diffusion cloud chamber at sea-level, Relf[18)] concluded that the lateral structure up to 0.6 m from the axis was described by the Molière theory within Gaussian fluctuations, and that each shower, within statistical errors, consists of a single core. He observed only one event which showed a very steep distribution up to 1 m from the axis. Vernov et al.[19)] observed the core structure with a diffusion chamber of 0.6 m^2 together with ionization chamber arrays. As one can see in Fig. 7 a and Fig. 7 b the observed lateral distribution of electrons within a few meter from the axis varies gradually from r^{-1} to $r^{-0.4}$. These features depend slightly on the value of s but do not depend on the shower size. The predicted distribution from the theory can not be adopted in the region very close to the axis because the assumption made in the theory is not correct in that region.

The altitude of first nuclear interaction has a dominant effect on the lateral structure of EAS, but the change of the interaction mean free path of particles with their energy and successive interactions also have some effect. Recently it has been observed that the energy spectrum of γ-rays observed at high altitude shows a steep slope in the region beyond 10^{12} ev compared to its slope in the lower energy region.[20)] If the γ-rays are produced from the decay of π°-mesons, it is considered that the energy spectrum of secondaries at a high energy interaction may be affected by the initial energy and the interaction mean free path may also have some depedency on the particle energy. Indeed, the structure of EAS is the accumulated phenomenon, therefore the lateral distribution of electrons should be discussed considering the nuclear component, μ-meson component, and the electron mean energy which will be discussed in next section.

C. Lateral distribution of the mean energy of particles

Recently Danilova et al.[21)] and Miyake et al.[22)] observed EAS at mountain altitude with a multiplate cloud chamber, and it was observed that the lateral distribution of particles and also the development of showers in the chamber showed a large fluctuation from case to case. Vernov et al.[19),23)] observed the energy flux of the electron-photon component with ion-chamber arrays and found sharp fluctuations therein. Porter et al.[24)] observed the lateral distribution of energy flow at distances of 60–500 m from the axis using a water Čerenkov detector and concluded that the results were consistent with the theoretical distribution predicted by the N.K. function for the mean energy with $s=1.0$. Dmitriev et al.[14)] and Vernov et al.[15)] obtained the lateral distribution of the energy flux using ion-chambers. As seen in Fig. 9, their results are in an excellent agreement with the present results.

In the present experiment the amount of the energy flow estimated by the Čerenkov detector needs a correction which is found to be not very large. The thickness of the detector is not enough to absorb the entire process of the electron cascade shower carried by the high energy electron-photon component. This correction is estimated to be at most 20 to 30% when an electron of energy of more than 1 Bev strikes the detector. The correction for the contribution by the nuclear-active component is estimated using the result obtained with the transition chamber and it does not seem to exceed 20% near the axis. The fluctuation of the particle density and of the process of the energy dissipation in the detector has a large effect on the estimated value of the energy flow. Therefore, it can not be clearly determined whether or not the lateral distribution of the energy flow depends on the shower size and on the value of s-parameter.

The observed lateral distribution of the mean energy of electrons is well expressed by $E \fallingdotseq 7.5\times10^{8}\,r^{-0.7\pm0.1}$ ev within 7 m from the axis, where the distance r is measured in meters. As seen in Fig. 9, the theoretical curve predicted by the N.K. function for the mean energy with $s=1.0$ lies above the experimental points. The initial energy of the electron shower is taken to be infinite in the theory, but that of the actual shower has a finite value. Moreover it should be noted that in the estimation of the mean energy, the energy which is carried by the photons is ignored because the photons are not counted in the particle density.

Even for a composite EAS consisting of the superposition of an old shower and a young one, as discussed in § **4.B**, the energy flow is not clearly distinguished from the average value because of satistical fluctuations. In order to examine the energy flow of EAS precisely, further experimental investigations are needed.

D. Very high electron density observed by scintillation detectors near the axis

Some EAS show the feature that the electron densities estimated by scintillation detectors are three or five times of those obtained by the neon hodoscope in the region 1 m or 2 m from the axis. The discrepancy is too great to be explained by statistical fluctuation and the lateral distribution of particles of these EAS is observed to be very steep in this region. The rate of occurrence of these EAS was observed to be about 40% of the total number of EAS analyzed and to be independent of the s-value. As the amount of material between the neon hodoscope and the scintillation detectors is very small, the materialization of particles in that space should be negligible.

Therefore other possible contribution must be considered. If neutral particles produce secondary events in scintillators, they give a high amplitude of the pulse, but the tubes of the neon hodoscope are not discharged by neutral particles. At first let us assume these particles are photons. As the thickness of a scintillator is about 0.1 r.l., ten photons present an amplitude equivalent to a single electron if the photons produce electron pairs. Therefore, the number of photons required is more than 30 times the number of electrons to increase the pulse amplitude to the observed value. As a second case let us assume neutrons instead of photons. A star produced by a neutron of energy of several hundreds of Mev presents, on the average, a pulse amplitude about 50% of the amplitude produced by an electron of 100 Mev. If the stars thus produced raise the pulse amplitude to the observed value, the number of neutrons needed is several times the number of electrons. Photons and neutrons exist in relatively large number near the axis but from the data already obtained, the amount of increase of the amplitude of the pulse which could be attributed to these components is estimated to be at most several ten percent of electrons. It appears very hard to explain the above mentioned phenomenon in terms of either photons or neutrons.

If local concentrations of charged particles are superposed on the main distribution, the pulse amplitude is raised but the number of lighted tubes in the neon hodoscope can not be changed if the area of the concentration is smaller than 10 cm × 10 cm. These local concentrations, e.g., narrow showers, may be composed of groups of electrons or μ-mesons. If the nuclear interaction occurs at lower atmospheric depth, as discussed above, some of the γ-rays may produce narrow electron showers and such γ-rays will be in the region near the axis. The observed energy flow of EAS which present this phenomenon is not higher than that of other EAS within the present accuracy of estimation, though it shows slight higher value. Therefore, narrow electron showers may be excluded in explaining such phenomena, because the energy flow must be raised considerably by these electron showers.

If this concentration is compose of μ-mesons, the energy flow detected by the Čerenkov detectors is not raised greatly by these μ-mesons. But the mechanism of production of such μ-mesons comes into question. μ-mesons in EAS are considered to be produced in the early stages of development of EAS. These narrow concentrations are not readily explained in terms of μ-mesons because of the high density required unless a narrow shower of μ-mesons can be produced by a process which is unknown.

Recently, Vernov et al.[25)] observed the possible presence of collimated particle beams in the cores by means of a diffusion cloud chamber. The beams were concentrated in a circle of diameter 4 cm and the number of particles within that circle was 5 to 15. The phenomena observed by Vernov et al. may be the same as that observed by us. The lumpy distribution near the axis observed by Heineman[26)] and Davis et al.[27)] was not observed in the present experiment because of the lack of spatial resolution of the neon hodoscope. However, that kind of distribution may be partly attributed to the phenomena described above.

Acknowledgements

The author is greatly indebted to many individuals in connection with this work. In particular he wishes to thank Professor Y. Watase and Professor S. Kikuchi for their encouragement and continuous interest in this experiment and Professor J. Nishimura for his suggestion of the utility of the neon hodoscope and also for his encouragement. The author is especially indebted to Professors I. Miura, M. Oda and K. Suga and Messrs. T. Matano, G. Tanahashi and Y. Tanaka for their help in performing the experiment and for their encouragement and valuable discussions. He would like to thank other staff of the Cosmic-Ray Laboratory of INS for their help in maintenance of the apparatus and for their assistance in analyzing the data. He also wishes to thank Mr. S. Miyamoto and Mr. M. Teranaka for their assistance in preparing the neon hodoscope. Finaly the author wishes to express his thanks to Professor. M. Crouch of Case Institute of Technology, who is a staff member of the Science Office of the American Embassy in Tokyo, and Professor S. Hayakawa for their discussions and help in the preparation of this manuscript.

Addendum

After this observation the subsequent measurements of EAS have been performed with the modified detector array by the members* of INS. By the new arrangement the location of the shower axis can be determined accurately even when the axis does not strike the neon hodoscope and the lateral distribution of particles can be measured at far 200 m from the axis. The preliminary results of these subsequent measurements show that the lateral distribution of particles within 3 m from the axis fluctuates from shower to shower and that if the slope of the lateral distribution is expressed by the s-parameter of N.K. function, s is to be assigned as 0.6∼0.8 for 3 m∼30 m and $s=1.2\sim1.4$

beyond 30 m from the axis.

It may be pointed that the individuality of the structure of EAS is shown by the lateral distribution close to the axis. The discrepancy in the observed value of s for the region of a few m～several tens m may be understood by considering the accuracy of s dermined in the two different experimental arrangements. The essential parts of discussions in this report will not be changed by this discrepancy. The structure of EAS should be precisely discussed considering the inter-relations between the multi-parameters of EAS.

On the Transport Equation in Quantum Mechanics

By Lesser BLUM

Facultad de Ciencias Exactas y Naturales, Buenos Aires Argentina

(Received May 20, 1960)

By means of a time-dependent perturbation procedure similar to that developed by Prigogine, the transport equation for a particle in a Bose-Einstein medium is obtained. This equation shows also a non local character.

§ 1. Introduction

In the theory of quantum transpot processes two ways seem to be most the important in obtaining the evolution equation, namely the time coarsing, which gives the quantum mechanical version of Boltzmnn's equation (classic approximation), and the perturbation theory, which seems more appropriated for the Born approximation. (Prigogine and Ono.[1),2)])

In the present paper we shall make a derivation of the transport equation using a procedure which is very appropriated for the case of the Brownian motion of a particle in an homegoneous medium, that is to say, we take random a priori phases for the states of the medium, but not for the particle. Furthermore, we do not refer to any kind of energy spectrum, as we use the second quantization formalism.

In § 2 we describe the hamiltonian and the basic representation of the system; the Wigner function is used here, and its application to our problem is treated in § 3, the notation is that of Massignon[3)] in which a very good review on this subject is also found. In § 4 the evolution equations for the terms in the Wigner function is obtained. Finally in § 5 we get the transport equation, and some of its features are discussed.

§ 2. Hamiltonian and the Basic Representation

We may write the hamiltonian of our system as

$$H=H_0+\lambda H' \tag{2.1}$$

were we take $\lambda H'$ as the interaction of the particle with the medium λ being the coupling parameter; also we will suppose that only the binary interactions are important.

In the formalism of the second quantization we may then write

$$H'=\frac{1}{2\Omega}\sum_{\alpha\beta kl} v(\alpha kl\beta)a_\alpha{}^+a_k{}^+a_\beta a_l\delta^{Kr}(\alpha+k-l-\beta) \tag{2.2}$$

$$v(\alpha k,\, l\beta)=v(\alpha-\beta)=v^K(k-l)=\int dre^{i(r-r')(\alpha-\beta)}v(r-r'); \tag{2.3}$$

where we take the greek subindices for the states of the particles, the latin for those of the medium, Ω is the total volume of the system of and the a^+, a are usual creation destruction operators. $\delta(x)$ is the tree dimensional kroneker delta $\delta_x{}^{Kr}$, which is 1 if the argument is zero and otherwise 0, and α, β etc. are vector momenta. We shall take $\hbar=1$ for convenience. We shall also assume that the medium obeys the B. E. statistics, i.e.

$$[a_k{}^+a_l]=\delta^{Kr}(k-l) \qquad [a_k{}^+a_l{}^+]=[a_ka_l]=0 \tag{2.4}$$

also we have for our system

$$[a_\alpha{}^+a_k]=[a_k{}^+a_\alpha]=0 \tag{2.4'}$$

in the interaction representation we have

$$H(t)=e^{iH_0t}H'e^{-iH_0t} \tag{2.5}$$

so that from (2.2) and (2.5) we get

$$<n|H(t)|n'>=\frac{1}{2\Omega}\sum_{\alpha\beta ke}\delta^{Kr}(k+\alpha-l-\beta)v(k\alpha l\beta)e^{it(\varepsilon_k+\varepsilon_\alpha-\varepsilon_l-\varepsilon_\beta)}\times\langle n|a_k{}^+a_\alpha{}^+a_la_\beta|n'\rangle \tag{2.6}$$

§ 3. The Wigner Formalism

This formalism is very convenient to show the classical limit of quantum phenomena; let us take the reduced Wigner function for one particle (see for example Massignon (3) p. 213)

$$f_w(x,p)=Tr\left\{\rho,\ \int d\nu\psi^+(x-\pi\nu)\psi(x+\pi\nu)e^{-2\pi i\nu p}\right\} \tag{3.1}$$

with

$$\left.\begin{aligned}\psi^+(x-\pi\nu)&=\sum_\alpha a_\alpha{}^+\varphi_\alpha{}^*(x-\pi\nu)\\ \psi(x+\pi\nu)&=\sum_\beta a_\beta\varphi_\beta(x+\pi\nu)\end{aligned}\right\} \tag{3.2}$$

If we take the φ's as plane waves we get

$$\varphi_\alpha(x)=L^{-3/2}e^{ix\alpha}\quad(\alpha=\text{proportional to }2\pi/L) \tag{3.3}$$

so that in the representation of the occupation numbers n

$$f_w(x,\ p)=\Omega^{-1}\sum_{n,n'}\sum_{\alpha,\beta}\langle n|\rho|n'\rangle\langle n'|a_\alpha{}^+a_\beta|n\rangle e^{ix(\alpha-\beta)}\delta^{Kr}(2p-\alpha-\beta) \tag{3.4}$$

Here as we take an homogeneous medium, the matrix are assumed to be diagonal for the states of the medium, and the only non diagonal states allowed are those for the particle we are studying. We have thus

$$f_w(x,\ p)=\Omega^{-1}\sum_n\sum_{\alpha\beta}\delta^{Kr}(2p-\alpha-\beta)e^{ix(\alpha-\beta)}\langle n1_\alpha|\rho|n1_\beta\rangle \tag{3.5}$$

where 1_α and 1_β are referred to the momentum of the particle under consideration. In the above we should note that the terms in (3–5) have different volume dependence according as they are homogeneous (i.e. diagonal, $\alpha=\beta$) or inhomogeneous (i.e. non-diagonal $\alpha\neq\beta$).

However, only for simplicity, we shall consider only the second case since the first is only a particular case of it.

In the interaction representation, the formule (3–5) can be written as

$$f_w(x,p,t)=\Omega^{-1}\sum_n\sum_{\alpha\beta}\delta^{Kr}(2p-\alpha-\beta)e^{i(\alpha-\beta)[x-t/2m(\alpha+\beta)]}\langle n1_\alpha|\rho|n1_\beta\rangle \tag{3.6}$$

from which we get

$$\partial_t f_w+\frac{(\alpha+\beta)}{2m}\partial_x f_w=\Omega^{-1}\sum_n\sum_{\alpha\beta}\delta^{Kr}(2p-\alpha-\beta)e^{i(\alpha-\beta)[x-t/2m(\alpha+\beta)]}\partial_t\langle n1_\alpha|\rho|n1_\beta\rangle \tag{3.7}$$

in these formulas, m is mass of the particle, and the notation $\partial_t\equiv\partial/\partial t$ is used.

§ 4. The Von Neumann Formalism

Our problem is then to calculate the value of $\partial_t\langle n1_\alpha|\rho|n1_\beta\rangle$ in (3–7); for doing this, let us start with the well known von Neumann equation in the interaction representation

$$i\partial_t\rho(t)=\lambda[H(t),\ \rho(t)];\quad \rho(t)\equiv e^{tH_0t}\rho e^{-tH_0t} \tag{4.1}$$

This equation can be solved by iteration: one can show that the dominant term when $t\to\infty$ and $\lambda\to0$ and $\lambda^2t=$finite (corresponding to the cycle inserted in a line, Prigogine and One (1) and Balescu (4), and in fact, the only terms different from zero under the conditions of our problem) is represented by

$$\partial_t\rho(t)=-\lambda^2\left[H(t),\int_0^t dt_1[H(t_1),\ \rho(t)]\right] \tag{4.2}$$

and in the representation of the occupation numbers

$$\partial_t\langle n1_\alpha|\rho|1_\beta n\rangle=-\lambda^2\int_0^t dt_1\sum_{n''}\sum_{n'''}\Big\{\overbrace{\langle n1_\alpha|H(t)|n''\rangle\langle n''|H(t_1)|n'''\rangle\langle n'''|\rho(t)|n1_\beta\rangle}^{\text{Term I}}$$

$$\overbrace{-\langle n1_\alpha|H(t)|n''))\langle n''|\rho(t)|n'''\rangle\langle n'''|H(t_1)|n1_\beta\rangle}^{\text{Term II}}$$

$$\overbrace{-\langle n1_\alpha|H(t_1)|n''\rangle\langle n''|\rho(t)|n'''\rangle\langle n'''|H(t)|n1_\beta\rangle}^{\text{Term III}}$$

$$\overbrace{+\langle n1_\alpha|\rho(t)|1n''\rangle\langle n''|H(t_1)|n'''\rangle\langle n'''|H(t)|n1_\beta\rangle}^{\text{Term VI}}\Big\}$$

so that because of (2.6) the terms of (4.3) which are non vanishing are

$$\begin{aligned}
\text{T. I}\ &\rightarrow\langle n1_\alpha|a_\alpha{}^+a_k{}^+a_\nu a_l|1_\nu n_k-1,\ n_l+1,\ n\rangle\langle n,\ 1_\nu,\ n_k-1,\ n_l+1|a_\nu{}^+a_l{}^+a_\mu a_k|1_\mu,\ n\rangle\\
&\times\langle n,\ 1_\mu|\rho|n1_\beta\rangle\delta^{Kr}(\alpha+k-l-\nu)\delta^{Kr}(\nu+l-k-\mu)v(\alpha k,\ \nu l)v(\nu l,\ k\mu)\\
&\times\exp\,[it(\mathcal{E}_\alpha+\mathcal{E}_k-\mathcal{E}_\nu-\mathcal{E}_l)]\int_0^t dt_1\exp\,[it_1(\mathcal{E}_\nu+\mathcal{E}_l-\mathcal{E}_k-\mathcal{E}_\mu)]\\
\text{T. II}\ &\rightarrow\langle n1_\alpha|a_\alpha{}^+a_k{}^+a_\nu a_l|1_\nu,\ n_k-1,\ n_l+1,\ n\rangle\langle n1_\nu,\ n_k-1,\ n_l+1,\ |\rho|n_k-1,\ n_l+1,\ 1_\mu,\ n\rangle\\
&\times\langle n_k-1,\ n_l+1,\ 1\mu,\ n|a_\mu{}^+a_l{}^+a_k a_\beta|n1_\beta\rangle\delta^{Kr}(\alpha+k-\nu-l)\delta^{Kr}(\mu+l-k-\beta)v(\alpha k,\ \nu l)\\
&\times v(\mu l,\ k\beta)\exp\,[it(\mathcal{E}_\alpha+\mathcal{E}_k-\mathcal{E}_\nu-\mathcal{E}_l)]\int_0^t dt_1\exp\,[it(\mathcal{E}_\mu+\mathcal{E}_l-\mathcal{E}_k-\mathcal{E}_\beta)|\\
\text{T. III}&\rightarrow\langle n,\ 1_\alpha|a_\alpha{}^+a_k{}^+a_\nu a_l|1_\nu,\ n_k-1,\ n_l+1,\ n\rangle\langle 1_\nu,\ n_k-1,\ n_l+1,\ n|\rho|n_k-1,\ n_l+1,\ n,\ 1_\mu\rangle\\
&\times\langle n,\ n_k-1,\ n_l+1,\ n,\ 1_\mu|a_\mu{}^+a_l{}^+a_\beta a_k|n,\ 1_\beta\rangle\delta^{Kr}(\alpha+k-\nu-l)\delta^{Kr}(\mu+l-k-\beta)\\
&\times v(\alpha k,\ \nu l)v(\mu l,\ k\beta)\exp\,[it(\mathcal{E}_\mu+\mathcal{E}_l-\mathcal{E}_k-\mathcal{E}_\beta)]\int_0^t dt_1\exp\,[it_1(\mathcal{E}_\alpha+\mathcal{E}_k-\mathcal{E}_l-\mathcal{E}_\nu)]\\
\text{T. IV}&\rightarrow\langle n,\ 1_\alpha|\rho|n1_\nu\rangle\langle n1_\nu|a_\nu{}^+a_k{}^+a_l a_\mu|1_\mu,\ n_k-1,\ n_l+1,\ n\rangle\\
&\times\langle n,\ 1_\mu,\ n_k-1,\ n_l+1|a_\mu{}^+a_l{}^+a_k a_\beta|n,\ 1_\beta\rangle\delta^{Kr}(\nu+k-l-\mu)\delta^{Kr}(\mu+l-k-\beta)v(\nu k,\ l\mu)\\
&\times\nu(\mu l,\ k\beta)\exp\,[it(\mathcal{E}_\mu+\mathcal{E}_l-\mathcal{E}_k-\mathcal{E}_\beta)]\int_0^t dt_1\exp\,[it_1(\mathcal{E}_\nu+\mathcal{E}_k-\mathcal{E}_l-\mathcal{E}_\mu)]
\end{aligned}\tag{4.4}$$

Asymptotic time integration of the time dependent terms in the last equation, i.e. considering that significant contributions arise only when the collision time t-t_1 is short in comparison with the time t (this has meaning only if we integrate first over the momenta, but is physically very reasonable) (see for example ref. (4) and (5)) leads to (4–6).

So we make use of the formula

$$e^{\mp i\alpha t}\int_0^t e^{\pm i\alpha t}dt=\pi\delta_\pm(\alpha),\quad\text{if}\quad t\rightarrow\infty\tag{4.5}$$

where δ_+ and δ_- are given by (6)

$$\pi\delta_\pm(\alpha)=\pi\delta(\alpha)\pm iP({}^1/_\alpha)$$

$P({}^1/_\alpha)$ being the principal part; then the time dependent factors in the terms I and IV become simply $\delta_-(\mathcal{E}_k+\mathcal{E}_\alpha-\mathcal{E}_l-\mathcal{E}_\nu)$ and $\delta_+(\mathcal{E}_\beta+\mathcal{E}_k-\mathcal{E}_l-\mathcal{E}_\mu)$, and the terms II and III give no systematic contribution in the limit $t\rightarrow\infty$, $\lambda\rightarrow 0$, $\lambda^2 t$=finite (this can be shown by simple iteration of (4.6)): they must be retained, however, because in certain cases (homogeneous systems, phonon type of spectra), they give: in these cases, there are, of course, not oscillating. We get

$$\partial_t\langle n1_\alpha|\rho|n1_\beta\rangle = -\frac{\lambda^2}{4\Omega^2}\pi\sum n_k(n_l+1)\delta^{Kr}(k+\alpha-l-\nu)\delta^{Kr}(\alpha-\beta+\mu-\nu)|v(k\alpha l\mu)|^2 \tag{4.6}$$
$$\{[\delta_-(\mathcal{E}_k+\mathcal{E}_\alpha-\mathcal{E}_l-\mathcal{E}_\nu)+\delta_+(\mathcal{E}_\beta+\mathcal{E}_k-\mathcal{E}_l-\mathcal{E}_\mu)]\langle n1_\alpha|\rho|n1_\beta\rangle-[\delta_-(\mathcal{E}_\beta-\mathcal{E}_k-\mathcal{E}_l-\mathcal{E}_\mu)$$
$$+\delta_+(\mathcal{E}_\alpha+\mathcal{E}_k-\mathcal{E}_\nu-\mathcal{E}_l)]\ \exp\ [it(\mathcal{E}_\alpha+\mathcal{E}_\mu-\mathcal{E}_\nu-\mathcal{E}_\beta)[\langle n, 1_\nu, n_k-1, n_l+1|\rho|n, n_k-1, n_l+1, 1_\mu\rangle\}$$

to stress the analogy with Prigogine and Ono's result, we may write the (4.6) as

$$\partial_t\langle n,\ 1_{\alpha+(K/2)}|\rho|1_{\alpha-(K/2)},\ n\rangle = -\frac{\pi\lambda^2}{4\Omega^2}\sum_{nkK'}|v(K')|^2 n_k(n_{k-K'}+1)$$
$$\times\exp\ [it(\mathcal{E}_{\alpha+(K/2)}-\mathcal{E}_{\alpha-(K/2)})]\left\{\exp\left[\frac{K'}{2}\left(\frac{\partial}{\partial\alpha}-\frac{\partial}{\partial k}\right)\right]-\exp\left[-\frac{K'}{2}\left(\frac{\partial}{\partial\alpha}-\frac{\partial}{\partial k}\right)\right]\right\}$$
$$\times\{\delta_-(\mathcal{E}_{\alpha+(K'/2)}+\mathcal{E}_{\alpha+(K/2)-(K'/2)}-\mathcal{E}_{k-(K'/2)}-\mathcal{E}_{\alpha+(K/2)+(K'/2)})\ \exp\left[-\frac{K'}{2}\left(\frac{\partial}{\partial\alpha}-\frac{\partial}{\partial k}\right)\right]$$
$$+\left\{\delta_+(\mathcal{E}_{\alpha-(K'/2)}+\mathcal{E}_{\alpha-(K/2)+(K'/2)}-\mathcal{E}_{k+(K'/2)}-\mathcal{E}_{\alpha+(K/2)+(K'/2)})\ \exp\left[\frac{K'}{2}\left(\frac{\partial}{\partial\alpha}-\frac{\partial}{\partial k}\right)\right]\right\}$$
$$\times\exp\left[-it(\mathcal{E}_{\alpha+(K/2)}-\mathcal{E}_{\alpha-(K/2)})\right]\langle n1_{\alpha+(K/2)}|\rho|n1_{\alpha-(K/2)}\rangle$$

where we have put $\alpha-\beta=\nu-\mu=K$; $\alpha-\nu=\beta-\mu=K'$ this last equation may be justified if we carry out the operations of the displacement operators on the functions of the right (this is permitted only in the sens of the Schwartz's distributions, for the δ_+, δ_- are singular functions) we re-obtain then (4-6), by making the suitable change of variables.

§ 5. The Transport Equation

Putting (4-6) in the Wigner function (3-2) we obtain

$$\partial_t f_w+(\alpha/m)\partial_x f_w = -\frac{\lambda^2\pi}{\Omega^3}\sum_n\sum_{klKK'} n_k(n_l+1)\delta^{Kr}(k-l+K')|v(K')|^2 e^{iK(x-(\alpha t/m))}$$
$$\left\{\left[\delta_-\left[\phi\left(\alpha+\frac{K}{2}\right)\right]+\delta_+\left[\phi\left(\alpha-\frac{K}{2}\right)\right]\right]\langle n,\ 1_{\alpha+(K/2)}|\rho|n1_{\alpha-(K/2)}\rangle-\left[\delta_-\left[\phi\left(\alpha-\frac{K}{2}\right)\right]\right.\right.$$
$$\left.+\delta_+\left[\phi\left(\alpha+\frac{K}{2}\right)\right]\right]\langle n,\ n_k-1,\ n_l+1,\ 1_{\alpha+(K/2)+K'}|\rho|n,\ n_k-1,\ n_l+1,\ 1_{\alpha-(k/2)+K'}\rangle$$
$$\left.\times\exp\left[it\left(f\left(\alpha+\frac{K}{2}\right)-f\left(\alpha-\frac{K}{2}\right)\right)\right]\right\} \tag{5.1}$$

in which we have made the following abbreviations

$$\phi\left(\alpha\pm\frac{K}{2}\right)\equiv\mathcal{E}_k-\mathcal{E}_l+\mathcal{E}_{\alpha\pm(K/2)}-\mathcal{E}_{\alpha+K'\pm(K/2)}$$
$$f\left(\alpha\pm\frac{K}{2}\right)=\mathcal{E}_{\alpha\pm(K/2)}-\mathcal{E}_{\alpha+K'\pm(K'/2)}$$

finally this formula can be transformed to give (see Appendix)

$$\partial_t f_w+(\alpha/m)\partial_x f_w = -\frac{\lambda^2\pi}{\Omega^3}\sum_n\sum_{klKK'} n_k(n_l+1)\delta^{Kr}(k-l+K')|v(K')|^2$$
$$\left\{\left[\delta_-\left[\phi\left(\alpha-\frac{i}{2}\frac{\partial}{\partial x}\right)\right]+\delta_+\left[\phi\left(\alpha+\frac{i}{2}\frac{\partial}{\partial x}\right)\right]\right]f_w(x,\ \alpha)-\left[\delta_-\left[\phi\left(\alpha+\frac{i}{2}\frac{\partial}{\partial x}\right)\right]\right.\right.$$
$$\left.\left.+\delta_+\left[\phi\left(\alpha-\frac{i}{2}\frac{\partial}{\partial x}\right)\right]\right]\ \exp\left\{it\left[f\left(\alpha-\frac{i}{2}\frac{\partial}{\partial x}\right)-f\left(\alpha+\frac{i}{2}\frac{\partial}{\partial x}\right)\right]\right\}f_w\left(x+\frac{K't}{m},\ \alpha+K'\right)\right\} \tag{5.2}$$

If the energy spectrum of both components is that of a perfect gas and if we suppose factorized distribution functions, and take continuous spectrum for k and K'

$$\partial_t f_w(x,\alpha,t)+\frac{\alpha}{m}\partial_x f_w(\alpha,x,t)=-\frac{\lambda^2 m}{2}\int dK'\int dk|v(K')|^2\int_0^\infty d\tau$$
$$\cos[\tau K'(\alpha-k+K')]\times\left\{f_w\left(\alpha,x-\frac{K'\tau}{2}\right)\varphi(k)[\varphi(k-K')+1]-f_w\left(\alpha+K',x+\frac{K'\tau}{2}\right)\right.$$
$$\left.\varphi(k-K')\times[\varphi(k)+1]\right\} \tag{5.3}$$

which shows the non-local character observed by Prigogine and Ono.

This effect is noticeable when

$$K^{-1}\le\alpha^{-1}=\lambda_B \quad (de\ \text{Broglie's wave length})$$

Another simple example is a system for which $\mathcal{E}_k=c|k|$ we obtain then

$$\partial_t f_w(x,\alpha,t)+\frac{\alpha}{m}\partial_x f_w(x,\alpha,t)=-\frac{\lambda^2\pi}{2c}\int dkdK'|v(K')|^2$$
$$\times\left\{\varphi(k)[\varphi(k-K')+1]f_w(x,\alpha,t)-\varphi(k-K')[\varphi(k)+1]f_w\left(x+\frac{K't}{m},\alpha+K't\right)\right\}$$

where the uncertainty can be related to the collision process and becomes appreciable when

$$\Delta\mathcal{E}(K')\cdot t<1$$

Aknowledgements

I am very indebted to Prof. Prigogine for many discussions and to the Consejo Nacional de Investigaciones Cientificas of Argentina, who supported this work;

Appendix

The term of (5-1) may generally be written, for this purpose

$$\sum_K e^{ikx}\Psi\left(\alpha-\frac{K}{2}\right)\chi\left(\alpha+\frac{K}{2}\right)\rho(\alpha+K') \tag{A1}$$

which by application of displacement operators becomes succesively

$$=\sum_K\chi\left(\alpha+\frac{K}{2}\right)\rho(\alpha+K')e^{ik(x+(i/2)(\partial/\partial\alpha))}\Psi(\alpha) \tag{A2}$$

$$=\sum_K\chi\left(\alpha+\frac{K}{2}\right)\rho(\alpha+K')e^{(i/2)(\partial/\partial x)(\partial/\partial\alpha)}e^{ixK}\Psi(\alpha) \tag{A3}$$

$$=\sum_K\chi\left(\alpha+\frac{K}{2}\right)\rho(\alpha+K')\Psi\left(\alpha+\frac{i}{2}\frac{\partial}{\partial x}\right)e^{ixK} \tag{A4}$$

$$=\sum_K\rho(\alpha+K')\chi\left(\alpha-\frac{i}{2}\frac{\partial}{\partial x}\right)\Psi\left(\alpha+\frac{i}{2}\frac{\partial}{\partial x}\right)e^{ixK} \tag{A5}$$

one can easily see how this works in the case of (5-1)

On the Theory of Adiabatic and Isolated Susceptibilities*

Nobuhiko SAITÔ**

Department of Chemistry, University of Oregon, Eugene, Oregon, U.S.A.

(Received December 8, 1960)

A quantum statistical mechanical proof of the equivalence of adiabatic and isolated susceptibilities in large systems is given by Broer's method using a Gibbs relation. Further a brief mention is made of the susceptibilities in non-equilibrium cases.

§ 1.

According to Broer[1] and Wright[2], a doubt was raised by Polder and Van Vleck that the two susceptibilities χ_s and χ_{iso} which are called adiabatic susceptibility and isolated susceptibility respectively (for the definition see Eqs. (4), (5) and (7)) do not always coincide. A partial solution of this problem was made by Broer. He showed that χ_s is equivalent to χ_{iso} in a large classical system. This is an important contribution to the theories of χ_s and χ_{iso}. However he found a difference between them in the quantum mechanical case. Thus the ratio of these two susceptibilities was calculated quantum mechanically by Wright[2], Broer[1] and Caspers[3]. However it is inconceivable that the difference of χ_s and χ_{iso} is due to a quantum effect. In effect Caspers[4] has shown $\chi_s=\chi_{iso}$ by making use of several assumptions about the structure of the energy levels. Recently Yamamoto[5] discussed more generally the equivalence of χ_s and χ_{iso}. To do this, however, he had to introduce the idea of the *approximate Hamiltonian* with negligible perturbations which give rise to the ergodic property. His argument is correct as far as this approximate Hamiltonian is concerned, but it leaves some doubt about the exact Hamiltonian and the introduction of the approximate Hamiltonian seems rather artificial.

The purpose of this short note is to give a proof of the equivalence of χ_s and χ_{iso} in a large system in the quantum mechanical case.

§ 2.

We consider a Hamiltonian H which is a function of an external parameter F. In the magnetic case, F is a component of the magnetic field. Define an operator A by

$$A=-\partial H/\partial F\,. \tag{1}$$

The density matrix ρ at the temperature T is given by

$$\rho=\exp[(\Omega-H)/kT]\,, \qquad \mathrm{Tr}\,\rho=1\,. \tag{2}$$

where Ω is the free energy of the total system. The average of any dynamical quantity B representing a physical quantity is given by

$$\langle B\rangle=\mathrm{Tr}\,B\rho=\sum_n B_n\exp(\Omega-E_n)/kT\,, \tag{3}$$

where E_n's are the eigenvalues of H and B_n's are the diagonal elements of B in the energy representation which diagonalizes the total Hamiltonian H. Since B is hermitian, B_n's are real quantities.

According to thermodynamics, the isothermal and adiabatic susceptibilities per unit volume are defined by

$$\left.\begin{aligned}\chi_T&=\left(\frac{\partial\bar{B}}{\partial F}\right)_T,\\ \text{and}\qquad&\\ \chi_s&=\left(\frac{\partial\bar{B}}{\partial F}\right)_S\end{aligned}\right\} \tag{4}$$

respectively where $\bar{B}$ is the macroscopic value of B per unit volume, and is given, by statistical mechanics, as

$$\bar{B}=\lim\frac{1}{V}\,\mathrm{Tr}\,B\rho=\lim\frac{1}{V}\langle B\rangle \tag{5}$$

where $\lim(1/V)$ is the abbreviated notation for $\lim\limits_{\substack{V\to\infty,\,N\to\infty\\ N/V=\mathrm{const.}}}(1/V)$. By means of thermodynamical relations and statistical mechanical expressions for thermodynamical quantities, we have[1]

---

** Now returned to the Department of Applied Physics, Waseda University, Tokyo.

$$\chi_T-\chi_s=\lim\frac{1}{V}\frac{1}{kT}\left[\frac{(\langle BH\rangle-\langle B\rangle\langle H\rangle)(\langle AH\rangle-\langle A\rangle\langle H\rangle)}{\langle H^2\rangle-\langle H\rangle^2}\right]. \tag{6}$$

On the other hand statistical mechanics gives another direct expression for the adiabatic susceptibility,

$$\chi_{iso}=\lim\frac{1}{V}\sum_n\frac{\partial B_n}{\partial F}\exp\left[(\Omega-E_n)/kT\right], \tag{7}$$

since the population of the energy levels is to be held constant while taking the derivative of $\bar{B}$ with respect to F. As was mentioned in § 1, this quantity, called isolated susceptibility, has been regarded to be distinguished from χ_s.

Now define an operator $B^{(d)}$ as the operator which is diagonal in the energy representation and has the diagonal elements equal to B_n's. Then we first notice the following property

$$\frac{\partial B_n}{\partial F}=\left(\frac{\partial B^{(d)}}{\partial F}\right)_n \tag{8}$$

where the right hand side means a diagonal element of the operator $\partial B^{(d)}/\partial F$ in the energy representation and is not always equal to a diagonal element of the operator $\partial B/\partial F$. As is defined above, B_n is not always an eigenvalue of B. If B_n happens to be an eigenvalue of B, then we have

$$\frac{\partial B_n}{\partial F}=\left(\frac{\partial B}{\partial F}\right)_n. \tag{9}$$

A proof of the above mentioned property is immediately obtained from the similar discussion by Riddell and Uhlenbeck[6] and is given in the Appendix. As a particular case of Eq. (9), if we take H for B, we have

$$\frac{\partial E_n}{\partial F}=\left(\frac{\partial H}{\partial F}\right)_n=-A_n. \tag{10}$$

From Eqs. (4), (3) and (10), we have

$$\chi_T=\lim\frac{1}{V}\left[\sum_n\frac{\partial B_n}{\partial F}\exp\left(\frac{\Omega-E_n}{kT}\right)+\frac{1}{kT}\sum_n B_nA_n\exp\left(\frac{\Omega-E_n}{kT}\right)-\frac{\langle B\rangle\langle A\rangle}{kT}\right], \tag{11}$$

where

$$\langle A\rangle=\mathrm{Tr}\,A\rho=\sum A_n\exp\left(\frac{\Omega-E_n}{kT}\right)=-\left(\frac{\partial\Omega}{\partial F}\right)_T=kT\frac{\partial}{\partial F}\ln\mathrm{Tr}\exp\left(-\frac{H}{kT}\right). \tag{12}$$

The first term of the right-hand side of Eq. (11) is just equal to χ_{iso} and is rewritten, by virture of Eq. (8), as

$$\begin{aligned}\chi_{iso}&=\lim\frac{1}{V}\sum_n\frac{\partial B_n}{\partial F}\exp\left(\frac{\Omega-E_n}{kT}\right)=\lim\frac{1}{V}\sum_n\left(\frac{\partial B^{(d)}}{\partial F}\right)_n\exp\left(\frac{\Omega-E_n}{kT}\right)\\&=\lim\frac{1}{V}\mathrm{Tr}\frac{\partial B^{(d)}}{\partial F}\rho=\lim\frac{1}{V}\left\langle\frac{\partial B^{(d)}}{\partial F}\right\rangle.\end{aligned} \tag{13}$$

It should be noted that this is not always equal to $\mathrm{Tr}\,((\partial B/\partial F)\rho)=\langle\partial B/\partial F\rangle$. In the same way, the second term of Eq. (11) is equal to

$$\frac{1}{kT}\mathrm{Tr}\,B^{(d)}A^{(d)}\rho=\frac{1}{kT}\langle B^{(d)}A^{(d)}\rangle,$$

where $A^{(d)}$ is defined similarly to $B^{(d)}$. Thus we finally have

$$\chi_T-\chi_{iso}=\lim\frac{1}{V}\frac{1}{kT}[\langle B^{(d)}A^{(d)}\rangle-\langle B\rangle\langle A\rangle]\,. \tag{14}$$

A confusion of Broer's consideration lies here. He wrote Eq. (11) and (14) as (see p. 537 in Broer's paper)

$$\chi_T=\lim\frac{1}{V}\left[\left\langle\frac{\partial B}{\partial F}\right\rangle+\frac{1}{kT}(\langle BA\rangle-\langle B\rangle\langle A\rangle)\right],$$

$$\chi_T-\chi_{iso}=\lim\frac{1}{V}\frac{1}{kT}[\langle BA\rangle-\langle B\rangle\langle A\rangle]\,,$$

which are not always true.

In the notation of Gibbs and of Broer for microcanonical averages, $\mathrm{Tr}\,B^{(d)}A^{(d)}$ is written as

$$\mathrm{Tr}\,(B^{(d)}A^{(d)}\rho)=\sum_n\overline{B_n}|\,\overline{A_n}|\exp(\Omega-E_n)/kT\,. \tag{15}$$

Eq. (15) holds irrespective of whether the energy levels are degenerate or not, because $A_n=-\partial E_n/\partial F$ and $\overline{B_nA_n}|_{E_n}=\overline{B_n}|_{E_n}\overline{A_n}|_{E_n}$. Eq. (14) with Eq. (15) is identical to the result obtained by Yamamoto through the consideration of the approximate Hamiltonian. On the other hand Broer showed that the quantities in $[\cdots]$ in the right-hand sides of Eqs. (14) and (6) are equivalent in the limit of a large system, by making use of the Gibbs expansion which holds for any quantity G in a large system,

$$\langle G\rangle=\overline{G}|_{\langle H\rangle}+\frac{1}{2}(\langle H^2\rangle-\langle H\rangle^2)\frac{\partial^2\langle G\rangle}{\partial\langle H\rangle^2}\,. \tag{16}$$

Therefore it will be redundant to repeat the calculation leading to $\chi_s=\chi_{iso}$ here. Thus we get a proof of the equivalence of the two quantities of χ_s and χ_{iso}.

The condition for $\chi_{iso}=\chi_s$ of Klein[8], and also that of Wright[2], which is a special case of the former, are too severe. They are the condition for χ_{iso} to be *exactly* equal to χ_s irrespective of the size of the system.

§ 3.

In this section another discussion on the papers of Broer[2] and Caspers[3] will be given. We have already pointed out the mistake of Broer's general argument on quantum mechanical case. In a later section of his paper, Broer assumed the energy level of the form,

$$E_n=-FM_n+U_n+D_n/F \tag{17}$$

and under the approximation of high temperature and high magnetic field (large F) he obtained $\chi_{iso}/\chi_s=4/5$. In this calculation, however, there was no complication arising from the difference between, e.g., $A^{(d)}$ and A. Essentially the same calculation was carried out by Caspers[3]. One of their assumptions is that

$$\langle MU\rangle\equiv\frac{1}{p}\sum_n M_nU_n=0\,,$$

where p is the number of levels. However we first assume $\langle MU\rangle\neq0$, then we have, revising the calculations of Broer in case of $A=B$ in the notation of § 2,

$$\chi_s=\chi_TC_M/C_H=\lim\frac{1}{V}\left(\langle U^2\rangle-\frac{\langle MU\rangle^2}{\langle M^2\rangle}-2\langle MD\rangle\right)\Big/kTF^2 \tag{18}$$

and

$$\chi_{iso}=\lim\frac{1}{V}[-2\langle MD\rangle/kTF^2]\,, \tag{18'}$$

where C_M and C_H are specific heats at constant magnetization and at constant magnetic field respectively.

Eqs. (18) and (18′) yield as the condition for $\chi_s=\chi_{iso}$,

$$\langle U^2\rangle\langle M^2\rangle=\langle MU\rangle^2 . \tag{19}$$

This is also derived from Eqs. (6) and (14) by using the energy level (17). The condition (19) is really the case in a large system, as is shown in the following. First if we look at the fact that M_n is a sum of N spins which take either $+1/2$ or $-1/2$, we see that its probability distribution is expressed for large N by a Gaussian function,

$$f(M)=A\exp\left(-\frac{M^2}{2N\alpha}\right), \qquad A=(2\pi N\alpha)^{-1/2} . \tag{20}$$

Thus we have

$$\langle M^2\rangle=A\int_{-\infty}^{\infty}M^2\exp\left(-\frac{M^2}{2N\alpha}\right)dM=N\alpha \tag{21}$$

U_n is regarded as a function of M, and U_n corresponding to $M=0$ is zero. Therefore we obtain

$$\begin{aligned}\langle MU\rangle&=A\int_{-\infty}^{\infty}MU(M)\exp\left(-\frac{M^2}{2N\alpha}\right)dM\\&=A\int\left(U'(0)M^2+\frac{1}{2}U''(0)M^3+\cdots\right)\exp\left(-\frac{M^2}{2N\alpha}\right)dM\\&\simeq AU'(0)\int M^2\exp\left(-\frac{M^2}{2N\alpha}\right)dM ,\end{aligned} \tag{22}$$

where higher order terms of the expansion can be neglected for large N, since $U'''(0)$, for example, is of order N^{-2}. This expression corresponds just to the Gibb's relation (16). Similarly we have

$$\langle U^2\rangle=U'(0)^2A\int M^2\exp\left(-\frac{M^2}{2N\alpha}\right)dM . \tag{23}$$

Eqs. (21), (22) and (23) give Eq. (19) to prove $\chi_s=\chi_{iso}$.

Next we consider the case $\langle MU\rangle=0$. This may be realized in the spin-spin dipolar interaction, because U is regarded as an even function of M. In this case U can be expanded in the form

$$U=\frac{1}{2}U''(0)M^2+\cdots$$

then we have

$$\langle U^2\rangle=\frac{1}{2}[U''(0)]^2\langle M^4\rangle\sim O(N^0) ,$$

since $U''(0)$ is of the order N^{-1} and $\langle M^4\rangle\sim O(N^2)$. On the other hand we have

$$\langle MD\rangle\sim D'(0)\langle M^2\rangle\sim O(N) .$$

Therefore $\langle U^2\rangle$ term can be neglected compared with the term $\langle MD\rangle$ in Eq. (18). Thus we again obtain $\chi_s=\chi_{iso}$. The result $\chi_{iso}/\chi_s=4/5$, obtained by Broer, Wright and Caspers, is valid only for small systems, as was pointed out by Caspers[3),4)].

§ 4.

In this section we take A for B. We have shown that $\chi_s\doteq\chi_{iso}$, so we may write, according to Eq. (14),

$$\chi_T-\chi_s=\lim\frac{1}{V}\frac{1}{kT}[\langle A^{(d)2}\rangle-\langle A\rangle^2]\,. \tag{24}$$

We consider a Hamiltonian given as

$$H=H_0-AF \tag{25}$$

and we limit ourselves to $\langle A\rangle$ linear in F. Then χ is independent of F, and we have from Eq. (10)

$$\left.\begin{aligned}\langle A^{(d)2}\rangle&=\sum_n A_n{}^2\rho_n\simeq\sum_m A^2_{mm}\rho_{0m}\\ \langle A\rangle&=\sum_n A_n\rho_n\simeq\sum_m A_{mm}\rho_{0m}\end{aligned}\right\}\,. \tag{26}$$

where ρ_0 is the equilibrium density matrix of the system with Hamiltonian H_0 and suffix m means the eigenstate of H_0. A quantum statistical derivation of χ_T is given from Eqs. (4) and (12) by making use of the perturbation technique. For example, Nakajima[9] showed the following expansion

$$\begin{aligned}\mathrm{Tr}\,e^{-\beta(H_0-AF)}=&\,\mathrm{Tr}\,e^{-\beta H_0}+F\beta\,\mathrm{Tr}[\exp(-\beta H_0)A]\\ &+\frac{F^2}{2}\beta\int_0^\beta d\lambda\,\mathrm{Tr}[\exp(-\beta H_0)A(\lambda)A]+\cdots\,,\end{aligned} \tag{27}$$

where

$$A(\lambda)=\exp(\lambda H_0)A\exp(-\lambda H_0)\,.$$

Therefore we have

$$\begin{aligned}\chi_T&=\lim\frac{1}{V}\left[\int_0^\beta d\lambda\,\mathrm{Tr}\{\rho_0A(\lambda)A\}-\frac{1}{kT}(\mathrm{Tr}\,\rho_0A)^2\right]\\ &=\lim\frac{1}{V}\left[\sum_{m,m'}\frac{|A_{mm'}|^2(\rho_{0m}-\rho_{0m'})}{E_{0m'}-E_{0m}}-\frac{1}{kT}(\sum A_{mm}\rho_{0m})^2\right].\end{aligned} \tag{28}$$

On the other hand Kubo[10] gave a general method for calculating the dynamic susceptibility of an isolated system under external fields. Because the system does not exchange heat with surroundings, the dynamic susceptibility thus calculated is supposed to be adiabatic. This is in fact the case. In the limit of zero frequency, or in static case, we have[11], in a representation diagonalizing the operator H_0

$$\begin{aligned}\chi(0)&=\lim\frac{1}{V}\sum_{m,m'}\frac{|A_{mm'}|^2(\rho_{0m}-\rho_{0m'})}{\hbar}\,\mathrm{P}\int_{-\infty}^{\infty}\frac{\delta(p+\omega_{mm'})}{-p}dp\\ &=\lim\frac{1}{V}\left[\sum_{m,m'}\frac{|A_{mm'}|^2(\rho_{0m}-\rho_{0m'})}{E_{0m'}-E_{0m}}-\frac{1}{kT}\sum|A_{mm}|^2\rho_{0m}\right]\end{aligned} \tag{29}$$

where use is made of the relation

$$\begin{aligned}\mathrm{P}\int_{-\infty}^{\infty}\frac{\delta(p+\omega)}{p}dp&=-\frac{1}{\omega}\qquad\text{for}\quad\omega\neq0\\ &=0\qquad\text{for}\quad\omega=0\,.\end{aligned}$$

Thus we obtain from Eqs. (28) and (29)

$$\chi_T-\chi(0)=\lim\frac{1}{V}\frac{1}{kT}[\sum_m A^2_{mm}\rho_{0m}-(\sum A_{mm}\rho_{0m})^2]\,. \tag{30}$$

Referring to Eqs. (24) and (26), we see that Eq. (30) is identical to Eq. (24) in the linear approximation. Thus $\chi(0)$ is equal to χ_s.

Another method was developed by Kubo and Tomita[12] to obtain the dynamic susceptibility. However this method gives χ_T in zero frequency. In this method, one assumes that at first the system is in thermal equilibrium under an external field F and has a density matrix $\rho=\exp(\Omega-H_0+AF)/kT$. At the time $t=t_0$, the system is isolated from the heat reservoir and the field F is turned off. Thus the average of A, $\langle A\rangle$, will relax and may be expressed by a function of the type $F\phi(t-t_0)$ which can be obtained by the first order perturbation calculation. The derivative of $\phi(t-t_0)$ with respect to t_0 gives the response due to a single pulse at $t=t_0$. By the superposition of these responses due to pulses at different times, we obtain $\langle A\rangle$ for an arbitrary form of $F(t)$. However as is seen in the above derivation, the system is in thermal equilibrium and in thermal contact with the heat reservoir while the pulse is applied. This is the reason we get χ_T in zero frequency[13]. A more detailed discussion of the interaction of the system with a heat reservoir will be given later.

Acknowledgments

This paper was originated from the paper of Dr. Yamamoto and the discussion with him while he was staying at the University of Oregon. The author wishes to thank Professors T. L. Hill and T. Yamamoto for the pleasant discussion.

Appendix. A Proof of $\dfrac{\partial B_n}{\partial F}=\left(\dfrac{\partial B^{(d)}}{\partial F}\right)_n$

According to the definition of $B^{(d)}$, the Hamiltonian of the system H commutes with $B^{(d)}$. We denote the common normalized eigenfunctions of H and $B^{(d)}$ by ψ_n. B_n is the eigenvalue of $B^{(d)}$. Then we have

$$B^{(d)}\psi_n=B_n\psi_n\,. \tag{A.1}$$

By differentiating (A.1) with respect to F, we have

$$\frac{\partial B^{(d)}}{\partial F}\psi_n+B^{(d)}\frac{\partial\psi_n}{\partial F}=\frac{\partial B_n}{\partial F}\psi_n+B_n\frac{\partial\psi_n}{\partial F}\,. \tag{A.2}$$

Multiplying (A.2) by $\psi_n{}^*$ and integrating it over the whole space we have

$$\left(\frac{\partial B^{(d)}}{\partial F}\right)_n=\frac{\partial B_n}{\partial F}+\int\psi_n{}^*B_n\frac{\partial\psi_n}{\partial F}d\tau-\int\psi_n{}^*B^{(d)}\frac{\partial\psi_n}{\partial F}d\tau\,. \tag{A.3}$$

Since $B^{(d)}$ is hermitian, and B_n is its eigenvalue, the last two terms of the right-hand side of Eq. (A.3) cancel. Hence we have

$$\frac{\partial B_n}{\partial F}=\left(\frac{\partial B^{(d)}}{\partial F}\right)_n\,. \tag{A.4}$$

If B_n is an eigenvalue of B, $B^{(d)}$ in the above equations can be replaced by B, and we have

$$\frac{\partial B_n}{\partial F}=\left(\frac{\partial B}{\partial F}\right)_n\,. \tag{A.5}$$

Convex-Core Model of Molecules in Crystalline State. II

By Saburo KOBA

Department of Physics, Faculty of Science, University of Tokyo

(Received December 26, 1960)

The convex-core model of molecules, which has been effective for discussing thermodynamic properties of polyatomic gases, is applied to the crystals of benzene and ethylene as a continuation of a previous article of the same title, in which crystals of methane, carbon dioxide, and nitrogen were treated. By use of model parameters determined from the second virial coefficients, cohesive energies and lattice constants are calculated. When we neglect zero-point energies, potential non-additivities, and electric multipole interactions, then the calculated cohesive energies are close to the observed values for benzene and 16% higher for ethylene. The calculated lattice constants agree well with observed ones in both cases. Stability of the benzene crystal is discussed, but the conclusions are not as definite as in the case of carbon dioxide.

The convex-core model of molecles is applied in this paper to the crystals of benzene and ethylene, as a continuation of a previous article[1] of the same title, which is referred to as Part I.

In Part I, we have explained to some extent the crystal structure of carbon dioxide by taking into account the electric multipole moment. In Part II, we apply similar method to benzene.

In Part II, we neglect the zero point energy and non additivity of the intermolecular potential. The former is positive, and perhaps the latter is also positive (since it is positive for spherical molecules). The electric multipole interaction is negative for benzene and ethylene. Sum of these three effects is presumably less than 20% of the total cohesive energy.

For the purpose of treating polyatomic molecules, Kihara introduced a model which assumes an appropriate convex body called core inside each molecule[2]. The shortest distance between two cores is called intercore distance and denoted by ρ. The potential energy U between two molecules is assumed to be a function of this ρ only, and moreover

$$U(\rho)=U_0\left[\left(\frac{\rho_0}{\rho}\right)^{12}-2\left(\frac{\rho_0}{\rho}\right)^{6}\right]. \qquad (1)$$

Here ρ_0 and U_0 are model constants determined from the second virial conffiicient and, if necessary, from transport coefficients[3].

Benzene C_6H_6

Because of the π electrons, it would be more natural to adopt for a core of a benzene molelcule C_6H_6 a regular hexagon obtained by connecting the centers of six carbon atoms. But calculations show that for this core the cohesive energy is too high and this means that the core is too small. Therefore, giving up consistency with the case of ethylene, we choose, as a core of a benzene molecule a regular hexagon formed by connecting the midpoints of successive CH-bonds. (A more accurate shape would be a hexagon plate with nonvanishing thickness.) Since the length of a CC-bond in a benzene molecule is 1.397A and that of a CH-bond is 1.085A, the length l of one side of the hexagon core is calculated to be 1.940A. The values of ρ_0 and U_0 determined from the second virial coefficient are

$$\rho_0=3.6\text{A}\ , \qquad U_0/k=740°\text{K}\ ,$$

k being the Boltzmann constant. The parallel body of the core at the distance $\rho_0/2$ indicates the shape and size of the molecule as shown in Fig. 3.

At the time of publication of the reference 2 (1953), the value of ρ_0 for benzene was taken from the lattice constant of graphite, since observed values of the second virial coefficient were not sufficient to determine both ρ_0 and U_0. Recently, however, Andon and Cox et al.[4),5)] observed the second virial coefficients of benzene between 67.1°C and 164.6°C. By use of their results together with values of Francis et al.[6)] both ρ_0 and U_0 have been calculated from the second virial coefficient only.

The crystal of benzene is orthorhombic, the corner and the face centers of a unit cell being occupied by centers of molecules. The x-, y-, and z-dimensions of a unit cell are

$a=7.46$, $b=9.67$, $c=7.03$A at −3°C,

$a=7.29$, $b=9.47$, $c=6.74$A at −195°C.

Space group is $Pbca-D_{2h}^{15}$. The cohesive energy measured as sublimation heat at 0°C is −10.67 kcal/mol.

According to Cox[7] details of the molecular orientation are the following. The molecule situated at the corner has, at −3°C, three successive carbon atoms C_1, C_2, and C_3, with coordinates

$x=-0.383$, $y=1.339$, $z=-0.040$A for C_1,

$x=-0.971$, $y=0.465$, $z=0.873$A for C_2,

$x=-0.591$, $y=-0.870$, $z=0.921$A for C_3.

The direction of the normal to the molecular plane is very close to (3, 1, 3). The orientation of the molecule at the center of the c-face is derived from the orientation at the cell corner by reflection with respect to a plane at $x=\frac{1}{4}a$ followed by a translation $\frac{1}{2}b$ in the y-direction; that of the a-face, by reflection with respect to a plane at $y=\frac{1}{4}b$ with a translation $\frac{1}{2}c$; that of the b-face, by reflection with respect to a plane at $z=\frac{1}{4}c$ with a translation $\frac{1}{2}a$.

In order to calculate the cohesive energy and the lattice constants let us somewhat idealize the crystal structure. We namely simplify the orientation of the molecule at the corner to

$x=z=0$ $y=1.397$A for C_1,

$-x=z=0.855$ $y=0.699$A for C_2,

$-x=z=0.855$ $y=-0.699$A for C_3,

the direction of the normal to the molecular plane being (1, 0, 1). The structure is shown in Fig. 1. In Fig. 1, molecules and cores shown by the dotted lines lie at a distance $b/2$ below and above the plane of drawing.

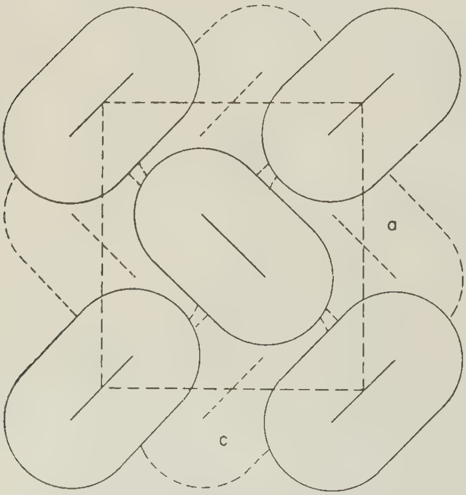

Fig. 1. Benzene crystal.

It should be noted that de Boer[8] has evaluated the sublimation heat of benzene crystal by use of this idealization. He assumed the observed lattice constants and summed up the attractive potential between CH groups which is inversely proportional to the sixth power of the distance. The cohesive energy calculated by him is −11.3 kcal/mol.

Let us denote by n_{ij} the number of (i, j)th neighboring lattice points at the distance r_{ij}. The subscript i is such that $\sum_j n_{ij}$ becomes the number of ith neighbors when the present lattice is reduced to a face-centered cubic lattice. The lattice point distribution is given

Table I

i	j	r_{ij}^2	n_{ij}
1	1	$\frac{1}{4}(a^2+b^2)$	4
1	2	$\frac{1}{4}(b^2+c^2)$	4
1	3	$\frac{1}{4}(c^2+a^2)$	4
2	1	a^2	2
2	2	b^2	2
2	3	c^2	2
3	1	$a^2+\frac{1}{4}(b^2+c^2)$	8
3	2	$b^2+\frac{1}{4}(c^2+a^2)$	8
3	3	$c^2+\frac{1}{4}(a^2+b^2)$	8
4	1	a^2+b^2	4
4	2	b^2+c^2	4
4	3	c^2+a^2	4
5	1	$\frac{1}{4}(9a^2+b^2)$	4
5	2	$\frac{1}{4}(9a^2+c^2)$	4
5	3	$\frac{1}{4}(9b^2+a^2)$	4
5	4	$\frac{1}{4}(9b^2+c^2)$	4
5	5	$\frac{1}{4}(9c^2+a^2)$	4
5	6	$\frac{1}{4}(9c^2+b^2)$	4

in Table I. The intercore distances ρ_{ij} to the cores of (i, j)th neighbors are expressed in the form

$$\rho_{ij}^2 = Aa^2 + Bb^2 + Cc^2 + Dbc + Eca + Fab + Gal + Hbl + Icl + Jl^2 .$$

Here a, b, and c are the lattice constants and l is the side length of the hexagon core of our molecular model. The coefficients A, B, ..under the coditions

$$\sqrt{6}\, l \leq c < a < b ,$$

$$\sqrt{\frac{3}{2}}(a-c) \leq b - \sqrt{\frac{3}{2}}\, a \leq l \leq b - \sqrt{\frac{3}{2}}\, c ,$$

are given in Table II. The core-model interaction energy per molecule

$$\frac{1}{2} U_0 \sum_{ij} n_{ij} \left[\left(\frac{\rho_0}{\rho_{ij}} \right)^{12} - 2 \left(\frac{\rho_0}{\rho_{ij}} \right)^{6} \right] \qquad (2)$$

can be evaluated by use of this table.

The expression (2) takes its minimum -10.2 kcal/mol at

$$a = 7.6\text{A} , \quad b = 11.0\text{A} , \quad c = 6.9\text{A} .$$

These values of the cohesive energy and the lattice constants are satisfactorily close to the corresponding observed values.

The orthorhombic crystal which we have treated is not a structure of closest packing. For the core-model of benzene we consider a structure of closest packing in which the flat hexagonal molecules are piled. This piled structure corresponds to, say, cubic closest packing of spheres.

On the other hand, we approximate electric multipole interactions of benzene molecules by quadrupole interactions. The benzene molecule

has an electric quadrupole[9)]

$$Q=6.24\times10^{-26}\text{ e.s.u.}\ ,$$

the axis being perpendicular to the molecular plane.

Contribution of the quadrupole interaction to the cohesive energy is evaluated up to the neighbors corresponding to $i=4$ for both orthorhombic and piled structure. This calculation is elementary but laborious.

If we consider the sums of the core-model interaction (2) and the quadrupole interaction for each of the two strucures, the orthorhombic structure is more stable than the piled one, the difference being of the order of 0.5 kcal/mol.

But if we consider that several approximations and simplifications are introduced in our method, and the difference 0.5 kcal/mol being small, the crystal stability is not explained as definitely as in the case of carbon dioxide.

Moreover, cyclohexane-hexachloride molecule $C_6H_6Cl_6$, which is considered to be oblate, has the crystal structure similar to that of carbon dioxide[10)]. Therefore for a more complete discussion of stability, it is desired to consider the structure in which benzene molecules are arranged as in the crystal of carbon dioxide.

However, we do not go deep into the stability problem because of two reasons. Firstly, a view point which considers the arrangement of benzene molecules as a set of six-toothed bevel gear-wheels is also possible, so the application of the convex-core model itself has some problems. Secondly, as stated before the core used can be improved though calculation will become rather complicated.

Ethylene C_2H_4

As the core of an ethylene molecule C_2H_4 we choose a thin rod connecting two carbon atoms with the length $l=1.33$A. The choice of a rod core may be reasonable because of the π-electrons and because of the fact that each molecule in an ethylene crystal can rotate round the CC-bond. The values of ρ_0 and U_0 determined from the second virial coefficient are

$$\rho_0=4.2\text{A}\ ,\qquad U_0/k=256°\text{K}\ .$$

The parallel body of the core at the distance $\rho_0/2$ indicates the shape and size of the molecule as shown in Fig. 3.

The crystal of ethylene is orthorhombic, the corner and the body center of a unit cell being occupied by centers of molecules. The x-, y-, and z-dimensions of a unit cell are, according to Bunn[11)],

$$a=4.87\text{A}\ ,\qquad b=6.46\text{A}\ ,\qquad c=4.14\text{A}\ ,$$

space group is $Pnnm-D_{2h}{}^{12}$, the CC-bonds being parallel to the ab-plane. Coordinates of carbon atoms of the molecule at the corner are

$$(x,\ y,\ 0)\ \text{ and }\ (-x,\ -y,\ 0)$$

where $x=0.11a$ and $y=0.06b$; and those of

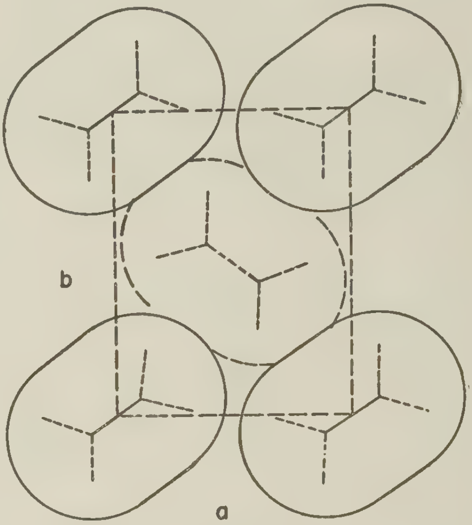

Fig. 2. Ethylene crystal.

Table III

i	j	$\rho_{ij}{}^2$	n_{ij}
1	1	$\frac{a^2}{2}+\frac{c^2}{4}-2au+2u^2$	8
2	1	$a^2-4au+8u^2$	4
2	2	c^2	2
3	1	$2a^2-8au+8u^2$	2
3	2	$2a^2$	2
3	3	$a^2+c^2-4au+8u^2$	8
4	1	$\frac{5}{2}a^2+\frac{c^2}{4}-6au+4u^2$	16
4	2	$\frac{a^2}{2}+\frac{9}{4}c^2-2au+2u^2$	8
5	1	$2a^2+c^2-8au+8u^2$	4
5	2	$2a^2+c^2$	4
6	1	$4a^2-8au+8u^2$	4
6	2	$4c^2$	2
7	1	$\frac{9}{2}a^2+\frac{c^2}{4}-6au+2u^2$	8
7	2	$\frac{5}{2}a^2+\frac{9}{4}c^2-6au+4u^2$	16

the molecule at the body center are

$$\left(\frac{a}{2}-x,\frac{b}{2}+y,\frac{c}{2}\right) \text{ and } \left(\frac{a}{2}+x,\frac{b}{2}-y,\frac{c}{2}\right).$$

The crystal structure is shown in Fig. 2. The angle between the CC-bond and the a-axis is about 35°.

It is impossible to explain the difference between a and b by use of our molecular model. We approximately assume, therefore, that a be equal to b and that the angle between the CC-bond and the a-axis be 45°.

Let us denote by ρ_{ij} the intercore distance to an (i, j)th neighboring molecule, and by n_{ij} the number of (i, j)th neighboring molecules. The subscript i is such that $\sum_j n_{ij}$ becomes the number of ith neighboring lattice points when the present lattice is reduced to a body-centered cubic one:

$$\sum n_{1j}=8\,, \qquad \sum n_{2j}=6\,,\cdots$$

The values of of ρ_{ij} and n_{ij} are given in Table III, which holds for

$$a \geqq 4u \equiv \sqrt{2}\, l\,,$$

l being the length of the rod core.

The cohesive energy and the lattice constants are given by the minimum of the sum (2). The values, which have been calculated by use of the Parametron Computer PC–1, are −3.79 kcal/mol for the cohesive energy and

$$a=b=5.8\text{A}\,, \qquad c=4.3\text{A}\,.$$

The cohesive energy thus obtained is 16% higher than −4.5 kcal/mol, which is the sublimation heat calculated from the specific heat observed by Egan and Kemp[12]. The agreement can be improved by choosing somewhat larger core, although such rectangular core as adopted in the reference 2 is too large.

The ethylene molecule has an electric quadrupole[9]

$$Q=2.30\times10^{-26}\text{ e.s.u.}\,,$$

the axis being the CC-bond. We mention here that, in rod-like molecules, the stability of closest packing structure with parallel arrangement of molecules is much hampered by the electric quadrupole interaction. The discussion of crystal stability is postponed in following papers.

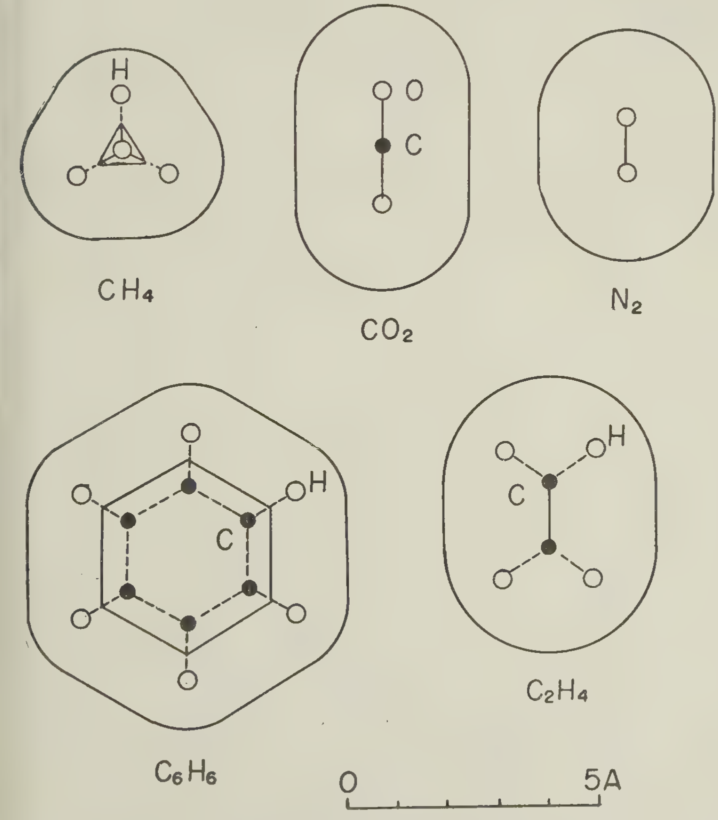

Fig. 3. The used core-models of molecules.

General Conclusion

We have investigated, in Part I and II, methane CH_4, carbon dioxide CO_2, nitrogen N_2, benzene C_6H_6, and ethylene C_2H_4 crystals by use of our convex-core model of molecules. The cores of these molecules are shown in Fig. 3.

When we neglect zero-point energies, potential non-additivities, and electric multipole interactions, then the calculated cohesive energies are 24% lower for methane, 27%, higher for carbon dioxide, 17% lower for nitrogen, little higher for benzene, and 16% higher for ethylene in comparison with observed values. Main cause of the energy discrepancy for methane is the neglect of both the zero-point energy and the potential non-additivity. That for carbon dioxide is the neglect of the quadrupole interaction and the core thickness, because a more appropriate core of the carbon dioxide molecule would be such as shown in Fig. 4. In general, when the core is enlarged, the potential depth U_0 increases and hence calculated value of the cohesive energy becomes lower. The energy discrepancy for ethylene may also be partly due to the choice of the thin core, because a more adequate core would be such as shown in Fig. 4.

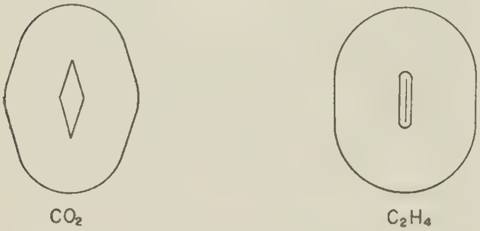

Fig. 4. Cores of carbon dioxide and ethylene which will be closer to the reality, the non-vanishing thickness corresponding to π-electrons.

Thus we reach the following conclusion. For simple non-polar convex molecules the core-model interaction explains the cohesive energies and lattice constants if appropriate cores are chosen, although the stability of their crystal structures depends greatly on the electric multipole interaction as shown recently by Kihara[10].

Acknowledgements

In conclusion the author wishes to express his sincere thanks to Prof. T. Kihara for his continual guidance and valuable suggestions. He also wishes to express his cordial thanks to Dr. Y. Midzuno and Dr. S. Kaneko for their kind guidance in programming and operating the Parametron Computor PC-1.

Entropy Production and Variation Principle in The Kinetic Theory of Rigid-Sphere Gas Mixture

By Terutosi MURAKAMI

Department of Applied Science, Faculty of Engineering,
Kyushu University, Fukuoka, Japan

(Received January 7, 1961)

The balance equations and the fluxes of thermodynamical variables are obtained on the basis of the modified Boltzmann equation for a multicomponent rigid-sphere gas. The kinetic expression of entropy balance is obtained in terms of the H-theorem, the correction to the entropy due to imperfectness of the gas being added. The correction is calculated from the equation of state, which is derived from the momentum transport equation. The entropy balance is also formulated thermodynamically with the aid of the Gibbs relation. By the use of these two expressions a variational problem concerning the entropy production rate can be set up. The solution of this problem leads to the first approximation equation for singlet distribution function, which is identical with Enskog's one apart from the terms independent of the energy dissipation.

§ 1. Introduction

The variation principles in the kinetic theory of gases[1),2),3)] seem to have a close relation to the extremum properties of the entropy production in thermodynamics of irreversible processes. These principles are established on the basis of the linearized Boltzmann integro-differential equation. Since the kinetic theory of gases based on the linearized Boltzmann equation is limited to the case of low density, it is desirable to inquire to what extent the variation principle is applicable to the transport processes in dense gases.

A great deal of attention has been concentrated to the transport properties of the dense fluid of rigid-sphere molecules.[4)-14)] The modified Boltzmann equation was derived by Enskog[4)] at first on the basis of plausible physical arguments. From the statistical mechanical point of view, Rice and et al.[7),8)] reinvestigated this equation and proposed a new equation of transport different from the Enskog equation, but recently O'Toole and Dahler[9)] and Hollinger and Curtiss[10)] have confirmed independently that the equation for the singlet distribution function has exactly the same form as that originally suggested by Enskog.

In a previous paper[11)] the variation principle in the kinetic theory of gases was extended to the case of a dense gas made of rigid-sphere molecules with finite diameter. It was also shown that the solution of Enskog's first approximation equation for a dense gas can be derived from the variation principle with respect to the entropy production rate, provided that the correction to the entropy due to imperfectness of a gas would be taken into account.

It is the purpose of the present paper to establish a thermodynamical descriptions of linear transport processes in a multicomponent dense gas consisting of rigid-sphere molecules with different diameters and masses on the basis of the kinetic theory.

At first we shall briefly mention of derivation of the modified Boltzmann equation following O'Toole and Dahler's and Enskog's method (§ 2.). The problem of our attention is confined to solving such a fundamental equation with use of suitable approximation methods. For this purpose equations of balance such as equation of continuity, equation of motion and equation of energy balance, will be obtained by means of the general equation of change derived from our modified Boltz- mann equation (§ 3.).

We shall confine ourselves to the study of the system in which the macroscopic state varies so slowly that the system may be well described with use of perturbed singlet distribution function corresponding to small deviation from the Maxwell distribution and of the equilibrium pair correlation function. The the fluxes appearing in the hydrodynamic equations are expressible in terms of these functions (§ 4.).

To determine the perturbation functions, the various approximation methods have been proposed. Enskog's method of direct solution of the basic Boltzmann integro-differential equation is well known. This method will be followed in the present paper for the system of moderately dense gases, and the first approximation equation identical with Thorne's equation[12] for two component system will be derived in § 5. Another purpose of this investigation is to establish the method for obtaining the solution of such a fundamental equation from entirely physical considerations. To complete the description of irreversible processes, we shall consider the equation of entropy balance. In usual kinetic theory of gases the entropy is given as $-k$ time the H-function, which is considered as the average of logarithm of a singlet distribution function assigned to each molecule. Then the balance equation of entropy is derived with help of the general equation of change in terms of statistical expression (§ 6.). In our case of a dense gas the correction to the entropy due to imperfectness of the gas should be taken into account. The first approximation to this correction is achieved by adding the equilibrium value of additional entropy calculated from the virial expansion form of the usual equation of state, which is obtained from the momentum transport equation. The expression of entropy production rate thus obtained is not so simple function of molecular properties, but may be written in quadratic integral form concerning the perturbation function as far as it is confined to linear processes.

On the other hand, the entropy production rate can be expressed as a bilinear form of the fluxes of molecular properties and the conjugate driving forces according to the thermodynamic considerations of irreversible processes based on the Gibbs relation (§ 7.). The equation to be satisfied by the perturbation function is obtained if these two expressions for the entropy productions are equated. Then the variational problem concerning this entropy production rate is established and from this variational problem the first approximation equation for the perturbation function is obtained (§ 8.).

§ 2. The Modified Boltzmann Equation for the Gas Mixtures of Rigid-Sphere Molecules

Let us consider a multicomponent gas consisting of ν kinds of rigid-sphere molecules with different diameters and masses in non-equilibrium state; the mass and diameter of a molecule of the species i will be denoted by m_i and σ_i, respectively. As is well known, a state of the system under consideration is well described by the singlet distribution functions $f_i^{(1)}(\boldsymbol{r}, \boldsymbol{v}_i; t)$ and the pair distribution functions $f_{ij}^{(2)}(\boldsymbol{r}_i, \boldsymbol{v}_i; \boldsymbol{r}_j, \boldsymbol{v}_j; t)$ which are defined in usual manner. The function $f_i^{(1)}$ is normalized to the number density n_i of kind i:

$$\int f_i^{(1)}(\boldsymbol{r}, \boldsymbol{v}_i; t)\, d\boldsymbol{v}_i = n_i(\boldsymbol{r}, t) \ . \tag{2.1}$$

The pair distribution function $f_{ij}^{(2)}$ is assumed to be given in the form

$$f_{ij}^{(2)}(\boldsymbol{r}_i, \boldsymbol{v}_i; \boldsymbol{r}_j, \boldsymbol{v}_j; t) = \chi_{ij}(\boldsymbol{r}_i, \boldsymbol{r}_j)\, f_i^{(1)}(\boldsymbol{r}_i, \boldsymbol{v}_i; t)\, f_j^{(1)}(\boldsymbol{r}_j, \boldsymbol{v}_j; t) \tag{2.2}$$

where the correlation functions $\chi_{ij}(\boldsymbol{r}_i, \boldsymbol{r}_j)$ depend only on the location of the two molecules but not on the momenta, just as in the case of uniform equilibrium state. This is the basic assumption of our kinetic theory of moderately dense gases, besides the assumption of binary collisions. In a uniform equilibrium state the functions χ_{ij} depend only upon the densities and are reduced to the radial distribution functions, while in a non-uniform state the value of χ_{ij} may be expected to involve also the spatial derivatives of the densities. However, if the gradients of temperature, velocities, and concentrations are small, the local equilibrium value χ_{ij}^0 can be used for χ_{ij} in successive points to the second approximation. Then the central problem in the present theory is to determine the singlet distribution function $f_i^{(1)}$ in non-equilibrium state, and to obtain the transport of the molecular properties in terms of this function, regarding χ_{ij}^0 as a parameter of the state.

From statistical mechanics the rate of change in the singlet distribution function $f_i^{(1)}$ is determined by the equation

$$\left\{\frac{\partial}{\partial t}+\boldsymbol{v}_i\cdot\nabla+\frac{\boldsymbol{F}_i}{m_i}\cdot\nabla_{\boldsymbol{v}_i}\right\}f_i^{(1)}(\boldsymbol{r},\boldsymbol{v}_i;t)=\sum_j\iint\{f_{ij}^{(2)}(\boldsymbol{r},\boldsymbol{v}_i';\boldsymbol{r}+\sigma_{ij}\boldsymbol{k},\boldsymbol{v}_j';t)$$
$$-f_{ij}^{(2)}(\boldsymbol{r},\boldsymbol{v}_i;\boldsymbol{r}-\sigma_{ij}\boldsymbol{k},\boldsymbol{v}_j;t)\}\sigma_{ij}^2(\boldsymbol{g}_{ji}\cdot\boldsymbol{k})\,d\boldsymbol{k}\,d\boldsymbol{v}_j\,, \tag{2.3}$$

with

$$\sigma_{ij}\equiv\frac{1}{2}(\sigma_i+\sigma_j)\,, \tag{2.4}$$

where $\boldsymbol{F}_i$ is the external force acting on a molecule of kind i, $\boldsymbol{k}$ the unit vector in the direction of line of centers of the two molecules in contact, $\boldsymbol{g}_{ji}=\boldsymbol{v}_j-\boldsymbol{v}_i$ the relative velocity, and $\boldsymbol{v}_i'$, $\boldsymbol{v}_j'$ the velocities of molecules after the collision characterized by $\boldsymbol{v}_i$, $\boldsymbol{v}_j$ and $\boldsymbol{k}$. The derivation of (2.3) is closely parallel to that given by O'Toole and Dahler[9] for the modified Boltzmann equation in the case of simple dense gases composed of rigid-sphere molecules.

Inserting (2.2) into (2.3), we obtain Enskog's modified Boltzmann equation for multi-component dense gases of rigid-sphere molecules:

$$\left\{\frac{\partial}{\partial t}+\boldsymbol{v}_i\cdot\nabla+\frac{\boldsymbol{F}_i}{m_i}\cdot\nabla_{\boldsymbol{v}_i}\right\}f_i^{(1)}=\left(\frac{\partial f_i^{(1)}}{\partial t}\right)_{\text{coll}}\,,$$

$$\left(\frac{\partial f_i^{(1)}}{\partial t}\right)_{\text{coll}}=\sum_j\iint\left\{\chi_{ij}^0\left(\boldsymbol{r}+\frac{\sigma_{ij}}{2}\boldsymbol{k}\right)f_i^{(1)}(\boldsymbol{r},\boldsymbol{v}_i';t)\,f_j^{(1)}(\boldsymbol{r}+\sigma_{ij}\boldsymbol{k},\boldsymbol{v}_j';t)\right.$$
$$\left.-\chi_{ij}^0\left(\boldsymbol{r}-\frac{\sigma_{ij}}{2}\boldsymbol{k}\right)f_i^{(1)}(\boldsymbol{r},\boldsymbol{v}_i;t)\,f_j^{(1)}(\boldsymbol{r}-\sigma_{ij}\boldsymbol{k},\boldsymbol{v}_j;t)\right\}\sigma_{ij}^2(\boldsymbol{g}_{ji}\cdot\boldsymbol{k})\,d\boldsymbol{k}\,d\boldsymbol{v}_j\,, \tag{2.5}$$

where the local equilibrium value of the function χ_{ij}^0 is evaluated at the center of colliding two molecules.

If the conditions in gases are slowly varying in space, we may expand $f_j^{(1)}(\boldsymbol{r}\pm\sigma_{ij}\boldsymbol{k},\boldsymbol{v}_j;t)$ and $\chi_{ij}\left(\boldsymbol{r}\pm\frac{1}{2}\sigma_{ij}\boldsymbol{k}\right)$ in Taylor's series about the point $\boldsymbol{r}$, and retain the terms only up to the second. Then (2.5) is written in the form:

$$\frac{\partial f_i}{\partial t}+\boldsymbol{v}_i\cdot\nabla f_i+\frac{\boldsymbol{F}_i}{m_i}\cdot\nabla_{\boldsymbol{v}_i}f_i=\sum_{\gamma=1}^{6}\sum_{j=1}^{\nu}J_{ij}^{(\gamma)}\,, \tag{2.6}$$

$$J_{ij}^{(1)}\equiv\chi_{ij}^0\iint(f_i'f_j'-f_if_j)\sigma_{ij}^2(\boldsymbol{g}_{ji}\cdot\boldsymbol{k})\,d\boldsymbol{k}\,d\boldsymbol{v}_j\,, \tag{2.6–1}$$

$$J_{ij}^{(2)}\equiv\chi_{ij}^0\iint\{\boldsymbol{k}\cdot(f_i'\nabla f_j'+f_i\nabla f_j)\}\sigma_{ij}^3(\boldsymbol{g}_{ji}\cdot\boldsymbol{k})\,d\boldsymbol{k}\,d\boldsymbol{v}_j\,, \tag{2.6–2}$$

$$J_{ij}^{(3)}\equiv\frac{1}{2}\iint(\boldsymbol{k}\cdot\nabla\chi_{ij}^0)(f_i'f_j'+f_if_j)\sigma_{ij}^3(\boldsymbol{g}_{ji}\cdot\boldsymbol{k})\,d\boldsymbol{k}\,d\boldsymbol{v}_j\,, \tag{2.6–3}$$

$$J_{ij}^{(4)}\equiv\frac{1}{2}\chi_{ij}^0\iint[\boldsymbol{k}\boldsymbol{k}:(f_i'\nabla\nabla f_j'-f_i\nabla\nabla f_j)]\sigma_{ij}^4(\boldsymbol{g}_{ji}\cdot\boldsymbol{k})\,d\boldsymbol{k}\,d\boldsymbol{v}_j\,, \tag{2.6–4}$$

$$J_{ij}^{(5)}\equiv\frac{1}{2}\iint(\boldsymbol{k}\cdot\nabla\chi_{ij}^0)[\boldsymbol{k}\cdot(f_i'\nabla f_j'-f_i\nabla f_j)]\sigma_{ij}^4(\boldsymbol{g}_{ji}\cdot\boldsymbol{k})\,d\boldsymbol{k}\,d\boldsymbol{v}_j\,, \tag{2.6–5}$$

$$J_{ij}^{(6)}\equiv\frac{1}{8}\iint(\boldsymbol{k}\boldsymbol{k}:\nabla\nabla\chi_{ij}^0)(f_i'f_j'-f_if_j)\sigma_{ij}^4(\boldsymbol{g}_{ji}\cdot\boldsymbol{k})\,d\boldsymbol{k}\,d\boldsymbol{v}_j\,, \tag{2.6–6}$$

where f_i' and f_j' denote $f_i(\boldsymbol{r},\boldsymbol{v}_i';t)$ and $f_j(\boldsymbol{r},\boldsymbol{v}_j';t)$, respectively. This equation (2.6) is our fundamental equation for the singlet distribution function.

§ 3. The General Equation of Change and the Flux Vector

Before solving the equation (2.6), we consider the general hydrodynamic equation of change. The macroscopic conditions in a fluid in non-equilibrium may be well described by a set of thermodynamical quantities and their derivatives in space, together with the equations governing these quantities. These thermodynamical quantities are given as the averages of the molecular properties which are functions of the molecular velocities.

Let us denote one of such properties associated with molecules of kind i by ψ_i. The average of this property $\overline{\psi}_i$ at each point of space is given by

$$n_i\overline{\psi}_i=\int\psi_i f_i\, d\boldsymbol{v}_i\,. \tag{3.1}$$

Thus the stream velocity (mass average velocity) $\boldsymbol{v}_0$ is given by

$$\rho\boldsymbol{v}_0(\boldsymbol{r},t)=\sum_i m_i\int\boldsymbol{v}_i f_i\, d\boldsymbol{v}_i\,, \tag{3.2}$$

in which $\rho(\boldsymbol{r},t)=\sum_i n_i m_i$ is the mass density of the gas at a point $\boldsymbol{r}$.

Multiplying (2.6) by ψ_i and integrating over the velocity space we find the equation of change

$$\frac{\partial(n_i\overline{\psi}_i)}{\partial t}+\nabla\cdot n_i\overline{\psi_i\boldsymbol{v}_i}-n_i\overline{\left\{\frac{\partial}{\partial t}+\boldsymbol{v}_i\cdot\nabla+\frac{\boldsymbol{F}_i}{m_i}\cdot\nabla_{\boldsymbol{v}_i}\right\}}\psi_i=\sum_{\gamma=1}^{6}I_i^{(\gamma)}(\psi)\,, \tag{3.3}$$

where

$$I_i^{(\gamma)}(\psi)\equiv\sum_j\int\psi_i J_{ij}^{(\gamma)}\, d\boldsymbol{v}_i\,. \tag{3.4}$$

If we use (2.6–1) to (2.6–6) and consider the inverse encounters, the collisional changes given by (3.4) are expressed in the form

$$I_i^{(1)}=\sum_j \chi_{ij}^0\sigma_{ij}^2\iiint(\psi_i'-\psi_i)f_if_j(\boldsymbol{g}_{ji}\cdot\boldsymbol{k})\, d\boldsymbol{k}\, d\boldsymbol{v}_i\, d\boldsymbol{v}_j\,, \tag{3.5–1}$$

$$I_i^{(2)}=\sum_j \chi_{ij}^0\sigma_{ij}^3\iiint(\psi_i-\psi_i')(\boldsymbol{k}\cdot f_i\nabla f_j)(\boldsymbol{g}_{ji}\cdot\boldsymbol{k})\, d\boldsymbol{k}\, d\boldsymbol{v}_i\, d\boldsymbol{v}_j\,, \tag{3.5–2}$$

$$I_i^{(3)}=\sum_j \frac{1}{2}\sigma_{ij}^3\iiint(\psi_i-\psi_i')(\boldsymbol{k}\cdot\nabla\chi_{ij}^0)f_if_j(\boldsymbol{g}_{ji}\cdot\boldsymbol{k})\, d\boldsymbol{k}\, d\boldsymbol{v}_i\, d\boldsymbol{v}_j\,, \tag{3.5–3}$$

$$I_i^{(4)}=\sum_j \frac{1}{2}\sigma_{ij}^4\iiint(\psi_i'-\psi_i)[\boldsymbol{k}\boldsymbol{k}:f_i\nabla\nabla f_j](\boldsymbol{g}_{ji}\cdot\boldsymbol{k})\, d\boldsymbol{k}\, d\boldsymbol{v}_i\, d\boldsymbol{v}_j\,, \tag{3.5–4}$$

$$I_i^{(5)}=\sum_j \frac{1}{2}\sigma_{ij}^4\iiint(\psi_i'-\psi_i)(\boldsymbol{k}\cdot\nabla\chi_{ij}^0)(\boldsymbol{k}\cdot f_i\nabla f_j)(\boldsymbol{g}_{ji}\cdot\boldsymbol{k})\, d\boldsymbol{k}\, d\boldsymbol{v}_i\, d\boldsymbol{v}_j\,, \tag{3.5–5}$$

$$I_i^{(6)}=\sum_j \frac{1}{8}\sigma_{ij}^4\iiint(\psi_i'-\psi_i)f_if_j(\boldsymbol{k}\boldsymbol{k}:\nabla\nabla\chi_{ij}^0)(\boldsymbol{g}_{ji}\cdot\boldsymbol{k})\, d\boldsymbol{k}\, d\boldsymbol{v}_i\, d\boldsymbol{v}_j\,. \tag{3.5–6}$$

If ψ_i is one of the summational invariants, we can obtain the contribution of over all kinds to the collisional change, summing over i, and symmetrizing by the same arguments as that in Appendix I in the author's previous paper[11], in the following form

$$\sum_i^{\nu}\sum_{\gamma}^{6}I_i^{(\gamma)}(\psi)=-\nabla\cdot\Big[\sum_{\alpha}^{2}\mathbf{J}_c^{(\alpha)}(\psi)\Big]+\sum_{\alpha}^{2}R^{(\alpha)}(\psi)\,, \tag{3.6}$$

where

$$\mathbf{J}_c^{(1)}(\psi)=\frac{1}{2}\sum_{ij}\sigma_{ij}^3\chi_{ij}^0\iiint(\psi_i'-\psi_i)f_if_j\boldsymbol{k}(\boldsymbol{g}_{ji}\cdot\boldsymbol{k})\, d\boldsymbol{k}\, d\boldsymbol{v}_i\, d\boldsymbol{v}_j\,, \tag{3.7–1}$$

$$\mathbf{J}_c^{(2)}(\psi)=\frac{1}{4}\sum_{ij}\sigma_{ij}^4\chi_{ij}^0\iiint(\psi_i'-\psi_i)f_if_j\left(\boldsymbol{k}\cdot\nabla\ln\frac{f_i}{f_j}\right)\boldsymbol{k}(\boldsymbol{g}_{ji}\cdot\boldsymbol{k})\,d\boldsymbol{k}\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j\,, \tag{3.7–2}$$

$$R^{(1)}(\psi)=\frac{1}{2}\sum_{ij}\sigma_{ij}^4\chi_{ij}^0\iiint f_if_j\{\boldsymbol{k}\cdot\nabla(\psi_i'-\psi_i)\}(\boldsymbol{g}_{ji}\cdot\boldsymbol{k})\,d\boldsymbol{k}\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j\,, \tag{3.8–1}$$

$$R^{(2)}(\psi)=\frac{1}{4}\sum_{ij}\sigma_{ij}^4\chi_{ij}^0\iiint f_if_j\left(\boldsymbol{k}\cdot\nabla\ln\frac{f_i}{f_j}\right)\{\boldsymbol{k}\cdot\nabla(\psi_i'-\psi_i)\}(\boldsymbol{g}_{ji}\cdot\boldsymbol{k})\,d\boldsymbol{k}\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j\,. \tag{3.8–2}$$

As was pointed out for one component gases[13], it is shown that $\mathbf{J}_c(\psi)$'s are the contribution of the collisional transfer of ψ to the flux vector, (see Appendix I). In addition to the abovementioned collisional transfer, there exists a flux due to the flow of molecules across the surface moving with the mass average velocity, given by

$$\mathbf{J}_{k_i}(\psi_i)=\int\psi_i\boldsymbol{V}_if_i\,d\boldsymbol{v}_i\,, \tag{3.9}$$

associated with the ith kind of molecules, where $\boldsymbol{V}_i=\boldsymbol{v}_i-\boldsymbol{v}_0$ is called the peculiar velocity. Then the whole flux in a gas mixture is given by the sum of such fluxes over all components:

$$\mathbf{J}_k(\psi)=\sum_i\mathbf{J}_{k_i}(\psi_i)=\sum_i^{\nu}\int\psi_i\boldsymbol{V}_if_i\,d\boldsymbol{v}_i\,. \tag{3.10}$$

It is now noticed that there remains the terms $R(\psi)$'s given by (3.8), which correspond to energy sources and are necessary for the correct expression of the energy balance.

We shall now consider the summational invariants, m_i, $m_i\boldsymbol{V}_i$ and $m_iV_i/2$ as ψ_i to get the hydrodynamical equations.

(I) *The equation of continuity*: Let ψ_i be m_i. Then using (2.1) and (3.3) we obtain

$$\frac{D\rho_i}{Dt}=-\rho_i\nabla\cdot\boldsymbol{v}_0-\nabla\cdot\boldsymbol{J}_i\,, \tag{3.11}$$

where $\rho_i=n_im_i$ and $\boldsymbol{J}_i=n_i\overline{m_i\boldsymbol{V}_i}$ are the mass density and the diffusion velocity flux of species i, respectively. D/Dt denotes the hydrodynamical operator $(\partial/\partial t-\boldsymbol{v}_0\cdot\nabla)$ and (3.11) is the equation of continuity for the ith species. If the equations of continuity (3.11) are summed over i, since $\sum_i^{\nu}\boldsymbol{J}_i=0$ according to the definition of $\boldsymbol{J}_i$, the overall equation of continuity is obtained:

$$\frac{D\rho}{Dt}=-\rho\nabla\cdot\boldsymbol{v}_0\,. \tag{3.12}$$

(II) *The equation of motion*: If we put $\psi_i=m_i\boldsymbol{V}_i$ in (3.3), and sum over i, then we obtain

$$\rho\frac{D\boldsymbol{v}_0}{Dt}=-\nabla\cdot\mathbf{P}+\sum_i n_i\boldsymbol{F}_i \tag{3.13}$$

where $\mathbf{P}$ is given by

$$\mathbf{P}=\mathbf{P}_k+\mathbf{P}_c\,, \tag{3.14}$$

$$\mathbf{P}_k=\sum_i m_i\int\boldsymbol{V}_i\boldsymbol{V}_if_i\,d\boldsymbol{v}_i=\sum_i\mathbf{P}_{k_i}\,, \tag{3.14–k}$$

$$\mathbf{P}_c=\sum_{\alpha}^{2}\mathbf{J}_c^{(\alpha)}[m_i\boldsymbol{V}_i]\,, \tag{3.14–c}$$

since $R(m_i\boldsymbol{V}_i)$'s all vanish. We can immediately see that (3.13) is the equation of motion and $\mathbf{P}$ is the pressure tensor. The momentum flux arising from the collisional transfer of momentum $\mathbf{J}_c[m_i V_i]$'s are respectively written in the following forms:

$$\mathbf{J}_c^{(1)}[m_i V_i]=\frac{\pi}{15}\sum_{ij}\sigma_{ij}^3\chi_{ij}^0 M_{ji}m_i\iint(2\boldsymbol{gg}+g^2\mathbf{U})f_i f_j\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j \tag{3.15–1}$$

$$\mathbf{J}_c^{(2)}[m_i V_i]=\frac{\pi}{48}\sum_{ij}\sigma_{ij}^4\chi_{ij}^0 M_{ji}m_i\iint f_i f_j\Big[\frac{(\boldsymbol{gg}+g^2\mathbf{U})}{g}\Big(\boldsymbol{g}\cdot\nabla\ln\frac{f_j}{f_i}\Big)$$
$$+g\Big\{\Big(\nabla\ln\frac{f_i}{f_j}\Big)\boldsymbol{g}+\boldsymbol{g}\Big(\nabla\ln\frac{f_i}{f_j}\Big)\Big\}\Big]d\boldsymbol{v}_i\,d\boldsymbol{v}_j\,, \tag{3.15–2}$$

where

$$M_{ij}=2m_i/m_i+m_j\,, \tag{3.16}$$

$\mathbf{U}$ is the unit tensor, and for simplicity the suffices j, i in $\boldsymbol{g}_{ji}$ are droped hereafter. (see Appendix II).

(III) *The equation of energy balance*: If we put $\psi_i=m_i V_i^2/2$ in (3.3) and sum over i, we obtain

$$\rho\frac{D\hat{U}}{Dt}=-\nabla\cdot\boldsymbol{q}-\mathbf{P}:\nabla\boldsymbol{v}_0+\sum_i\frac{\boldsymbol{F}_i}{m_i}\cdot\boldsymbol{J}_i\,, \tag{3.17}$$

where $\hat{U}$ is the kinetic contribution to the internal energy per unit mass given by

$$\rho\hat{U}=\frac{1}{2}\sum_i m_i\int V_i^2 f_i\,d\boldsymbol{v}_i\,, \tag{3.18}$$

and $\boldsymbol{q}$ is the thermal energy flux given by

$$\boldsymbol{q}=\boldsymbol{q}_k+\boldsymbol{q}_c\,, \tag{3.19}$$

$$\boldsymbol{q}_k\equiv\frac{1}{2}\sum_i m_i\int V_i^2\boldsymbol{V}_i f_i\,d\boldsymbol{v}_i=\sum_i\boldsymbol{q}_{k_i}\,, \tag{3.19–k}$$

$$\boldsymbol{q}_c\equiv\sum_{\alpha=1}^{2}\mathbf{J}_c^{(\alpha)}\Big[\frac{1}{2}m_i V_i\Big]. \tag{3.19–c}$$

We use the mark ^ to denote the quantity per unit mass. It should be noted that $R(m_i V_i^2/2)$ does not vanish and is given by (see Appendix II)

$$\sum_{\alpha=1}^{2}R^{(\alpha)}\Big[\frac{1}{2}m_i V_i^2\Big]=-\nabla\boldsymbol{v}_0:\sum_{\alpha=1}^{2}\mathbf{J}_c^{(\alpha)}[m_i V_i]=-\mathbf{P}_c:\nabla\boldsymbol{v}_0\,. \tag{3.20}$$

The energy fluxes arising from the collisional transfer of energy $\mathbf{J}_c[m_i V_i^2/2]$ are respectively given by (see Appendix II)

$$\mathbf{J}_c^{(1)}\Big[\frac{m_i V_i^2}{2}\Big]=\frac{\pi}{15}\sum_{ij}\sigma_{ij}^3\chi_{ij}^0 M_{ji}m_i\iint[2\boldsymbol{g}(\boldsymbol{g}\cdot\boldsymbol{G})+\boldsymbol{g}^2\boldsymbol{G}]f_i f_j\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j\,, \tag{3.21–1}$$

and

$$\mathbf{J}_c^{(2)}\Big[\frac{m_i V_i^2}{2}\Big]=\frac{\pi}{48}\sum_{ij}\sigma_{ij}^4\chi_{ij}^0 M_{ji}m_i\iint\Big[\frac{\boldsymbol{g}}{g}\Big(\boldsymbol{G}\nabla\ln\frac{f_i}{f_j}:\boldsymbol{gg}\Big)+g\Big\{\Big(\boldsymbol{G}\cdot\nabla\ln\frac{f_i}{f_j}\Big)\boldsymbol{g}$$
$$+\Big(\boldsymbol{g}\cdot\nabla\ln\frac{f_i}{f_j}\Big)\boldsymbol{G}+(\boldsymbol{g}\cdot\boldsymbol{G})\nabla\ln\frac{f_i}{f_j}\Big\}\Big]f_i f_j\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j\,, \tag{3.21–2}$$

where $\boldsymbol{G}_{ij}$ is the velocity of mass center of i and j molecules, defined by

$$\boldsymbol{G}_{ij}\equiv\frac{m_i\boldsymbol{V}_i+m_j\boldsymbol{V}_j}{m_i+m_j}\,. \tag{3.22}$$

The local temperature T is defined by

$$\frac{3}{2}nkT=\frac{1}{2}\sum_i m_i\int \boldsymbol{V}_i^2 f_i\,d\boldsymbol{v}_i\ , \tag{3.23}$$

which leads to

$$\rho\hat{U}=\frac{3}{2}nkT\ , \tag{3.24}$$

where n is the number density of the whole gasgiven by the relation

$$n=\sum_i^{\nu} n_i\ . \tag{3.25}$$

§ 4. The First Approximations to Fluxes

If the system is not so far from equilibrium, we may choose as the zeroth approximation to f_i the Maxwell distribution given by

$$f_i{}^0(\boldsymbol{r},\boldsymbol{v}_i;\,t)=n_i(\boldsymbol{r},t)\left(\frac{m_i}{2\pi kT}\right)^{3/2}\exp\left\{-\frac{m_i\boldsymbol{V}_i^2}{2kT(\boldsymbol{r},t)}\right\}, \tag{4.1}$$

where n_i, $\boldsymbol{v}_0$ and T are respectively given by (2.1), (3.2) and (3.23), and are generally functions of the spatial coordinates. Then we may express f_i in terms of a perturbation function ϕ_i:

$$f_i=f_i{}^0(1+\phi_i)\ . \tag{4.2}$$

From (2.1), (3.2), (3.23) and (4.1) we can prove the following relations:

$$\int f_i{}^0\phi_i\,d\boldsymbol{v}_i=0\ , \tag{4.3–1}$$

$$\sum_i m_i\int \boldsymbol{V}_i f_i{}^0\phi_i\,d\boldsymbol{v}_i=0\ , \tag{4.3–2}$$

$$\frac{1}{2}\sum_i m_i\int \boldsymbol{V}_i^2 f_i{}^0\phi_i\,d\boldsymbol{v}_i=0\ . \tag{4.3–3}$$

These auxiliary conditions imposed on f_i imply the physical assumption that the system may be well described by a set of the thermodynamical variables in successive local equilibrium states. Then we can express the fluxes in terms of the perturbation function ϕ_i and the pair correlation function $\chi_{ij}{}^0$.

If we consider the mass flow vector, for which the flux is only kinetic one given by (3.9), then we obtain from (4.3–1)

$$\boldsymbol{J}_i=m_i\int \boldsymbol{V}_i f_i\,d\boldsymbol{v}_i=m_i\int \boldsymbol{V}_i f_i{}^0\phi_i\,d\boldsymbol{v}_i\ . \tag{4.4}$$

The pressure tensor given by (3.16) is reduced to the following form to the first approximation. The kinetic contribution $\mathbf{P}_{k_i}$ is written as

$$\mathbf{P}_{k_i}=n_ikT\,\mathbf{U}+m_i\int \boldsymbol{V}_i\boldsymbol{V}_i f_i{}^0\phi_i\,d\boldsymbol{v}_i\ , \tag{4.5}$$

or we can rewrite, using the hydrostatic pressure $p_{id}{}^0=\sum_i p_{k_i}{}^0=\sum_i n_ikT$ for an ideal gas, as

$$\mathbf{P}_k-p_k{}^0\mathbf{U}=\sum_i\int m_i\boldsymbol{V}_i\boldsymbol{V}_i f_i{}^0\phi_i\,d\boldsymbol{v}_i=\sum_i m_i\int\left(\boldsymbol{V}_i\boldsymbol{V}_i-\frac{1}{3}\boldsymbol{V}_i^2\mathbf{U}\right)f_i\,d\boldsymbol{v}_i\ . \tag{4.6}$$

The collisional transfers of momentum given by (3.15) are respectively reduced after rather tedious but straightforward calculations to

$$\mathbf{J}_c^{(1)}[m_i V_i] = \sum_{ij} n_i n_j b_{ij} \chi_{ij}^0 kT\,\mathbf{U} + \frac{2}{5}\sum_{ij} n_j b_{ij} \chi_{ij}^0 M_{ji} m_i \int V_i V_i f_i^0 \phi_i \, dv_i \,, \tag{4.7-1}$$

$$\mathbf{J}_c^{(2)}[m_i V_i] = -\sum_{ij} \tilde{\omega}_{ij} \left[\frac{6}{5}\frac{\mathbf{S}}{T} + \frac{\nabla \cdot v_0}{T}\mathbf{U} \right], \tag{4.7-2}$$

where $\mathbf{S}$ is the rate of shear tensor defined by (see Appendix III)

$$S_{ij} \equiv \frac{1}{2}\left[\frac{\partial v_{0j}}{\partial x_i} + \frac{\partial v_{0i}}{\partial x_j} \right] - \frac{1}{3}\delta_{ij}(\nabla \cdot v_0) \,, \tag{4.8}$$

$$b_{ij} \equiv \frac{2}{3}\pi \sigma_{ij}^3 \,, \tag{4.9}$$

$$\tilde{\omega}_{ij} \equiv \frac{4}{9} n_i n_j \sigma_{ij}^4 \chi_{ij}^0 (\pi M_{ji} k T^3)^{1/2} \,. \tag{4.10}$$

Consequently the pressure tensor as a whole, is given by

$$\mathbf{P} = \mathbf{P}_k + \mathbf{P}_c = \left[p^0 - \sum_{ij} \tilde{\omega}_{ij} \frac{\nabla \cdot v_0}{T} \right] \mathbf{U} - \frac{6}{5}\sum_{ij} \tilde{\omega}_{ij} \frac{\mathbf{S}}{T}$$
$$+ \sum_i \left(1 + \frac{2}{5}\sum_j M_{ji} b_{ij} \chi_{ij}^0 n_j \right) m_i \int V_i V_i f_i^0 \phi_i \, dv_i \,, \tag{4.11}$$

where

$$p^0 = \sum_i p_i^0 = \sum_i \left\{ p^0{}_{k_i} + \sum_j n_i n_j b_{ij} \chi_{ij}^0 kT \right\} \tag{4.12}$$

is the equilibrium hydrostatic pressure at the local temperature T and densities n_i's. The difference from that of an ideal gas is $\sum_{ij} n_i n_j b_{ij} \chi_{ij}^0 kT$, and means that the gas is imperfect.

On the other hand the equation of state of the equilibrium gases composed of the rigid-spheres can be obtained from the equilibrium statistical mechanics in the virial expansion form:

$$p^0 = kT \left[n + \sum_{ij} n_i n_j B_{ij} + \sum_{ijk} n_i n_j n_k C_{ijk} + \cdots \right], \tag{4.13}$$

where the second virial coefficient B_{ij} is given by

$$B_{ij} = \frac{2}{3}\pi \sigma_{ij}^3 = b_{ij} \,. \tag{4.14}$$

Thus b_{ij} is the second virial coefficient per molecule, and χ_{ij}^0 is expressible in the form

$$\chi_{ij}^0 = 1 + \frac{1}{b_{ij}} \sum_k n_k C_{ijk} + \frac{1}{b_{ij}} \sum_{k,l} n_k n_l D_{ijkl} + \cdots \,, \tag{4.15}$$

which depends only on the concentrations of chemical species.

With use of the perturbation functions the thermal energy fluxes, $\mathbf{q}_k$ and $\mathbf{q}_c$, given by (3.19) are reduced as follows: the kinetic contribution $\mathbf{q}_k$ is written as

$$\mathbf{q}_k = \sum_i \mathbf{q}_{k_i} = \sum_i \frac{1}{2} m_i \int V_i^2 V_i f_i^0 \phi_i \, dv_i \,, \tag{4.16}$$

and the collisional contributions to the energy transfer $\mathbf{J}_c\left[\frac{1}{2} m_i V_i^2\right]$'s are reduced, with use of (3.21) and (4.2), to (see Appendix III)

$$\mathbf{J}_c{}^{(1)}\left[\frac{m_i V_i^2}{2}\right]=\frac{2\pi}{5}\sum_{i,j}\sigma_{ij}{}^3\chi_{ij}{}^0 M_{ij}M_{ji}n_j\boldsymbol{q}_{k_i}+\sum_{i,j}\frac{1}{2}b_{ij}\chi_{ij}{}^0 M_{ij}M_{ji}\frac{m_i-2m_j}{m_i m_j}n_j\boldsymbol{J}_i kT\ , \tag{4.17-1}$$

$$\mathbf{J}_c{}^{(2)}\left[\frac{m_i V_i^2}{2}\right]=\sum_{i,j}\tilde{\omega}_{ij}\left(\frac{3kT}{m_i+m_j}\right)\nabla\frac{1}{T}\ . \tag{4.17-2}$$

Consequently we can write the total energy flux in the form:

$$\boldsymbol{q}=\boldsymbol{q}_k+\boldsymbol{q}_c=\boldsymbol{E}+\sum_i\frac{\bar{H}_i}{m_i}\boldsymbol{J}_i\ , \tag{4.18}$$

where

$$\boldsymbol{E}=\sum_i\left(1+\frac{3}{5}\sum_j M_{ij}M_{ji}b_{ij}\chi_{ij}{}^0 n_j\right)\boldsymbol{E}_{k_i}-\sum_{ij}\tilde{\omega}_{ij}\left(\frac{3kT}{m_i+m_j}\right)\nabla\frac{1}{T}\ , \tag{4.18-1}$$

$$\boldsymbol{E}_{k_i}\equiv\int\left(\frac{m_i V_i^2}{2}-\frac{5}{2}kT\right)\boldsymbol{V}_i f_i\,d\boldsymbol{v}_i\ , \tag{4.18-2}$$

and

$$\bar{H}_i\equiv\left(\frac{5}{2}+\sum_j M_{ij}b_{ij}\chi_{ij}{}^0 n_j\right)kT\ . \tag{4.18-3}$$

The first term in (4.18) is the thermal energy flux and the second is the energy transfer associated with the molecular flows. It is noticed that $\bar{H}_i$ is a partial molar enthalpy in a sense and $\sum_i n_i\bar{H}_i$ is exactly the enthalpy per unit volume of our rigid-sphere gas.

If we find the function f_i which satisfy (2.6), then we have the complete description of the non-equilibrium system by means of the hydrodynamic equations (3.11), (3.13) and (3.17), with the fluxes (4.4), (4.11) and (4.18).

§ 5. Enskog's First Approximation Equation

One of the solution of (2.6) is that analogous to well known Enskog's solution in one component system. We shall derive the first approximation equation following Enskog.

In the left-hand side of (2.6) the terms containing the perturbation function ϕ_i may be neglected to the first approximation, and then the streaming term is written in the form:

$$\begin{aligned}\left\{\frac{\partial}{\partial t}+\boldsymbol{v}_i\cdot\nabla_r+\frac{\boldsymbol{F}_i}{m_i}\cdot\nabla_{v_i}\right\}f_i{}^0=f_i{}^0\Bigg[&\frac{D\ln n_i}{Dt}+\left(\frac{m_i V_i^2}{2kT}-\frac{3}{2}\right)\frac{D\ln T}{Dt}\\&+\frac{m_i}{kT}\boldsymbol{V}_i\boldsymbol{V}_i:\nabla\boldsymbol{v}_0+\boldsymbol{V}_i\cdot\left\{\nabla\ln n_i+\left(\frac{m_i V_i^2}{2kT}-\frac{3}{2}\right)\nabla\ln T+\left(\frac{D\boldsymbol{v}_0}{Dt}-\frac{\boldsymbol{F}_i}{m_i}\right)\frac{m_i}{kT}\right\}\Bigg].\end{aligned} \tag{5.1}$$

The right hand side of (2.6) becomes, if the terms of second order is neglected,

$$\left(\frac{\partial f_i}{\partial t}\right)^0_{\text{coll}}=\sum_\gamma{}^0J_i{}^{(\gamma)}\ , \tag{5.2}$$

$${}^0J_i{}^{(1)}=\sum_j{}^0J_{ij}{}^{(1)}=\sum_j\chi_{ij}{}^0\iint f_i{}^0 f_j{}^0(\phi_i'+\phi_j'-\phi_i-\phi_j)\sigma_{ij}{}^2(\boldsymbol{g}\cdot\boldsymbol{k})\,d\boldsymbol{k}\,d\boldsymbol{v}_j \tag{5.2-1}$$

$$\begin{aligned}{}^0J_i{}^{(2)}=\sum_j{}^0J_{ij}{}^{(2)}=f_i{}^0\sum_j b_{ij}\chi_{ij}{}^0 n_j\Bigg[&\left(M_{ij}M_{ji}-\frac{1}{2}M_{ij}{}^2\right)\boldsymbol{V}_i\cdot\nabla\ln T\\&-2\boldsymbol{V}_i\cdot\nabla\ln n_j-\frac{3}{5}M_{ij}M_{ji}\frac{m_i V_i^2}{2kT}\boldsymbol{V}_i\cdot\nabla\ln T\\&+M_{ij}\left(1-\frac{2}{5}\frac{m_i V_i^2}{2kT}\right)\nabla\cdot\boldsymbol{v}_0-\frac{2}{5}M_{ji}\frac{m_i}{kT}\boldsymbol{V}_i\boldsymbol{V}_i:\nabla\boldsymbol{v}_0\Bigg],\end{aligned} \tag{5.2-2}$$

$${}^0J_i{}^{(3)}=\sum_j{}^0J_{ij}{}^{(3)}=f_i{}^0\left[-\sum_j n_i b_{ij}\boldsymbol{V}_i\cdot\nabla\chi_{ij}{}^0\right], \tag{5.2-3}$$

$$\sum_j {}^0J_{ij}^{(4)}=\sum_j {}^0J_{ij}^{(5)}=\sum_j {}^0J_{ij}^{(6)}=0\ . \tag{5.2–4}$$

Then we have the equation of change in the zero order:

$$\int\psi_i\left(\frac{\partial}{\partial t}+\boldsymbol{v}_i\cdot\nabla+\frac{\boldsymbol{F}_i}{m_i}\nabla\cdot\right)f_i^0\,d\boldsymbol{v}_i=\int\psi_i\left(\frac{\partial f_i}{\partial t}\right)^0_{\text{coll}}d\boldsymbol{v}_i\ . \tag{5.3}$$

If we put $\psi_i=m_i$, $\psi_i=m_iV_i$ and $\psi_i=m_iV_i^2/2$ in the above equation, then we obtain the continuity equation, the equation of motion and the equation of energy balance to the zeroth approximation, respectively,

$$\frac{D\rho_i}{Dt}+\rho_i\cdot\nabla\boldsymbol{v}_0=0\ , \tag{5.4}$$

$$\rho\frac{D\boldsymbol{v}_0}{Dt}=\sum_i\left[\frac{\rho_i}{\rho}\frac{\boldsymbol{F}_i}{m_i}-\frac{1}{\rho}\nabla\left\{n_ikT\left(1+\sum_j n_jb_{ij}\chi_{ij}^0\right)\right\}\right], \tag{5.5}$$

$$n\frac{D\ln T}{Dt}=-\frac{2}{3}(\nabla\cdot\boldsymbol{v}_0)\left\{\sum_i n_i\left(1+\sum_j n_jb_{ij}\chi_{ij}^0\right)\right\}\ . \tag{5.6}$$

Substituting (5.4), (5.5) and (5.6) into (5.1), we obtain the extension of Enskog's first approximation equation to multicomponent gas which determine the perturbation function ϕ_i:

$$\begin{aligned}f_i^0\Bigg[&\left(1+\frac{3}{5}\sum_j M_{ij}M_{ji}b_{ij}n_j\chi_{ij}^0\right)\left(\frac{m_iV_i^2}{2kT}-\frac{5}{2}\right)\boldsymbol{V}_i\cdot\nabla\ln T+\frac{n}{n_i}\boldsymbol{V}_i\cdot\boldsymbol{d}_i\\&+\left(1+\frac{2}{5}\sum_j M_{ji}b_{ij}n_j\chi_{ij}^0\right)\frac{m_i}{kT}\left(\boldsymbol{V}_i\boldsymbol{V}_i-\frac{1}{3}V_i^2\mathbf{U}\right):\nabla\boldsymbol{v}_0\\&+\sum\left(M_{ji}b_{ij}\chi_{ij}^0n_j-\frac{n_j}{n}\sum_k b_{jk}\chi^0{}_{jk}n_k\right)\left(\frac{m_iV_i^2}{3kT}-1\right)\nabla\cdot\boldsymbol{v}_0\\&=\sum_j\chi_{ij}^0\sigma_{ij}^2\iint f_i^0f_j^0(\phi_i'+\phi_j'-\phi_i-\phi_j)(\boldsymbol{g}\cdot\boldsymbol{k})\,d\boldsymbol{k}\,d\boldsymbol{v}_j\ ,\end{aligned} \tag{5.7}$$

where

$$\begin{aligned}\boldsymbol{d}_i\equiv&\frac{\rho_i}{\rho nkT}\left[\sum_j\frac{\rho_j\boldsymbol{F}_j}{m_i}-\rho\frac{\boldsymbol{F}_i}{m_i}\right]+\frac{\rho-\rho_i}{\rho nkT}\nabla p_i^0-\frac{\rho_i}{\rho nkT}\nabla(p^0-p_i^0)\\&+\frac{n_i}{n}\sum_k n_kb_{ik}\chi_{ik}^0\left\{\nabla\ln\frac{n_i}{n}+\frac{1}{2}(M_{ik}-M_{ki})\nabla\ln T\right\}\ ,\end{aligned} \tag{5.8}$$

which agrees with Thorne's equation for a two component system.

§ 6. The Statistical Expressions of the Irreversible Production of Entropy

Thus far in our description of the non-equilibrium system the entropy S, which plays a significant role in the theory of irreversible processes, has been left out of our considerations. We shall now consider the entropy and the balance equation for it, to complete the thermodynamic description of the system.

Let us first consider the equilibrium values of some thermodynamic potentials of an imperfect gas composed of rigid-spheres. The Helmholtz free energy and the entropy of an imperfect gas can be written in the form:

$$F^0=F_{id}^0+\lim_{V_0\to\infty}\int_{V_0}^{V}(p^0-p^0{}_{id})\,dV\ , \tag{6.1}$$

and

$$S^0=S^0{}_{id}+\frac{\partial}{\partial T}\left\{\lim_{V_0\to\infty}\int_{V_0}^{V}(p^0-p_{id}^0)\,dV\right\}\ , \tag{6.2}$$

respectively, where the subscript *id* denote the functions for the corresponding perfect gas with the same temperature and densities. The equation alows us to calculate the equilibrium value of the thermodynamical potentials, if we know the equation of state.

Then we obtain from (6.1) and (4.12) the free energy per unit volume of the rigid-sphere gas mixture:

$$\rho\hat{F}^0=\rho\hat{F}_{id}{}^0+kT\sum_{ij} n_i n_j b_{ij}\left(\frac{1}{n}\int^n \chi_{ij}{}^0\, dn\right), \tag{6.3}$$

where we have used n instead of V as the independent variable. Since $\chi_{ij}{}^0$ is independent of the temperature as seen from (4.13) in a rigid-sphere system, the entropy per unit volume is expressed as

$$\rho\hat{S}^0=\rho\hat{S}_{id}{}^0+\rho\hat{S}^0_{\mathrm{corr}}, \tag{6.4}$$

$$\rho\hat{S}^0_{\mathrm{corr}}=-k\sum_{i,j} n_i n_j b_{ij}\left(\frac{1}{n}\int^n \chi_{ij}{}^0\, dn\right), \tag{6.5}$$

where $\hat{S}_{\mathrm{corr}}$ is the correction to the entropy per unit mass due to imperfectness of the gas. On the other hand, the entropy per unit volume of an ideal gas composed point molecules is known to be

$$\rho\hat{S}_{id}=\sum_i kn_i\left[\frac{3}{2}\ln T-\ln n_i+\ln\left(\frac{2\pi m_i k}{h^2}\right)^{3/2}+\frac{5}{2}\right]-k\sum_i n_i \ln\frac{n_i}{n}. \tag{6.6}$$

According to the H-theorem, the entropy density of the gas of point molecules in non-equilibrium state is given by

$$\rho\hat{S}_{\mathrm{I}}=k\sum_i\int_{-\infty}^{\infty}(1-\ln f_i)f_i\, d\boldsymbol{v}_i, \tag{6.7}$$

which becomes identical with (6.6) for the equilibrium distribution $f_i=f_i{}^0$ apart from an additive constant.

For the present case of a moderately dense gas the correction due to the gas imperfection appears through the pair correlation function χ_{ij}, and furthermore we have assumed that χ_{ij} can be replaced by its equilibrium value $\chi_{ij}{}^0$ without appreciable error. Then we may write the entropy density of an imperfect gas slightly deviated from equilibrium as the sum of (6.7) and (6.5):

$$\begin{aligned}\rho\hat{S}&=\rho\hat{S}_{\mathrm{I}}+\rho\hat{S}_{\mathrm{II}},\\ \rho\hat{S}_{\mathrm{II}}&=\rho\hat{S}^0_{\mathrm{corr}}=-k\sum_{i,j} n_i n_j b_{ij}\left(\frac{1}{n}\int^n \chi_{ij}\, dn\right).\end{aligned} \tag{6.8}$$

Multiplying (2.6) by $k(1-\ln f_i)$, integrating over $\boldsymbol{v}_i$ and summing over i, we obtain the equation of entropy balance

$$\rho\frac{D\hat{S}_{\mathrm{I}}}{Dt}+\nabla\cdot k\sum_i\int(1-\ln f_i)\boldsymbol{V}_i f_i\, d\boldsymbol{v}_i=-k\sum_i\sum_\gamma I_i{}^{(\gamma)}(\ln f_i), \tag{6.9}$$

where $I_i{}^{(\gamma)}$ is given by (3.4). The manner of derivation of (6.9) is similar to that of (3.3). Substituting (4.1) and (4.2) into (6.9), and remembering that $m_i V_i{}^2/2$ is one of the summational invariants, we can write the right-hand side of (6.9), with use of (3.6), (3.7) and (3.8) in the form

$$\begin{aligned}-k\sum_\gamma\sum_i I_i{}^{(\gamma)}(\ln f_i)&=\nabla\cdot\left[\sum_\alpha \boldsymbol{J}_c{}^{(\alpha)}\left[-\frac{m_i V_i{}^2}{2T}\right]\right]-\sum_\alpha R^{(\alpha)}\left(\frac{m_i V_i{}^2}{2T}\right)-k\sum_\gamma^6\sum_i^\nu I_i{}^{(\gamma)}(\phi_i)\\ &=-\frac{1}{T}\nabla\cdot\boldsymbol{q}_0-\frac{1}{T}\mathbf{P}_c:\nabla\boldsymbol{v}_0-k\sum_\gamma^6\sum_i^\nu I_i{}^{(\gamma)}(\phi_i),\end{aligned} \tag{6.10}$$

where we have ignored the terms higher than the square of ϕ_i. $\mathbf{P}_c$ and $\boldsymbol{q}_c$ in (6.10) are given by (4.7) and (4.17), respectively. To the same approximation $\sum_{i=1}^{\nu} I_i(\phi_i)$'s are reduced to

$$k\sum_i^{\nu} {}^0I_i^{(1)}(\phi_i)=k\sum_i^{\nu}\int \phi_i {}^0J_i^{(1)}\,d\boldsymbol{v}_i -\frac{k}{4}\sum_{ij}\chi_{ij}^0\iint f_i^0 f_j^0(\phi_i'+\phi_j'-\phi_i-\phi_j)\phi_i\sigma_{ij}^2(\boldsymbol{g}\cdot\boldsymbol{k})\,d\boldsymbol{k}\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j\,, \tag{6.11–1}$$

$$k\sum_i {}^0I_i^{(2)}(\phi_i)=k\sum_i\int\phi_i {}^0J_i^{(2)}\,d\boldsymbol{v}_i=\sum_i\Big[\mathbf{E}_{k_i}\cdot\nabla\frac{1}{T}\sum_j\frac{3}{5}M_{ij}M_{ji}b_{ij}n_j\chi_{ij}^0 +\boldsymbol{J}_i\cdot\frac{kT}{m_i}\sum_j b_{ij}n_j\chi_{ij}^0\Big(M_{ij}\nabla\frac{1}{T}-2\frac{1}{T}\nabla\ln n_j\Big) +(\mathbf{P}_{k_i}-p_{k_i}{}^0\mathrm{U}):\Big(\frac{\nabla\boldsymbol{v}_0}{T}\Big)\sum_j\frac{2}{5}M_{ji}b_{ij}\chi_{ij}^0 n_j\Big]\,, \tag{6.11–2}$$

$$k\sum_i {}^0I_i^{(3)}(\phi_i)=k\sum_i\int\phi_i {}^0J_i^{(3)}\,d\boldsymbol{v}_i=\sum_i\boldsymbol{J}_i\cdot\Big\{\frac{kT}{m_i}\sum_j b_{ij}n_j\chi_{ij}^0\frac{\nabla\ln\chi_{ij}^0}{T}\Big\}\,, \tag{6.11–3}$$

$$\sum_i {}^0I_i^{(4)}(\phi_i)=\sum_i {}^0I_i^{(5)}(\phi_i)=\sum_i {}^0I_i^{(6)}(\phi_i)=0, \tag{6.11–4}$$

where $(\mathbf{P}_{k_i}-p_{k_i}{}^0\mathrm{U})$ and $\boldsymbol{E}_k$ and $\boldsymbol{J}_i$ are given by (4.6), (4.18–2) and (4.4), respectively. Here ${}^0I_i^{(\gamma)}$ and ${}^0J_i^{(\gamma)}$ indicate the first approximations to the integrals $I_i^{(\gamma)}$ and $J_i^{(\gamma)}$, respectively.

If we use (4.2) and neglect ϕ_i^2 in the second term of the left hand side of (6.9), we immediately obtain from (4.16) and (4.4)

$$k\sum_i\int(1-\ln f_i)V_i f_i\,d\boldsymbol{v}_i=\frac{\boldsymbol{q}_k}{T}-\sum_i\frac{\mu_i^{id}}{T}\frac{\boldsymbol{J}_i}{m_i}\,, \tag{6.12}$$

with

$$\mu_i^{id}\equiv kT\Big[\ln n_i-\frac{3}{2}\ln T+\frac{3}{2}\ln\Big(\frac{m_i}{2\pi k}\Big)\Big]\simeq\frac{\partial}{\partial n_i}(\rho\hat{F}_{id}{}^0) \tag{6.13}$$

which stands for the chemical potential of species i of an ideal gas mixture.

From (6.9), (6.10), (6.11) and (6.12), we finally obtain the expression for the entropy balance equation given by

$$\rho\frac{D\hat{S}_{\mathrm{I}}}{Dt}+\nabla\cdot\boldsymbol{\sigma}_{\mathrm{I}}^{(\mathrm{i})}[s]=\tau_{\mathrm{I}}^{(\mathrm{i})}[s]\,, \tag{6.14}$$

where $\boldsymbol{\sigma}_{\mathrm{I}}$ and τ_{I} are given respectively by

$$\boldsymbol{\sigma}_{\mathrm{I}}^{(\mathrm{i})}[s]\equiv\frac{\boldsymbol{q}}{T}-\sum_i\frac{\mu_i^{id}}{T}\frac{\boldsymbol{J}_i}{m_i}\,, \tag{6.15}$$

$$\tau_{\mathrm{I}}^{(\mathrm{i})}[s]=-k\sum_i {}^0I_i^{(1)}(\phi_i)+\sum_{ij}\tilde{\omega}_{ij}\Big(\frac{3kT}{m_i+m_j}\Big)\Big(\nabla\frac{1}{T}\Big)^2+\frac{6}{5}\sum_{ij}\tilde{\omega}_{ij}\Big[\frac{\mathbf{S}}{T}:\frac{\mathbf{S}}{T}\Big] +\sum_{ij}\tilde{\omega}_{ij}\Big(\frac{\nabla\cdot\boldsymbol{v}_0}{T}\Big)^2+(p^0-p_{id}{}^0)\Big(-\frac{\nabla\cdot\boldsymbol{v}_0}{T}\Big)+kT\sum_{ij}b_{ij}n_j\chi_{ij}^0\Big(2\frac{\nabla\ln n_j}{T}+\frac{\nabla\ln\chi_{ij}^0}{T}\Big)\cdot\frac{\boldsymbol{J}_i}{m_i}\,, \tag{6.16}$$

where we have substituted (4.7) and (4.17) for $\mathbf{P}_c$ and $\boldsymbol{q}_c$ into (6.10).

On the other hand, since the entropy due to the gas imperfection, $\hat{S}_{\mathrm{II}}$, depends on the spatial coordinates only through the number densities n_i's, as seen from (4.15) and (6.8), we can easily obtain

$$\rho\frac{DS_{\mathrm{II}}}{Dt}=(p^0-p_{id}{}^0)\nabla\cdot\boldsymbol{v}_0$$
$$+\sum_i k\left\{\frac{2}{1}\sum_j n_jB_{ij}+\frac{3}{2}\sum_{j,k}n_jn_kC_{ijk}+\frac{4}{3}\sum_{j,kl}n_jn_kn_lD_{ijkl}+\cdots\right\}\nabla\cdot\frac{\boldsymbol{J}_i}{m_i}\,. \tag{6.17}$$

Further the additional chemical of ith species arising from the imperfectness of gas mixtures is given by

$$\mu_i{}^{\mathrm{corr}}\equiv\frac{\partial}{\partial n_i}(\rho\hat{F}_{\mathrm{corr}})=kT\left\{\frac{2}{1}\sum_j n_jB_{ij}+\frac{3}{2}\sum_{jk}n_jn_kC_{ijk}+\frac{4}{3}\sum_{jkl}n_jn_kn_lD_{ijkl}+\cdots\right\}. \tag{6.18}$$

Therefore, the balance equation of the entropy due to imperfectness can be written in the form

$$\rho\frac{D\hat{S}_{\mathrm{II}}}{Dt}+\nabla\cdot\boldsymbol{\sigma}_{\mathrm{II}}{}^{(\mathrm{i})}[s]=\tau_{\mathrm{II}}{}^{(\mathrm{i})}[s]\,, \tag{6.19}$$

where

$$\boldsymbol{\sigma}_{\mathrm{II}}{}^{(\mathrm{i})}[s]=-\sum_i\frac{\mu_i{}^{\mathrm{corr}}}{T}\cdot\frac{\boldsymbol{J}_i}{m_i}\,, \tag{6.20}$$

$$\tau_{\mathrm{II}}{}^{(\mathrm{i})}[s]=-\sum_i\frac{\boldsymbol{J}_i}{m_i}\cdot\nabla\frac{\mu_i{}^{\mathrm{corr}}}{T}+(p^0-p_{id}{}^0)\frac{\nabla\cdot\boldsymbol{v}_0}{T}\,. \tag{6.21}$$

Then the balance equation of total entropy is written as

$$\rho\frac{DS}{Dt}+\nabla\cdot\boldsymbol{\sigma}^{(\mathrm{i})}[s]=\tau^{(\mathrm{i})}[s]\,, \tag{6.22}$$

where

$$\boldsymbol{\sigma}^{(\mathrm{i})}[s]\equiv\boldsymbol{\sigma}_{\mathrm{I}}{}^{(\mathrm{i})}[s]+\boldsymbol{\sigma}_{\mathrm{II}}{}^{(\mathrm{i})}[s]=\frac{\boldsymbol{q}}{T}-\sum_i\frac{\mu_i{}^{id}+\mu_i{}^{\mathrm{corr}}}{T}\cdot\frac{\boldsymbol{J}_i}{m_i}\,, \tag{6.23}$$

$$\tau^{(\mathrm{i})}[s]=\tau_{\mathrm{I}}{}^{(\mathrm{i})}[s]+\tau_{\mathrm{II}}{}^{(\mathrm{i})}[s]=-k\sum_i{}^0I_i{}^{(1)}(\phi_i)+\sum_{ij}\tilde{\omega}_{ij}\left(\frac{3kT}{m_i+m_j}\right)\left(\nabla\frac{1}{T}\right)^2$$
$$+\frac{6}{5}\sum_{ij}\tilde{\omega}_{ij}\left[\frac{\mathbf{S}}{T}:\frac{\mathbf{S}}{T}\right]+\sum_{ij}\tilde{\omega}_{ij}\left[\frac{\nabla\cdot\boldsymbol{v}_0}{T}\right]^2. \tag{6.24}$$

This equation indicates that the change of the entropy $\rho\hat{S}$ of the gas within the local region moving with barycentric velocity $\boldsymbol{v}_0$ is arising from the reversible flow of entropy $\boldsymbol{\sigma}^{(\mathrm{i})}[s]$ and from the irreversible production of entropy $\tau^{(\mathrm{i})}[s]$.

Let us define the bracket expression given by

$$\{\psi,\phi\}\equiv-\sum_{ij}\chi_{ij}{}^0\iiint\psi_i(\phi_i'+\phi_j'-\phi_i-\phi_j)f_i{}^0f_j{}^0\sigma_{ij}{}^2(\boldsymbol{g}\cdot\boldsymbol{k})\,d\boldsymbol{k}\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j\,, \tag{6.25}$$

where ψ_i is an arbitrary function of $\boldsymbol{v}_i$ and ϕ_i is the perturbation function defined by (4.2). This may be symmetrized in the form (see Appendix I of the author's previous paper[11])

$$\{\psi,\phi\}=\frac{1}{4}\sum_{ij}\chi_{ij}{}^0\iiint(\psi_i'+\psi_j'-\psi_i-\psi_j)(\phi_i'+\phi_j'-\phi_i-\phi_j)$$
$$\times f_i{}^0f_j{}^0\sigma_{ij}{}^2(\boldsymbol{g}\cdot\boldsymbol{k})\,d\boldsymbol{k}\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j=\{\phi,\psi\}\,. \tag{6.26}$$

The operator { } is linear, and $\{\phi,\phi\}$ is non negative:

$$\{\psi+\varphi,\phi\}=\{\psi,\phi\}+\{\varphi,\phi\}\,, \tag{6.27}$$

$$\{\phi,\phi\}=\frac{1}{4}\sum_{ij}\chi_{ij}{}^0\iiint(\phi_i'+\phi_j'-\phi_i-\phi_j)^2f_i{}^0f_j{}^0(\boldsymbol{g}\cdot\boldsymbol{k})\,d\boldsymbol{k}\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j\geq0\,. \tag{6.28}$$

Since the integrand can never be negative, the expression $\{\phi, \phi\}$ vanishes if and only if ϕ_i is a linear combination of the summational invariants. With use of this bracket expression, (6.11–1) is reduced as

$$-k\sum_i {}^0I^{(1)}(\phi_i)=k\{\phi, \phi\}\ . \tag{6.29}$$

Then the entropy production rate (6.28) is written in the form:

$$\tau^{(i)}[s]=k\{\phi, \phi\}+\sum_{ij}\tilde{\omega}_{ij}\left(\frac{3kT}{m_i+m_j}\right)\left(\nabla\frac{1}{T}\right)^2+\frac{6}{5}\sum_{ij}\tilde{\omega}_{ij}\left[\frac{\mathbf{S}}{T}:\frac{\mathbf{S}}{T}\right]+\sum_{ij}\tilde{\omega}_{ij}\left(-\frac{\nabla\cdot\boldsymbol{v}_0}{T}\right)^2, \tag{6.30}$$

which can never be negative in accordance with the second law of thermodynamics. The first term is the contribution from the transport due to molecular flows, and the remainings are those from the collisional transfer which become significant in dense gases.

§ 7. Thermodynamic Description of Linear Transport Processes

As in the usual formulation of thermodynamics of irreversible processes, we shall calculate the local entropy production with use of the Gibbs relation:

$$T\,d\hat{S}=d\hat{U}+p^0d\left(\frac{1}{\rho}\right)-\sum_i \mu_i\,d\left(\frac{n_i}{\rho}\right), \tag{7.1}$$

assuming that the transport processes of fluid are completely described by the ordinary thermodynamical variables defined in local equilibrium state. According to (7.1) the change in entropy is given by

$$\rho\frac{D\hat{S}}{Dt}=\frac{1}{T}\left[\frac{1}{\rho}\frac{D\hat{U}}{Dt}-\frac{p^0}{\rho}\frac{D\rho}{Dt}-\sum_i\mu_i\left(\frac{Dn_i}{Dt}-\frac{n_i}{\rho}\frac{D\rho}{Dt}\right)\right]. \tag{7.2}$$

Using the equations of continuity, and the equation of energy balance respectively given by (3.11), (3.12) and (3.17), we obtain the following equation of entropy balance:

$$\rho\frac{D\hat{S}}{Dt}+\nabla\cdot\boldsymbol{\sigma}^{(\text{ii})}[s]=\boldsymbol{\tau}^{(\text{ii})}[s]\,, \tag{7.3}$$

$$\boldsymbol{\sigma}^{(\text{ii})}[s]\equiv\frac{\boldsymbol{q}}{T}-\sum_i\frac{\mu_i}{T}\cdot\frac{\boldsymbol{J}_i}{m_i}=\frac{\boldsymbol{E}}{T}+\sum_i\frac{\bar{H}_i-\mu_i}{T}\cdot\frac{\boldsymbol{J}_i}{m_i}\,, \tag{7.4}$$

$$\begin{aligned}\boldsymbol{\tau}^{(\text{ii})}[s]&\equiv\boldsymbol{q}\cdot\nabla\frac{1}{T}+(\mathbf{P}-p^0\mathbf{U}):\left(-\frac{\nabla\boldsymbol{v}_0}{T}\right)+\sum_i\frac{\boldsymbol{J}_i}{m_i}\cdot\left(\frac{\boldsymbol{F}_i}{T}-\nabla\frac{\mu_i}{T}\right)\\&=\boldsymbol{E}\cdot\nabla\frac{1}{T}+(\mathbf{P}-p^0\mathbf{U}):\left(\frac{\nabla\boldsymbol{v}_0}{T}\right)+\sum_i\boldsymbol{J}_i\cdot\boldsymbol{\Lambda}_i\,,\end{aligned} \tag{7.5}$$

where $\bar{H}_i$ denotes the partial molar enthalpy and $\boldsymbol{\Lambda}_i$ is the affinity for diffusion processes defined by

$$\boldsymbol{\Lambda}_i\equiv\frac{1}{T}\left[\frac{\boldsymbol{F}_i}{m_i}-\frac{T}{m_i}\nabla\frac{\mu_i}{T}+\frac{T\bar{H}_i}{m_i}\nabla\frac{1}{T}\right]. \tag{7.6}$$

Since $\boldsymbol{J}_i=0$ the thermodynamic expression of the entropy production rate is invariant, if $\boldsymbol{\Lambda}_i$ is replaced by

$$\boldsymbol{\Lambda}_i\equiv\boldsymbol{\Lambda}_i-\boldsymbol{C}\,, \tag{7.7}$$

$\boldsymbol{C}$ being an arbitrary constant. If the constant $\boldsymbol{C}$ is chosen such that

$$\boldsymbol{C}=\frac{1}{\rho}\sum_i\rho_i\boldsymbol{\Lambda}_i\qquad(\text{mass average of }\boldsymbol{\Lambda}_i)\,, \tag{7.8}$$

(7.7) is reduced to

$$\boldsymbol{A}_i=\frac{1}{T}\left[\frac{n_i\boldsymbol{F}_i}{\rho_i}-\frac{1}{\rho}\sum_j n_j\boldsymbol{F}_j\right]-\frac{1}{m_i}\nabla\frac{\mu_i}{T}+\frac{\bar{H}_i}{m_i}\nabla\frac{1}{T}+\frac{1}{\rho T}\nabla p^0\,, \tag{7.9}$$

where we have used the relations

$$\sum n_j\bar{v}_j=1\,, \tag{7.10}$$

$$\sum_j n_j\sum_k\left(\frac{\partial\mu_j}{\partial n_k}\right)_{T,p}\nabla n_k=0\,, \tag{7.11}$$

$\bar{v}_j$ being a partial molar volume of the ith component. It follows from the definition of $\boldsymbol{A}_i$ that

$$\sum_i \rho_i\boldsymbol{A}_i=0\,. \tag{7.12}$$

The reason why such an affinity of diffusion $\boldsymbol{A}_i$ is taken is that this choice makes the entropy production due to the diffusion processes to be independent of reference velocity of mass flows. If the diffusion velocity is referred to an arbitrary mean velocity $\boldsymbol{v}^a=\sum_i w_i\bar{\boldsymbol{v}}_i/\sum_i w_i$, where w_i is a weight function, i.e. $\boldsymbol{J}_i{}^a=\rho_i(\bar{\boldsymbol{v}}_i-\boldsymbol{v}^a)$ is employed, we can write the production of entropy with use of the normalized affinities $\boldsymbol{A}_i$:

$$\tau=\sum_i \boldsymbol{J}_i\cdot\boldsymbol{A}_i=\sum_i \rho_i\bar{\boldsymbol{v}}_i\cdot\boldsymbol{A}_i=\sum_i \boldsymbol{J}_i{}^a\cdot\boldsymbol{A}_i\,. \tag{7.13}$$

According to the law of phenomenological linear relation, we can easily obtain the connections between the various diffusion coefficients (i.e. molecular diffusion ($w_i=n_i$), barycentric diffusion ($w_i=\rho_i$) and etc.), by the use of (7.13) and similar arguments as those in mechanical equilibrium case[16] (see p. 109 in References 17)).

If we substitute the kinetic expressions of the fluxes for those in the equation of entropy balance (7.3), we can obtain another microscopic expressions of the entropy flux and the entropy production rate in terms of the distribution functions. These expressions are exact so far as the thermodynamic description is valid. In the present approximation we may employ the kinetic expressions (4.4), (4.11) and (4.18), respectively, for $\boldsymbol{J}_i$, $\mathbf{P}$ and $\boldsymbol{q}$ in (7.4) and (7.5). Then we have the entropy flow

$$\sigma^{(\mathrm{ii})}[s]=\frac{\boldsymbol{q}}{T}-\sum_i\frac{\mu_i}{T}\cdot\frac{\boldsymbol{J}_i}{m_i} \tag{7.14}$$

and the production of entropy

$$\begin{aligned}\tau^{(\mathrm{ii})}[s]=&\sum_{ij}\tilde{\omega}_{ij}\left(\frac{3kT}{m_i+m_j}\right)\left(\nabla\frac{1}{T}\right)^2+\sum_{ij}\tilde{\omega}_{ij}\left(\frac{\nabla\cdot\boldsymbol{v}_0}{T}\right)^2+\frac{6}{5}\sum_{ij}\tilde{\omega}_{ij}\left[\frac{\mathbf{S}}{T}:\frac{\mathbf{S}}{T}\right]\\&+\sum_i\left(1+\frac{3}{5}\sum_j M_{ij}M_{ji}b_{ij}\chi_{ij}{}^0 n_j\right)\boldsymbol{E}_{k_i}\cdot\nabla\frac{1}{T}+\sum_i\boldsymbol{J}_i\cdot\boldsymbol{A}_i\\&+\sum_i\left(1+\frac{2}{5}\sum_j M_{ji}b_{ij}\chi_{ij}{}^0 n_j\right)(\mathbf{P}_{k_i}-p_{k_i}{}^0\mathbf{U}):\left(-\frac{\nabla\boldsymbol{v}_0}{T}\right),\end{aligned} \tag{7.15}$$

where $\mathbf{P}_{k_i}-\boldsymbol{p}_{k_i}\mathbf{U}$, $\boldsymbol{E}_{k_i}$ and $\boldsymbol{A}_i$ are respectively given by (4.6), (4.18–2) and (7.9). Here the chemical potential μ_i only is an unknown quantity. The second law of thermodynamics states that the entropy production rate $\tau^{(\mathrm{ii})}[s]$ never be negative.

If the statistical entropy production $\tau^{(\mathrm{i})}[s]$ given by (6.30) is equated to the thermodynamic entropy production rate $\tau^{(\mathrm{ii})}[s]$ (7.15) obtained from the Gibbs relation, we have the following relation:

$$\begin{aligned}&\sum_i\left(1+\frac{3}{5}\sum_j M_{ij}M_{ji}b_{ij}\chi_{ij}{}^0 n_j\right)\boldsymbol{E}_{k_i}\cdot\nabla\frac{1}{T}+\sum_j \boldsymbol{J}_j\cdot\boldsymbol{A}_j\\&\quad+\sum_i\left(1+\frac{2}{5}\sum_j M_{ji}b_{ij}\chi_{ij}{}^0 n_j\right)(\mathbf{P}_{k_i}-p_{k_i}{}^0\mathbf{U}):\left(-\frac{\nabla\boldsymbol{v}_0}{T}\right)\\&\quad=k\{\phi,\phi\}\geq 0\,.\end{aligned}\tag{7.16}$$

The value of μ_i involved in the affinity $\boldsymbol{A}_i$ is determined by another condition that the entropy flow (7.14) must be equal to that given by (6.23). Thus the chemical potential is given by

$$\begin{aligned}\mu_i&=\mu_i{}^{id}+\mu_i{}^{\mathrm{corr}}\\&=kT\left\{\ln n_i-\frac{3}{2}\ln T+\frac{3}{2}\ln\left(\frac{m_i}{2\pi k}\right)\right\}\\&\quad+kT\left\{\frac{2}{1}\sum_j n_j B_{ij}+\frac{3}{2}\sum_{ij} n_j n_k C_{ijk}+\frac{4}{3}\sum_{jkl} n_j n_k n_l D_{ijkl}+\cdots\right\},\end{aligned}\tag{7.17}$$

and the affinity $\boldsymbol{A}_i$ is also determined.

§ 8. The Variation Principle and Enskog's First Approximation Solution of the Boltzmann Equation Modified for Dense Gases

From (7.16) is seen that the variation principle as shown in the author's previous paper[11] still valid. We shall now reformulate the problem, and establish again the variation principle such that physically reasonable approximation solution f_i of the modified Boltzmann equation for the linear transport processes is given as that to makes the entropy production rate a maximum under the condition compatible with the thermodynamical Gibbs relation.

Let us try to obtain an approximate perturbation function ϕ_i of a singlet distribution function f_i in non-equilibrium state on the basis of the variation principle mentioned above. In the present case this principle is

$$\tau^{(\mathrm{ii})}[s]=\text{Extremum}\tag{8.1}$$

with the restriction

$$\tau^{(\mathrm{ii})}[s]=\tau^{(\mathrm{i})}[s]\,,\tag{8.2}$$

where the variation may be taken with respect to the perturbation function ϕ_i.

With use of the Lagrangian undetermined multiplier λ, we have

$$\delta[(1+\lambda)\tau^{(\mathrm{ii})}[s]-\lambda\tau^{(\mathrm{i})}[s]]=0\,.\tag{8.3}$$

By the same argument as that in derivation of (6.26), the variation of bracket expression is reduced to

$$\begin{aligned}\delta\{\phi,\phi\}&=\frac{1}{4}\sum_{ij}\chi_{ij}{}^0\iiint 2(\phi_i'+\phi_j'-\phi_i-\phi_j)(\delta\phi_i'+\delta\phi_j'-\delta\phi_i-\delta\phi_j)f_i{}^0 f_j{}^0(\boldsymbol{g}\cdot\boldsymbol{k})\\&\quad\times\sigma_{ij}{}^2\,dk\,dv_i\,dv_j=-\sum_i\int\left[2\sum_j\chi_{ij}{}^0\sigma_{ij}{}^2\iint(\phi_i'+\phi_j'-\phi_i-\phi_j)f_i{}^0 f_j{}^0(\boldsymbol{g}\cdot\boldsymbol{k})\,dk\,dv_j\right]\delta\phi_i\,dv_i\,.\end{aligned}\tag{8.4}$$

Then substitution of (6.30) and (7.15) into (8.3) leads to

$$(1+\lambda)\sum_i\int\Xi_i\,\delta\phi_i\,dv_i-\lambda k\delta\{\phi,\phi\}=0\tag{8.5}$$

where

$$\Xi_i \equiv f_i^0\left[\left(1+\frac{3}{5}\sum_j M_{ij}M_{ji}b_{ij}\chi_{ij}^0 n_j\right)\left(\frac{m_i V_i^2}{2}-\frac{5}{2}kT\right)\boldsymbol{V}_i\cdot\nabla\frac{1}{T}+m_i\boldsymbol{V}_i\cdot\boldsymbol{A}_i\right.$$
$$\left.+\left(1+\frac{2}{5}\sum_j M_{ji}b_{ij}\chi_{ij}^0 n_j\right)m_i\left(\boldsymbol{V}_i\boldsymbol{V}_i-\frac{1}{3}V_i^2\mathbf{U}\right):\left(-\frac{\nabla\boldsymbol{v}_0}{T}\right)\right]. \tag{8.6}$$

Then we find

$$(1+\lambda)\Xi_i=-2\lambda k\sum_j \chi_{ij}^0\sigma_{ij}^2\iint f_i^0 f_j^0(\phi_i'+\phi_j'-\phi_i-\phi_j)(\boldsymbol{g}\cdot\boldsymbol{k})\,d\boldsymbol{k}\,d\boldsymbol{v}_j\,. \tag{8.7}$$

In order that this relation is compatible with the condition (8.2), λ must be equal to 1. Thus we obtain from (8.1)

$$\Xi_i=-k\sum_j \chi_{ij}^0\iint f_i^0 f_j^0(\phi_i^{*\prime}+\phi_j^{*\prime}-\phi_i^*-\phi_j^*)\sigma_{ij}^2(\boldsymbol{g}\cdot\boldsymbol{k})\,d\boldsymbol{k}\,d\boldsymbol{v}_j\,, \tag{8.8}$$

where the symbol ϕ_i^* is used to be distinguished from an arbitrary perturbation function ϕ_i. Thus the most probable approximation to the perturbation function ϕ_i is obtained by the solution of (8.8).

Further we can rewrite the variational problem (8.1) and (8.2) as

$$\Gamma(\phi)=2\tau^{(\mathrm{ii})}[s]-\tau^{(\mathrm{i})}[s]=\text{Extremum}\,. \tag{8.9}$$

This form resembles that of Onsager's variation principle[15]. The extremum of (8.9) is shown to be the maximum in the following way. The variational function $\Gamma(\phi)$ is written explicitly as a function of ϕ_i;

$$\Gamma(\phi)=\sum_{ij}\tilde{\omega}_{ij}\left(\frac{3kT}{m_i+m_j}\right)\left(\nabla\frac{1}{T}\right)^2+\sum_{ij}\tilde{\omega}_{ij}\left(-\frac{\nabla\cdot\boldsymbol{v}_0}{T}\right)^2+\frac{6}{5}\sum_{ij}\tilde{\omega}_{ij}\left[\frac{\mathbf{S}}{T}:\frac{\mathbf{S}}{T}\right]$$
$$+2\sum_i\int\Xi_i\phi_i\,d\boldsymbol{v}_i-k\{\phi,\phi\}\,. \tag{8.10}$$

On the other hand, multiplying (8.8) by ϕ_i, integrating $\boldsymbol{v}_i$ and summing over i, we obtain

$$\sum_i\int\Xi_i\phi_i\,d\boldsymbol{v}_i=k\{\phi,\phi^*\}\,,$$

where it must be borne in mind that ϕ_i^* is the solution of variational problem. Then from (6.27) and (6.28) we can obtain the relation

$$\Gamma(\phi^*)-\Gamma(\phi)=k\{\phi^*,\phi^*\}-2k\{\phi,\phi^*\}+k\{\phi,\phi\}=\{\phi^*-\phi,\phi^*-\phi\}\geqq 0\,. \tag{8.11}$$

Hence the extremum of $\Gamma(\phi)$ is the maximum when $\phi_i=\phi_i^*$.

If the expressions (7.17), (4.18–3) and (4.12) are used, we easily obtain the relation between $\boldsymbol{A}_i$ given by (7.9) and $\boldsymbol{d}_i$ given by (5.8)

$$\boldsymbol{d}_i=-\frac{\rho_i}{nk}\boldsymbol{A}_i\,. \tag{8.12}$$

Thus we can rewrite (5.7) as

$$\Xi_i+f_i^0\sum_j\left(M_{ji}b_{ij}\chi_{ij}^0 n_j-\frac{n_j}{n}\sum_k b_{jk}\chi_{jk}^0 n_k\right)kT\left(1-\frac{m_i V_i^2}{3kT}\right)\frac{\nabla\cdot\boldsymbol{v}_0}{T}$$
$$=-k\sum_j\chi_{ij}^0\iint f_i^0 f_j^0(\phi_i'+\phi_j'-\phi_i-\phi_j)\sigma_{ij}^2(\boldsymbol{g}\cdot\boldsymbol{k})\,d\boldsymbol{k}\,d\boldsymbol{v}_j\,, \tag{8.13}$$

which differs by only the second term on the left-hand side from the solution (8.8) of the present variational problem. The extra term appears only in the case of multicomponent dense gas, being small quantity in general. As is easily seen it vanishes both in the case of single-component dense gas and in the case of a dilute gas. As mentioned in previous paragraph the contribution to the entropy production from the transport due to molecular flows is given by $k\{\phi, \phi\}$, then the extra term gives no effect in ϕ_i other than that irrelevant to the dissipation of energy, owing to the relation

$$\int f_i^0 \left[\sum_j \left(M_{ji} b_{ij} \chi_{ij}^0 n_j - \frac{n_j}{n} \sum_k b_{jk} \chi_{jk}^0 n_k \right) kT \left(1 - \frac{m_i V_i^2}{3kT} \right) \frac{\nabla \cdot \boldsymbol{v}_0}{T} \right] \phi_i \, dv_i = 0 \, .$$

Consequently, it seems that the extension of Enskog's first approximation equation to multicomponent system make the entropy production rate a maximum under the constraints that the thermodynamical Gibbs relation is satisfied.

Acknowledgement

The author wishes to express his great gratitude to Professor N. Watanabe for his encouragement. The author is also greatly indebted to Professor S. Ono of University of Tokyo for his invaluable discussions and constant encouragement, and to Professor T. Yamamoto of the Kyoto University for his helpful discussions. This work has been supported in part by a Grant in Aid for Fundamental Scientific Research from the Ministry of Education.

Appendix I

Let us consider the collisional transfer of a molecular property ψ across an element of surface dS at the point $\boldsymbol{r}$. Let the normal to dS, drawn from its negative side to its positive, have a direction specified by unit vector $\boldsymbol{n}$. If a collision is to produce a transfer of ψ across dS, the centers of the colliding molecules must lie on opposite sides of dS, that is, the first molecule i lies on the positive side of dS and the second j on the negative, then the product $(\boldsymbol{k} \cdot \boldsymbol{n})$ is positive. Therefore, the center of molecule i must lie within a cylinder on dS as base with generators parallel to $\boldsymbol{k}$ of length σ_{ij}. The volume of this cylinder is $\sigma_{ij}(\boldsymbol{k} \cdot \boldsymbol{n})\, dS$. The mean position of the two molecules at the instant of the collisions are $\left(\boldsymbol{r} + \frac{1}{2}\sigma_{ij}\boldsymbol{k}\right)$ and $\left(\boldsymbol{r} - \frac{1}{2}\sigma_{ij}\boldsymbol{k}\right)$ and the mean position of the center of two colliding molecules is $\boldsymbol{r}$, at which the correlation function χ_{ij}^0 must be evaluated.

Hence the probable number of collisions in unit time, in which the velocities lie in ranges $d\boldsymbol{v}_i$ and $d\boldsymbol{v}_j$ about $\boldsymbol{v}_i$ and $\boldsymbol{v}_j$ and the collision parameters lie within range $d\boldsymbol{k}$, is

$$\chi_{ij}^0(\boldsymbol{r}) f_i\left(\boldsymbol{r} + \frac{\sigma_{ij}}{2}\boldsymbol{k}\right) f_j\left(\boldsymbol{r} - \frac{\sigma_{ij}}{2}\boldsymbol{k}\right) \sigma_{ij}^2 (\boldsymbol{g} \cdot \boldsymbol{k}) \, d\boldsymbol{k} \, d\boldsymbol{v}_i \, d\boldsymbol{v}_j \, \sigma_{ij} (\boldsymbol{k} \cdot \boldsymbol{n}) \, dS \, . \tag{A-I.1}$$

Since a quantity $(\psi_i' - \psi_i)$ of a property ψ_i is transferred across the surface on each collision of this sort, the total rate of transfer of the property by collisions per unit time and per unit area is

$$\begin{aligned} \{n \cdot \mathbf{J}_c(\psi)\} = n \cdot \frac{1}{2} \sum_{ij} \sigma_{ij}^3 \chi_{ij}(\boldsymbol{r}) \iiint (\psi_i' - \psi_i) \\ \times f_i\left(\boldsymbol{r} + \frac{1}{2}\sigma_{ij}\boldsymbol{k}\right) f_j\left(\boldsymbol{r} - \frac{1}{2}\sigma_{ij}\boldsymbol{k}\right) \boldsymbol{k}(\boldsymbol{g} \cdot \boldsymbol{k}) \, d\boldsymbol{k} \, d\boldsymbol{v}_i \, d\boldsymbol{v}_j \, . \end{aligned} \tag{A-I.2}$$

We thus carried out the integration, obtaining the contribution of the collisional transfer to the flux vector of property ψ_i is

$$\mathbf{J}_c(\psi) = \frac{1}{2} \sum_{ij} \sigma_{ij} \chi_{ij}^0(\boldsymbol{r}) \iiint (\psi_i' - \psi_i) f_i\left(\boldsymbol{r} + \frac{\sigma_{ij}}{2}\boldsymbol{k}\right) f_j\left(\boldsymbol{r} - \frac{\sigma_{ij}}{2}\boldsymbol{k}\right) \boldsymbol{k}(\boldsymbol{g} \cdot \boldsymbol{k}) \, d\boldsymbol{k} \, d\boldsymbol{v}_i \, d\boldsymbol{v}_j \, . \tag{A-I.3}$$

As in the derivation of (2.6), f_i, f_j and χ_{ij}^0 may be expanded in Taylor's series, and derivatives of higher order than the first are neglected. Then we have

$$\begin{aligned}\mathbf{J}_c(\psi)&=\frac{1}{2}\sum_{ij}\sigma_{ij}{}^3\chi_{ij}{}^0\iiint(\psi_i'-\psi_i)\,f_if_j\,\boldsymbol{k}(\boldsymbol{g}\cdot\boldsymbol{k})\,d\boldsymbol{k}\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j\\&\quad+\frac{1}{4}\sum_{ij}\sigma_{ij}{}^4\chi_{ij}{}^0\iiint(\psi_i'-\psi_i)\{(\boldsymbol{k}\cdot\nabla f_i)f_j-(\boldsymbol{k}\cdot\nabla f_j)f_i\}\boldsymbol{k}(\boldsymbol{g}\cdot\boldsymbol{k})\,d\boldsymbol{k}\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j\\&=\mathbf{J}_c{}^{(1)}(\psi)+\mathbf{J}_c{}^{(2)}(\psi)\;. \end{aligned}\tag{A–I.4}$$

We can see from the above equation that $\mathbf{J}_c$'s given by (3.7) are identical with the flux $\mathbf{J}_c$'s arising from the collisional transfer of molecular property.

Appendix II

A. *The derivation of (3.15)*: If we put $m_i\boldsymbol{V}_i$ in (3.7–1), we have

$$\begin{aligned}\mathbf{J}_c{}^{(1)}[m_i\boldsymbol{V}_i]&=\frac{1}{2}\sum_{ij}\sigma_{ij}{}^3\chi_{ij}{}^0\iiint m_i(\boldsymbol{V}_i'-\boldsymbol{V}_i)\,f_if_j\,\boldsymbol{k}(\boldsymbol{g}\cdot\boldsymbol{k})\,d\boldsymbol{k}\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j\\&=\frac{1}{2}\sum_{ij}\sigma_{ij}{}^3\chi_{ij}{}^0m_iM_{ij}\iiint f_if_j\,\boldsymbol{kk}(\boldsymbol{g}\cdot\boldsymbol{k})^2\,d\boldsymbol{k}\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j\\&=\frac{\pi}{15}\sum_{ij}\sigma_{ij}{}^3\chi_{ij}{}^0m_iM_{ij}\iint(2\boldsymbol{gg}+g^2\mathbf{U})\,f_if_j\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j\;,\end{aligned}\tag{A–II.1}$$

where we have used the relation (e.g. see p. 290 in references 13))

$$\int\boldsymbol{kk}(\boldsymbol{g}\cdot\boldsymbol{k})^2\,d\boldsymbol{k}=\frac{2\pi}{15}(2\boldsymbol{gg}+g^2\mathbf{U})\;.\tag{A–II.2}$$

Putting $m_i\boldsymbol{V}_i$ in (3.7–2), we obtain

$$\begin{aligned}\mathbf{J}_c{}^{(2)}[m_i\boldsymbol{V}_i]&=\frac{1}{4}\sum_{ij}\sigma_{ij}{}^4\chi_{ij}{}^0m_iM_{ij}\iiint f_if_j\left(\boldsymbol{k}\cdot\nabla\ln\frac{f_i}{f_j}\right)\boldsymbol{kk}(\boldsymbol{g}\cdot\boldsymbol{k})^2\,d\boldsymbol{k}\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j\\&=\frac{\pi}{48}\sum_{ij}\sigma_{ij}{}^4\chi_{ij}{}^0m_iM_{ij}\iint f_if_j\left[\frac{\boldsymbol{gg}+g^2\mathbf{U}}{g}\left(\boldsymbol{g}\cdot\nabla\ln\frac{f_i}{f_j}\right)\right.\\&\qquad\left.+g\left\{\left(\nabla\ln\frac{f_i}{f_j}\right)\boldsymbol{g}+\boldsymbol{g}\left(\nabla\ln\frac{f_i}{f_j}\right)\right\}\right]d\boldsymbol{v}_i\,d\boldsymbol{v}_j\;,\end{aligned}\tag{A–II.3}$$

using a relation for arbitrary vector $\boldsymbol{\nu}$

$$\int\boldsymbol{kk}(\boldsymbol{\nu}\cdot\boldsymbol{k})(\boldsymbol{g}\cdot\boldsymbol{k})^2\,d\boldsymbol{k}=\frac{\pi}{12}\left\{\frac{\boldsymbol{\nu}\cdot\boldsymbol{g}(\boldsymbol{gg}+g^2\mathbf{U})}{g}+g(\boldsymbol{\nu g}+\boldsymbol{g\nu})\right\}\;.\tag{A–II.4}$$

B. *The derivation of (3.20) and (3.21)*: Putting $\psi_i=\frac{1}{2}m_iV_i{}^2$ in (3.8–1), we can see

$$\begin{aligned}R_c{}^{(1)}\left(\frac{m_iV_i{}^2}{2}\right)&=\frac{1}{2}\sum_{ij}^{\nu}\sigma_{ij}{}^4\chi_{ij}{}^0\iiint f_if_j\left\{\boldsymbol{k}\cdot\nabla\left(\frac{m_i{}^2V_i{}^2}{2}-\frac{m_iV_i{}^2}{2}\right)\right\}(\boldsymbol{g}\cdot\boldsymbol{k})\,d\boldsymbol{k}\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j\\&=-\frac{1}{2}\sum_{ij}^{\nu}\sigma_{ij}{}^4\chi_{ij}{}^0\iiint f_if_j[\boldsymbol{k}m_i(\boldsymbol{V}_i'-\boldsymbol{V}_i):\nabla\boldsymbol{v}_0](\boldsymbol{g}\cdot\boldsymbol{k})\,d\boldsymbol{k}\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j\\&=-\nabla\boldsymbol{v}_0:\mathbf{J}_c{}^{(1)}[m_i\boldsymbol{V}_i]\;.\end{aligned}\tag{A–II.5}$$

In a similar way, we obtain from (3.8–2)

$$R_c{}^{(2)}\left(\frac{m_iV_i{}^2}{2}\right)=-\nabla\boldsymbol{v}_0:\mathbf{J}_c{}^{(2)}[m_i\boldsymbol{V}_i]\;.\tag{A–II.6}$$

If we put $\psi_i=m_iV_i{}^2/2$ in (3.7–1), we have

$$\mathbf{J}_c^{(1)}\left[\frac{m_iV_i^2}{2}\right]=\frac{1}{2}\sum_{ij}\sigma_{ij}^3\chi_{ij}^0\iiint m_iM_{ij}f_if_j(\boldsymbol{G}\cdot\boldsymbol{k})\boldsymbol{k}(\boldsymbol{g}\cdot\boldsymbol{k})^2\,d\boldsymbol{k}\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j$$

$$=\frac{\pi}{15}\sum_{ij}\sigma_{ij}^3\chi_{ij}^0M_{ij}m_j\iint\{2\boldsymbol{g}(\boldsymbol{g}\cdot\boldsymbol{G})+g^2\boldsymbol{G}\}f_if_j\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j\,, \tag{A–II.7}$$

where the following relation has been used

$$\int(\boldsymbol{G}\cdot\boldsymbol{k})\boldsymbol{k}(\boldsymbol{g}\cdot\boldsymbol{k})^2\,d\boldsymbol{k}=\frac{2\pi}{15}\{2\boldsymbol{g}(\boldsymbol{g}\cdot\boldsymbol{G})+g^2\boldsymbol{G}\}\;. \tag{A–II.8}$$

From (3.7–2) we can deduce

$$\mathbf{J}_c^{(2)}\left[\frac{m_iV_i^2}{2}\right]=\frac{1}{4}\sum_{ij}\sigma_{ij}^4\chi_{ij}^0M_{ij}m_i\iint f_if_j(\boldsymbol{G}\cdot\boldsymbol{k})\left(\boldsymbol{k}\cdot\nabla\ln\frac{f_i}{f_j}\right)\boldsymbol{k}(\boldsymbol{g}\cdot\boldsymbol{k})^2\,d\boldsymbol{k}\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j$$

$$=\frac{\pi}{48}\sum_{ij}\sigma_{ij}^4\chi_{ij}^0M_{ij}m_i\iint\left[\frac{\boldsymbol{g}}{g}\left(\boldsymbol{G}\nabla\ln\frac{f_i}{f_j}:\boldsymbol{gg}\right)+g\left\{\left(\boldsymbol{G}\cdot\nabla\ln\frac{f_i}{f_j}\right)\boldsymbol{g}\right.\right.$$

$$\left.\left.+\left(\boldsymbol{g}\cdot\nabla\ln\frac{f_i}{f_j}\right)\boldsymbol{G}+(\boldsymbol{g}\cdot\boldsymbol{G})\nabla\ln\frac{f_i}{f_j}\right\}\right]f_if_i\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j\,, \tag{A–II.9}$$

using the relation

$$\int(\boldsymbol{a}\cdot\boldsymbol{k})(\boldsymbol{b}\cdot\boldsymbol{k})\boldsymbol{k}(\boldsymbol{g}\cdot\boldsymbol{k})^2\,d\boldsymbol{k}=\frac{\pi}{12}\left[\frac{\boldsymbol{g}}{g}(\boldsymbol{ab}:\boldsymbol{gg})+\{(\boldsymbol{a}\cdot\boldsymbol{b})\boldsymbol{g}+(\boldsymbol{b}\cdot\boldsymbol{g})\boldsymbol{a}+(\boldsymbol{g}\cdot\boldsymbol{a})\boldsymbol{b}\}g\right]. \tag{A–II.10}$$

Appendix III

A. *The derivation of (4.7)*: If we use the singlet distribution function given by (4.2), retaining only the first order perturbation, (3.15–1) is reduced to

$$\mathbf{J}_c^{(1)}[m_i\boldsymbol{V}_i]=\frac{\pi}{15}\sum_{ij}\sigma_{ij}^3\chi_{ij}^0M_{ij}m_i\iint(2\boldsymbol{gg}+g^2\mathbf{U})f_i^0f_j^0(1+\phi_i+\phi_j)\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j$$

$$=\frac{\pi}{15}\sum_{ij}\sigma_{ij}^3\chi_{ij}^0M_{ij}m_i\left[\frac{10n_in_jkT}{m_iM_{ij}}\right]\mathbf{U}+\frac{4\pi}{15}\sum_{ij}\sigma_{ij}^3\chi_{ij}^0M_{ij}m_in_j\int\boldsymbol{V}_i\boldsymbol{V}_if_i^0\phi_i\,d\boldsymbol{v}_i$$

$$=\frac{2\pi}{3}\sum_{ij}\sigma_{ij}^3\chi_{ij}^0n_in_jkT\,\mathbf{U}+\frac{4\pi}{15}\sum_{ij}\sigma_{ij}^3\chi_{ij}^0M_{ij}m_in_j\int\boldsymbol{V}_i\boldsymbol{V}_jf_i^0\phi_i\,d\boldsymbol{v}_i\,, \tag{A–III.1}$$

where we have used the relations

$$\iint(2\boldsymbol{gg}+g^2\mathbf{U})f_i^0f_j^0\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j=\frac{10}{m_iM_{ij}}n_in_jkT\,\mathbf{U}\,, \tag{A–III.2}$$

and

$$\iint(2\boldsymbol{gg}+g^2\mathbf{U})f_i^0f_j^0\phi_i\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j=2n_j\int\boldsymbol{V}_i\boldsymbol{V}_jf_i^0\phi_i\,d\boldsymbol{v}_i\,. \tag{A–III.3}$$

Regarding as $b_{ij}=(2/3)\pi\sigma_{ij}^3$, we obtain (4.7–1).

Putting $f_i=f_i^0(1+\phi_i)$ in (3.17–2), and retaining the same order with (A–III.1), we can write $\mathbf{J}_c^{(2)}(m_i\boldsymbol{V}_i)$ as

$$\mathbf{J}_c^{(2)}[m_i\boldsymbol{V}_i]=\frac{\pi}{48}\sum_{ij}\sigma_{ij}^4\chi_{ij}^0m_iM_{ij}[A+B+C]\,,$$

$$A\equiv\iint\left[(\boldsymbol{gg}+g^2\mathbf{U})\left(\frac{\boldsymbol{g}}{g}\cdot\nabla\ln\frac{n_i}{n_j}\right)+g\left\{\left(\nabla\ln\frac{n_i}{n_j}\right)\boldsymbol{g}+\boldsymbol{g}\left(\nabla\ln\frac{n_i}{n_j}\right)\right\}\right]f_i^0f_j^0\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j$$

$$B\equiv\frac{1}{kT}\iint\left[(\boldsymbol{gg}+g^2\mathbf{U})\left\{\frac{\boldsymbol{g}}{g}\cdot(m_i\boldsymbol{V}_i+m_j\boldsymbol{V}_j)\cdot\nabla\boldsymbol{v}_0\right\}+g\{(m_i\boldsymbol{V}_i-m_j\boldsymbol{V}_j)\cdot\nabla\boldsymbol{v}_0\boldsymbol{g}\right.$$

$$\left.+\boldsymbol{g}(m_i\boldsymbol{V}_i-m_j\boldsymbol{V}_j)\cdot\nabla\boldsymbol{v}_0\}\right]f_i^0f_j^0\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j$$

$$C \equiv \frac{1}{2kT}\iint\Big[(\boldsymbol{g}\boldsymbol{g}+g^2\mathbf{U})\Big\{\frac{\boldsymbol{g}}{g}(m_iV_i^2-m_jV_j^2)\cdot\nabla\ln T+g(m_iV_i^2-m_jV_j^2)$$

$$\times\{(\nabla\ln T)\boldsymbol{g}+\boldsymbol{g}(\nabla\ln T)\}\Big\}\Big]f_i^0f_j^0\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j \tag{A–III.4}$$

where the all terms involving ϕ_i are neglected, since (3.17–2) involve the derivatives of the macro-variables. Changing the variables from $\boldsymbol{v}_i$, $\boldsymbol{v}_j$ to the $\boldsymbol{g}_{ji}$, $\boldsymbol{G}_{ji}$, we obtain

$$A=0\,,$$

$$B=-\frac{m_iM_{ji}}{kT}\iint\Big[\frac{1}{g}(\boldsymbol{g}\boldsymbol{g}+g^2\mathbf{U})\boldsymbol{g}\boldsymbol{g}:\nabla\boldsymbol{v}_0+g\{(\boldsymbol{g}\cdot\nabla\boldsymbol{v}_0)\boldsymbol{g}+\boldsymbol{g}(\boldsymbol{g}\cdot\nabla\boldsymbol{v}_0)\}f_i^0f_j^0\,d\boldsymbol{G}\,d\boldsymbol{g}$$

$$=-\frac{32}{3}(2kT)^{1/2}\left(\frac{m_iM_{ji}}{2}\right)^{-1/2}n_in_j\left[\frac{6}{5}\mathbf{S}+\mathbf{U}(\nabla\cdot\boldsymbol{v}_0)\right],$$

and

$$C=0\,.$$

Consequently we have

$$\mathbf{J}_c^{(2)}[m_i\boldsymbol{V}_i]=-\sum_{ij}\tilde{\omega}_{ij}\left[\frac{6}{5}\frac{\mathbf{S}}{T}+\mathbf{U}\frac{\nabla\boldsymbol{v}_0}{T}\right], \tag{A–III.5}$$

where $\tilde{\omega}_{ij}$ is given by (4.10).

B. *The derivation of (4.17)*: In the same manner as in the case of (4.7), we can evaluate the collisional transfer of energy.

Putting $f_i=f_i^0(1+\phi_i)$ in (3.23–1), we have

$$\mathbf{J}_c^{(1)}\left[\frac{m_iV_i^2}{2}\right]=\frac{\pi}{15}\sum_{ij}\sigma_{ij}^4\chi_{ij}^0M_{ji}m_i\iint\{2\boldsymbol{g}(\boldsymbol{g}\cdot\boldsymbol{G})+g^2\boldsymbol{G}\}f_i^0f_j^0(1+\phi_i+\phi_j)\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j$$

$$=\frac{1}{2}\sum_{ij}\sigma_{ij}^3\chi_{ij}^0M_{ji}m_i\iiint f_i^0f_j^0(\phi_i+\phi_j)\{(M_{ij}\boldsymbol{V}_i+M_{ji}\boldsymbol{V}_j)\cdot\boldsymbol{k}\}\boldsymbol{k}(\boldsymbol{g}\cdot\boldsymbol{k})^2\,d\boldsymbol{k}\,d\boldsymbol{v}_i\,d\boldsymbol{v}_j$$

$$=\frac{3}{5}\sum_{ij}b_{ij}\chi_{ij}^0M_{ij}M_{ji}n_j\boldsymbol{q}_{k_i}+\frac{1}{2}\sum_{ij}b_{ij}\chi_{ij}^0M_{ij}M_{ji}\frac{m_i-2m_j}{m_im_j}n_jkT\boldsymbol{J}_i\,, \tag{A–III.6}$$

and from (3.23–2) we have

$$\mathbf{J}_c^{(2)}\left[\frac{m_iV_i^2}{2}\right]=\frac{\pi}{48}\sum_{ij}\sigma_{ij}^4\chi_{ij}^0M_{ji}m_i\iint\Big[\frac{\boldsymbol{g}}{g}\left(\boldsymbol{G}\nabla\ln\frac{f_i^0}{f_j^0}:\boldsymbol{g}\boldsymbol{g}\right)$$

$$+g\left\{\left(\boldsymbol{G}\cdot\nabla\ln\frac{f_i^0}{f_j^0}\right)\boldsymbol{g}+\left(\nabla\ln\frac{f_i^0}{f_j^0}\cdot\boldsymbol{g}\right)\boldsymbol{G}+(\boldsymbol{g}\cdot\boldsymbol{G})\nabla\ln\frac{f_i^0}{f_j^0}\right\}\Big]f_i^0f_j^0\,d\boldsymbol{g}\,d\boldsymbol{G}$$

$$=-\frac{2}{3}\sum_{ij}\sigma_{ij}^4\chi_{ij}^0n_in_j\left(\frac{m_iM_{ji}}{2}\right)^{1/2}\frac{\pi^{1/2}}{m_i+m_j}(2kT)^{3/2}\nabla\ln T$$

$$=\sum_{ij}\tilde{\omega}_{ij}\left(\frac{3kT}{m_i+m_j}\right)\nabla\frac{1}{T}\,. \tag{A–III.7}$$

Temperature Dependence of Magnetic Susceptibilities of $KClO_3$, $KBrO_3$ and KIO_3

By Shōtarō TOBISAWA

Department of Chemistry, Defense Academy, Yokosuka

(Received May 6, 1960)

Magnetic susceptibilities of crushed samples of $KClO_3$, $KBrO_3$ and KIO_3 were measured with a recording magnetic balance which was operated by the Faraday method. The temperature was elevated at a constant rate, 250°C per hour. It was found that, being heated, $KClO_3$ showed irregular paramagnetic susceptibilities in the solid or liquid state, before the evolution of oxygen gas at 500°C. A possible explanation for the irregular paramagnetic behaviors is suggested.

On the contrary, $KBrO_3$ and KIO_3 showed the diamagnetic susceptibilities, which were independent of temperature below the temperatures of the evolution of oxygen gas, 370° and 550°C, respectively.

§1. Introduction

Recently, the paramagnetic resonance spectra of $Ba(ClO_3)_2 \cdot H_2O$, $NaClO_3$ and $Ba(BrO_3)_2 \cdot H_2O$, irradiated by 1 MeV electrons, have been observed by Cowen[1]. From the hyperfine structure of the paramagnetic resonance absorption spectra of a singe crystal of $NaClO_3$, it has been stated by Hastly et al.[2] that the V center produced by X-irradiation is a radical.

It is of particular interest to investigate the changes in physical properties of chlorate, bromate and iodate with elevating temperature. In the present paper, the temperature dependence of magnetic susceptibilities of $KClO_3$, $KBrO_3$ and KIO_3 is studied.

§2. Experimental Procedures

Potassium chlorate of commercial guaranteed reagent was recrystallized from water four times, potassium bromates of Merck (sample A) and of commercial guaranteed reagent (sample B) two and three times, respectively, and potassium iodate of Merck three times. A crushed sample was obtained by carefully squeezing each recrystallized sample in an agate mortar with a pestle.

Measurements were carried out with the recording magnetic balance described in detail in a previous report[3]. The crushed sample of about 15 mg. was charged into a fused quartz bulb made with the same dimension as the previously reported one. This bulb was sealed carefully, after being evacuated for several hours under a vacuum of 10^{-5} mmHg. The measurements were made by elevating the temperature at a constant rate, 250°C per hour, and by applying a constant field, 8650 Oersteds. In every measurement, one millimeter on a recording chart corresponded to 1.6×10^{-9} c.g.s.e.m.u. in magnetic susceptibility. In every experiment, by examining the temperature dependence of magnetic susceptibility of the residue obtained by removing oxygen gas evolved in the bulb as a result of the complete decomposition, it was ascertained that the sample used was not contaminated by paramagnetic or ferromagnetic impurities.

The decomposition temperatures of $KClO_3$, $KBrO_3$ and KIO_3 were determined by measuring losses in weight with a thermal balance without magnetic field. A sample packed in an open bulb, was thermally decomposed under the constant pressure of 50 mmHg. The rate of heating was the same as in the case of the magnetic measurement. When the magnetic balance was used as the thermal balance, one millimeter on the recording chart corresponded to 0.020 mg. In either case, the experiments were carried out under dark condition.

§ 3. Experimental Results

(1) *Paramagnetic susceptibility of $KClO_3$ in the solid or liquid state*

In Fig. 1, the curve (1) indicates that $KClO_3$ decomposes at 500°C. Although the measurements were made for the samples in different weight at constant rate of heating and for the samples in the same weight at different rate of heating, these samples decomposed at 500°C in all the measurements. The decomposition temperature of 500°C is higher than that obtained by Vitoria[4].

The magnetic susceptibility of $KClO_3$, obtained at room temperature, was -0.33×10^{-6} per g., and the value was in good agreement with that obtained by Meslin[5]. The curve (2) shows the first deflection toward paramagnetic side at 158°C, the second change at 352°C, the third change at 446°C, and the fourth change at 500°C. Both the curves (3) and (4) show the first deflections toward paramagnetic sides at 308°C, the second changes at 352°C, then show the third changes at 480° and 474°C, respectively, and the fourth changes at 500°C. In the curves (2), (3) and (4), the deflections toward paramagnetic side above 500°C increase abruptly with increasing temperature. The breaking points at 500°C corresponded to the decomposition temperature shown in the curve (1). The deflection toward paramagnetic side above 500°C can, therefore, be ascribed to paramagnetic contribution due to oxygen gas evolved by the thermal decomposition. It has been reported by Vitoria[4] that the melting point of $KClO_3$, determined by capillary-tube method, is 356°C. The changes in magnetic susceptibilities at

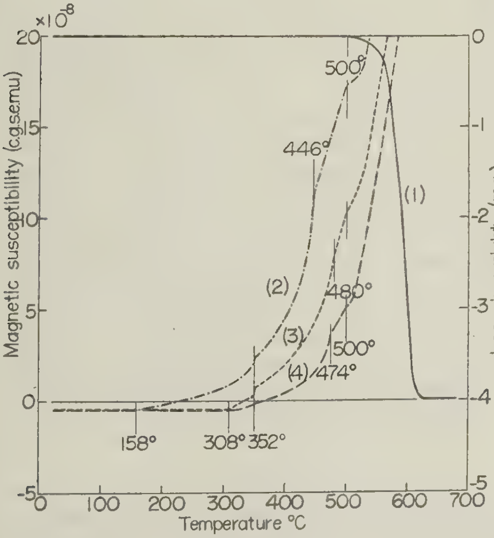

Fig. 1. Magnetic susceptibility and loss in weight versus temperature for $KClO_3$; (1): curve of loss in weight for the sample of 10.1 mg., (2), (3) and (4): curves of susceptibility for the samples of 15.1 mg.

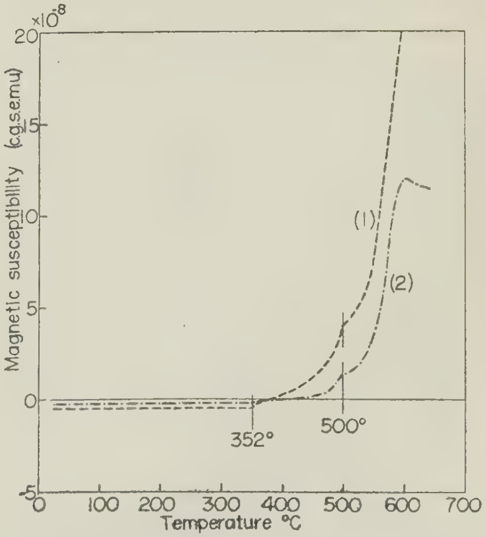

Fig. 2. Magnetic susceptibility versus temperature for $KClO_3$; (1): curve for the sample of 15.0 mg., (2): curve for the sample of 7.0 mg.

352°C in the curves (2), (3) and (4) can, therefore, be owing to the phase transition from solid to liquid. In Fig. 2, both the curves (1) and (2) show the first changes at 352°C, then deflect toward paramagnetic side with increasing temperature. The deflections toward paramagnetic side above 500°C increase abruptly with increasing temperature. In this case, the deflections toward paramagnetic side in the solid state could not be found. Besides, the changes corresponding to the third changes as shown in the curves (2), (3) and (4) in Fig. 1, could not also be recognized.

(2) *Diamagnetic susceptibilities of $KBrO_3$ and KIO_3 before the evolutions of oxygen gas*

The magnetic susceptibility of both the samples A (Merck) and B (commercial G. R.) of $KBrO_3$ was -0.32×10^{-6} per g. and that of KIO_3 was -0.31×10^{-6} per g., at room temperature. In Fig. 3, the curve (1) shows the first loss in weight at 370°C and the breaking point at 396°C. Both the curves (2) and (3) deflect toward paramagnetic side above 370°C and show the breaking points at 395°C. The deflections toward paramagnetic side above 370°C in the curves (2) and (3) can, therefore, be attributed to paramagnetic contribution due to oxygen gas evolved by the thermal decomposition. The breaking point at 395°C is considered to be owing to the phase transition from solid to liquid. This temperature, however, is lower than the melting point of 434°C, reported by Carnelley et al[6].

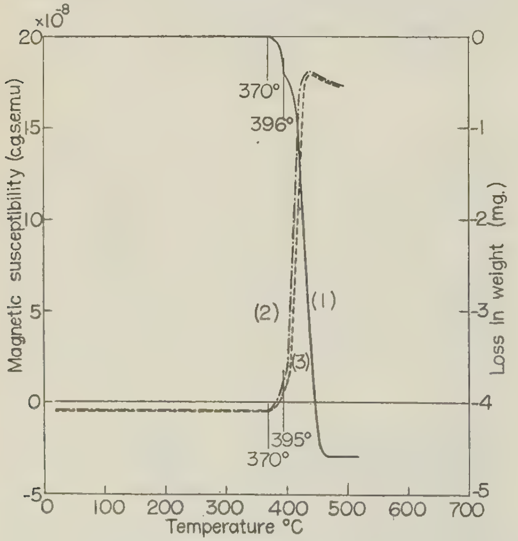

Fig. 3. Magnetic susceptibility and loss in weight versus temperature for $KBrO_3$; (1) curve of loss in weight for the sample of 15.1 mg., (2) and (3): curves of susceptibility for the samples A and B of 15.0 mg.

In Fig. 4, the curve (2) deflects toward paramagnetic side above 550°C and shows the breaking points at 560°C and other temperatures. The temperature of deflection corresponds to the decomposition temperature of 550°C found in the curve (1). The changes in magnetic susceptibility above 550°C can, therefore, be ascribed to paramagnetic contribution due to oxygen gas evolved by the thermal decomposition. The curve (1) also shows the breaking point at 560°C. It has been reported by Day et al.[7] that the melting point of KIO_3 is 560°C. From the above results, the breaking point at 560°C in both the curves (1) and (2) in Fig. 4 is owing to the phase transition from solid to liquid. As indicated in the curve (2), the magnetic behavior of KIO_3 after the evolution of oxygen gas is remarkably different from those of $KClO_3$ and $KBrO_3$.

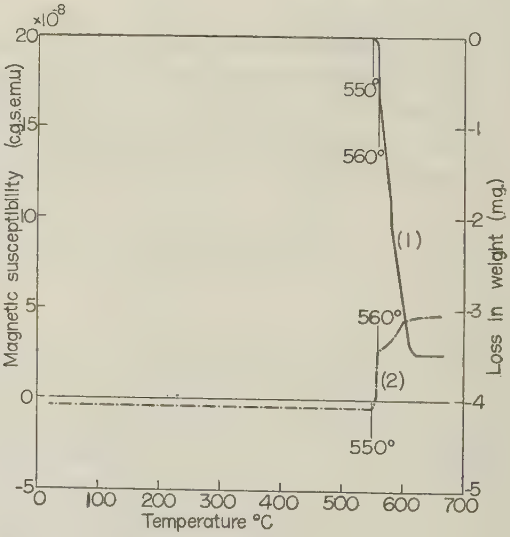

Fig. 4. Magnetic susceptibility and loss in weight versus temperature for KIO_3; (1): curve of loss in weight for the sample of 15.0 mg., (2): curve of susceptibility for the sample of 14.9 mg.

In spite of the fact that the crystal structure of $KBrO_3$ as well as $KClO_3$ contains a discrete XO_3^- ion, the magnetic behavior of $KBrO_3$ before the evolution of oxygen gas is different from those of $KClO_3$. Although KIO_3 is of perovskite structure, KIO_3 showed diamagnetic susceptibilities which were independent of temperature below the temperature of the evolution of oxygen gas similarly to the case of $KBrO_3$.

§ 4. Discussion on Paramagnetic Behavior of $KClO_3$

It has been known that, being heated, $KClO_3$ decomposes without evolution of oxygen gas according to the equation,

$$2KClO_3 \rightarrow KClO_2 + KClO_4 \qquad (1)$$

or

$$4KClO_3 \rightarrow 3KClO_4 + KCl\,. \qquad (2)$$

Osada[8] has found that the reaction (1) takes place at comparatively low temperature, and that the two reaction products release oxygen gas in accordance with the equations, $KClO_2 \rightarrow KCl + O_2$ and $KClO_4 \rightarrow KCl + 2O_2$, respectively. Most of previous investigators[9] have reported that the reaction (2) takes place simultaneously with the reaction $2KClO_3 \rightarrow 2KCl + 3O_2$, while Glasner et al.[10] have stated that the reaction (2) is not a simultaneous reaction with the reaction $2KClO_3 \rightarrow 2KCl + 3O_2$, but a consecutive reaction that $KClO_4$ in the equation (2) is formed according to the equation $KCl + 2O_2 \rightarrow KClO_4$, where KCl and O_2 result from the reaction $2KClO_3 \rightarrow 2KCl + 3O_2$. As it is apparent from these interpretations, the mechanism of decomposition of $KClO_3$ is complicated. Besides, these interpretations seem to suggest that both the reactions (1) and (2) take place indefinitely, and that each amount of the reaction products due to these reactions is not constant. Therefore, the paramagnetic behaviors over the range of temperatures below 500°C, shown in Figs. 1 and 2, lead to suggestion that $KClO_3$ may mainly convert into $KClO_2$ and $KClO_4$ through a certain transition state with unpaired electrons during the course of the reaction (1), in the solid or liquid state when $KClO_3$ is heated. Sometimes $KClO_3$ may partly convert into $KClO_4$ and KCl through an other transition state with unpaired electrons during the course of the reaction (2). This suggestion seems to be supported by appearance of the third changes in the curves of (2), (3) and (4) in Fig. 1. Although the samples of the same weight were decomposed under the same experimental condition, the results obtained showed irregular paramagnetic behaviors, as indicated in Fig. 1. The irregular paramagnetic behaviors may be attributed to the indefinite occurrences of the reactions (1) and (2).

Luminescence of Doped Silver Chloride Crystals

By Sanemi SONOIKE and Kazuo AKIMOTO

Faculty of Engineering, Chuo University, Bunkyo-ku, Tokyo

(Received July 1, 1960)

Luminescences of silver chloride crystals doped with $CdCl_2$ and $FeCl_3$ are measured spectroscopically at low temperatures. Effects of auxiliary infrared light on them and on photoconductivities are also measured. Cd ions change the normal luminescence of silver chloride of maximum at about 485 mμ to longer wavelength one of 545 mμ at low temperatures. When the latter luminescence is thermally quenched, the usual maximum of 485 mμ recovers and then it is also thermally quenched. The infrared light enhances the luminescence of 545 mμ and quenched that of 485 mμ. This quenching is drastic when Fe ions are added. The photoconductivity is enhanced by the infrared light in Cd doped crystals and almost not quenched in Fe doped crystals. An energy band model is given to explain the experimental results.

§ 1. Introduction

The nature of luminescence centers in solid has complicated character. In spite of a great number of investigations on it, generally acceptable conclusions are few. Especially silver halides are open to question. On the other hand the luminescence of silver halides has a fundamental character of polar crystals', then its investigation is important as the means of research of physical properties of silver halides.

The luminescence of silver halides was observed initially by Randall[1)] and Meidinger[2)], with crystals and emulsions at low temperatures. Farnell and Burton[3)] farther examined it in some detail by means of spectrographical method. They interpreted it as an edge luminescence because they used purest samples and got no after-glow, and explain the thermal quenching of the luminescence by configuration co-ordinates. Makishima and Tomotsu[4)] supported their idea though they noticed the connection with lattice defects, and criticized Seitz's mechanism[5)] which suggested forbidden transitions within silver ions. Moser and Urbach[6)] made some study of the luminescence in which they investigated the buildup of emission under excitation, the effects of infrared radiation of the luminescence, and cation-activated fluorescence. They concluded independently by Dorfner[7)] that the silver halides are clearly in the class of photoconduction phosphors, and proposed a band model with trap levels of electrons and holes. Makishima, Tomotsu and Hayakawa[8)] successively studied the luminescence of silver chloride with anion impurities, and from the buildup and decay types of the luminescence they found many levels of traps besides the centers intrinsic to the matrix.

Aline[8)] measured coincidently the luminescence and photoconductivity in the wide range of excitation spectrum, and obtained good correspondence between them in some peaks, though his interpretation was ambiguous. Wiegand[10)], however, measured the decay times of luminescence and photocurrent, which behaved independently under several treatments. Then he advanced the idea based upon the effects of vacuum and chlorine annealing on the results, that the recombination centers are silver ion vacancies which initially capture free holes radiatively.

Here we encounter a number of interests about the nature of luminescences such that whether the luminescence is only by photoconductive ones, next in that case, which are electrons or holes that radiate the luminescence by being trapped, and farthermore the trappings are whether first trappings or second recombination trappings. Finally we question what are the luminescence centers at which the trappings take place.

Since in silver halides the carrier of photocurrent is known undoubtedly as electrons[11)], Wiegand's measurements are rather affirmative to hole theory. However the experiments of infrared quenching of luminescence by Moser and Urbach suggest the second trapping theory which indirectly contradicts the hole theory. But Moser and Urbach's material was silver bromoiodide, moreover, from the complicated character of the luminescence, unless the comparison of infrared quenching of luminescence and photocurrent be made, the conclusion cannot be drawn. Therefore we try to measure the luminescence of silver chloride and its thermal quenchings, besides infrared quenchings of luminescence and photoconductivity in relation to the cation impurities such as Cd^{++}, Fe^{+++} additives.

§ 2. Apparatus

Silver chloride powder was precipitated from silver nitrate solution and hydrochloric acid using special pure chemical reagent. It was then melted in air in porcelain crucible and the crystal was drawn up from the melt at a point of platinum rod. The crystal then was cut by Ti-saw into discs of 2–3 mm thick and polished on a flat stone with sodium thiosulphate solution and at last rinsed with hydrochloric acid and distilled water. The impurities were added at the molten state in a form of $CdCl_2$ and $FeCl_3$. These processes were done under a safety light.

Such a specimen was settled in a cryostat cooled with liquid oxygen or liquid nitrogen. The temperature of the crystal was measured with a Cu-constantan thermocouple, the junction of which was touched to the crystal covered with a thin mica plate as a protector against chemical reactions.

The stimulating light was thrown through a quartz window from a distance of 40 cm, through a condenser lens and a slit. The light source was 100 W high pressure mercury lamp filtered by Matsuda UV–Dl filter. The infrared light was thrown through another window from a 250 W infrared lamp with Matsuda IR–Dl filter.

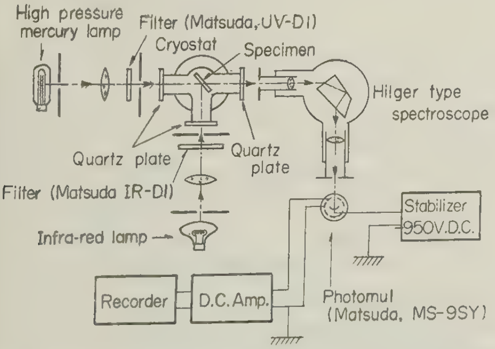

Fig. 1. Arrangement of apparatus to measure the luminescence.

The luminescence was observed from an opposite window and analized by Hilger spectroscope with Matsuda MS–9SY photomultiplier, the output of which was amplified with a sensitive direct current amplifier and automatically recorded. The arrangement of the apparatus is shown in Fig. 1.

The photocurrent was measured separately by a direct current amplifier and a recorder, in similar conditions.

§ 3. Experimental Results

The pure silver chloride powder and crystals showed a proper green luminescence having similar spectroscopic and thermal quenching characters to previous investigators[3),9),10)] the maximum intensity of which is at 485±5 mμ, and the activation energy of the thermal quenching is not far from 0.05 ev. A typical example is shown in Fig. 2. Submaxima were occasionally found at longer wave length side and they often change the form of the main peak at any temperatures to make the activation energy ambiguous.

Origin of these submaxima is attributed to residual impurities or excess silver atoms.

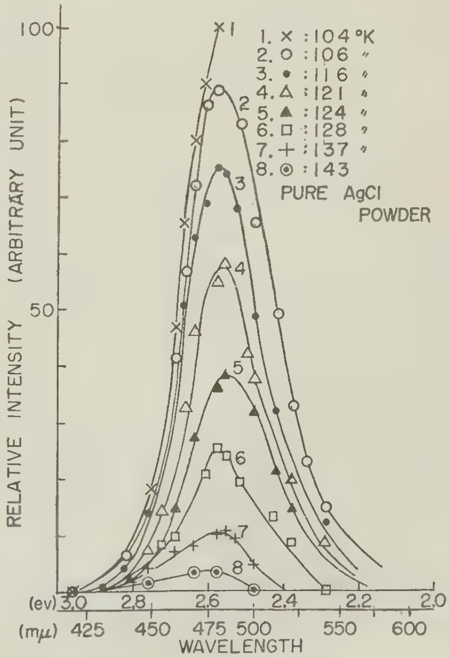

Fig. 2. Luminescence and its thermal quenching of pure AgCl powder.

The silver chloride which was subjected to photolysis and shows violet appearance gives some luminescence at shorter wave length than the maximum, and that of brown appearance shows yellow pink luminescence at longer wave length side. These luminescences were so weak that they can be merely detected as slight deviations from normal back grounds.

Transparent samples also often showed submaximum at about 580 mμ. It is not clear what imperfections are concerned. The room temperature illumination with non-filtered mercury lamp did not change the spectroscopic character essentially, but reduced the intensity over all, even when the darkening was not visible. Strong illumination at room temperature did not reduced the intensity beyond a certain limit —(so for as the shielding effect by photolytic silver dose not cause a remarkable effect)—, but enhanced the intensity slightly by solarization more than that of the specimen let alone after print out.

Silver chloride crystals doped with Cd^{++} ions showed an interesting character in luminescence. At liquid oxygen temperature they gave a luminescence having a single maximum at 545±5 mμ. When the temperature was raised the maximum was weakened, and instead the normal maximum of 485 mμ grew and took its place completely. Then the relief maximum also quenched thermally as usual. This process is shown in Figs. 3, 4 and 5. The greater the amount of Cd ions was, the stronger the intensity of both peaks became. But a small amount of Cd ions was rather suppressive. The amounts of Cd ions added were 2.5×10^{-5}, 5×10^{-5}, 10^{-4} and 5×10^{-4} in mol-ratio.

Auxiliary infrared light enhanced considerably the luminescence of 545 mμ by Cd ions at low temperatures, but it slightly

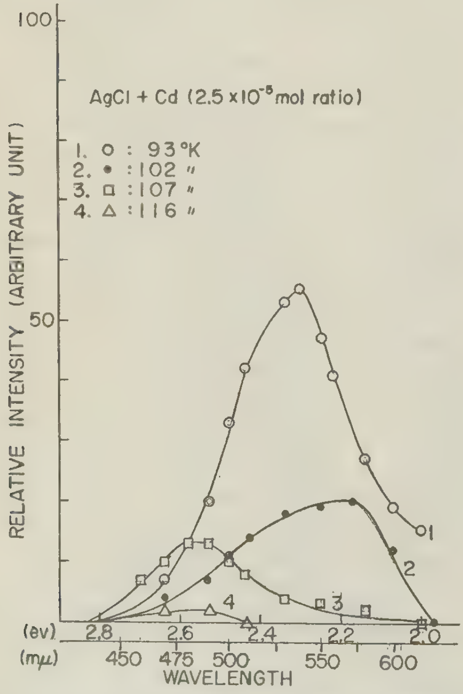

Fig. 3. Luminescence and its thermal quenching of a little Cd doped AgCl Crystal.

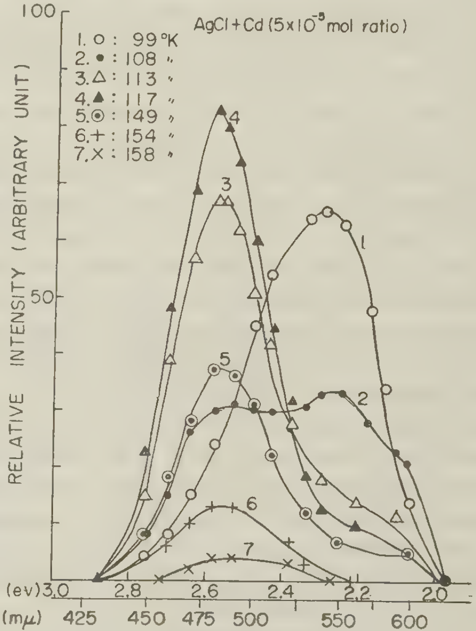

Fig. 4. Luminescence and its thermal quenching of Cd doped AgCl crystal.

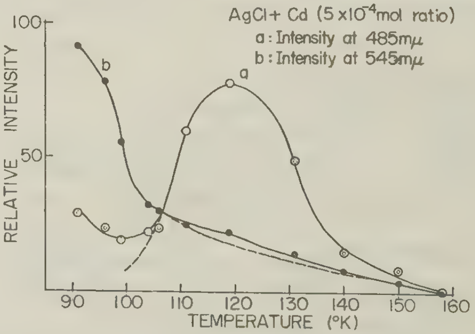

Fig. 5. Transition between two peacks of luminescence intensity with temperature in the Cd doped AgCl crystal. Broken lines avoid the overlapping of peaks one another.

quenched the luminescence of 485 mμ at moderately low temperatures.

Photoconductivity of the sample was also enhanced by the auxiliary infrared light. Those are shown in Figs. 6 and 7.

The buildup of the luminescence was delayed by additions of Cd ions, as well as decay times. The second run of the buildup became faster, but this effect was annihilated by infrared illumination inserted. Effect of the infrared illumination on the decay times was not considerable.

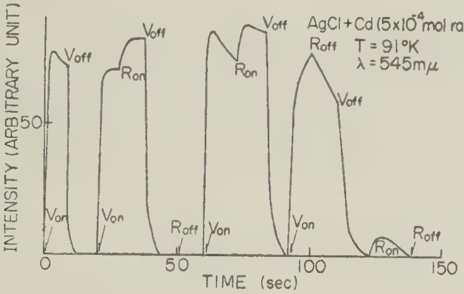

Fig. 6. Effect of auxiliary infrared light on the luminescence of Cd doped AgCl crystal. In diagram, *V* indicates the excitation light and *R* the infrared light.

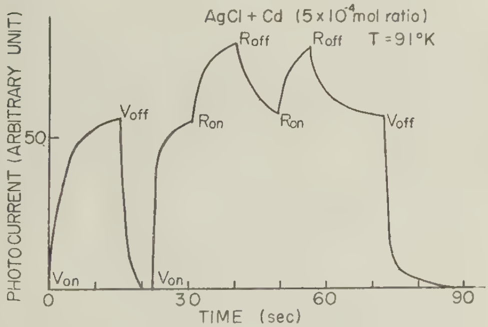

Fig. 7. Effect of auxiliary infrared light on photoconductivity of Cd doped AgCl crystal.

The luminescence of so called pure silver chloride of 485 mμ at low temperatures was also slightly quenched by auxiliary infrared light. In any case spectroscopic forms of individual peaks were not changed by the infrared illumination.

The silver chloride crystals doped with Fe^{+++} ions gave considerably reduced luminescence which besides showed different spectroscopic character. The maximum of 485 mμ was maintained but weak maximum of 550∼560 mμ and a third maximum of longer than 600 mμ were accompanied at low temperatures. These maxima were thermally quenched altogether

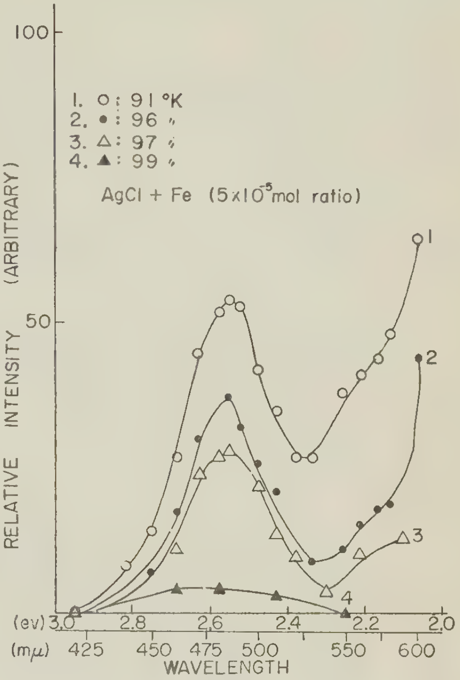

Fig. 8. Luminescence and its thermal quenching of Fe doped AgCl crystal.

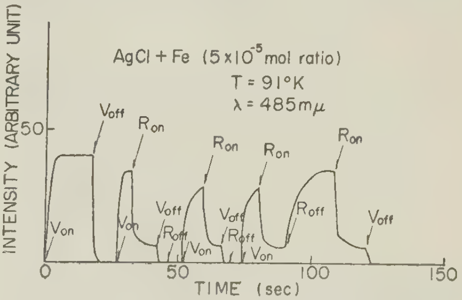

Fig. 9. Effect of auxiliary infrared light on the luminescence of Fe doped AgCl crystal.

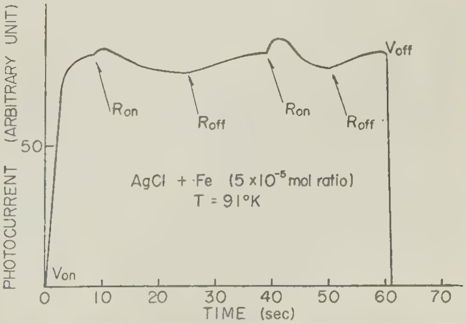

Fig. 10. Effect of auxiliary infrared light on photoconductivity of Fe doped AgCl crystal.

as shown in Fig. 8.

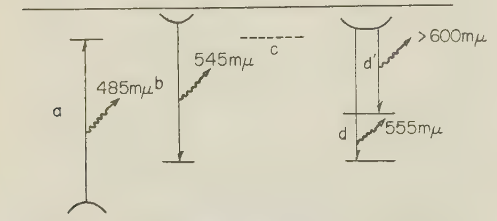
In the Fe doped crystals, the infrared quenching was remarkable at 485 mμ, and less at 555 mμ.

The photoconductivity of the sample showed almost no quenching by the infrared light. At first it enhanced a little and then slowly reduced till slightly under or near the initial current. These are shown in Figs. 9 and 10.

As the solubility of ferric ions in silver chloride is little, the concentration dependence of the luminescence was not determined.

§ 4. Discussion and Summary

The luminescence of maximum intensity at 485 mμ is well known in silver chloride which becomes very strong in purest samples. Then we may attribute it to what is proper to silver chloride. The possible mechanism of luminescence intrinsic to silver chloride is either edge luminescence, or the interstitial silver ions or the silver ion vacancies, both the constituents of Frenkel defects. The fact that this luminescence is replaced by that of at 545 mμ at low temperatures in Cd doped crystals, and quenched by the infrared illumination, suggests that it is not the edge luminescence that is persistent in cooling as suggested by Makishima.



Curved levels represent the excited states

Fig. 11. Energy band model of AgCl phosphor.

Taking account of the influences of the infrared illumination on the luminescence of 485 mμ and 545 mμ, we may assume a band model based on modifying Klick's theory[12] that explained the transition of the blue luminescence of ZnS to the green with temperature. The circumstances are opposit, however, in AgCl(Cd), as the shift of wavelength with temperature is reverse in direction. This is shown in Fig. 11.

In the figure, the notations of the centers are as follows.

a center (485 mμ); this center exists in a purest silver chloride, showing thermal quenching, and being quenched by infrarred illumination. In coexistence of *d* centers, the infrared quenching is drastic, while the photoconductivity is not quenched. In coexistence of *b* centers, it is vanished at low tempratures and appears in warming instead of the thermal quenching of *b* centers, and then also shows thermal quenching as usual. As the concentration of *b* centers is increased from zero, it disappears at once and then increases again as a intensity of relief maximum. After wiegand, the decay constant of the luminescence is very shorter than that of photoconductivity.

b center (545 mμ); this luminescence appears and increases with concentration of added Cd ions. It cancels *a* centers at low temperature completely, but the large amount of it again enhances the *a* center after thermal quenching of itself. Infrared illumination enhances the luminescence as well as photoconductivity.

c ecnter (shallow traps); this increases as the Cd ions are added and delays the decay constant of luminescence of *b* centers.

dd' centers (555 mμ, >600 mμ); this appears as the Fe^{+++} ions are added. It surpresses the efficiency of *a* center, but is thermally quenched together with *a* center. It makes the infrared quenching of *a* center remarkable while is quenched itself somewhat.

This model gives good account of the experimental results.

Thermal quenchings are attributed to the thermal excitation of the electrons or holes in the excited or trapping states of the centers to the conduction or the valence band. We can make any form of the thermal transitions of maxima of luminescence provided the killer centers exist in suitable form. For example we have a equation for stationally state as follows.

$$\frac{dn}{dt}=I-\frac{N_1}{N_c}(1-e^{-E_1/kT})nv\sigma_1\xi_1'-\frac{N_2}{N_c}(1-e^{-E_2/kT})nv\sigma_2\xi_2'$$
$$-\frac{N_3}{N_c}nv\sigma_3\xi_3'-\frac{N_4}{N_c}(1-e^{-E_4/kT})nv\sigma_4\xi_4'=0$$

Where,

n: concentration of conduction electrons
I: excitation rate
N: number of centers
N_c: number of states
E: energy depth of the excited states or the trapping states of centers
V: velocity of electrons
σ: cross section
ξ: recombination probability
1, 2, 3, 4: identification of centers

and prime notation designates that of holes.

Then we get

$$n=\frac{IN_c}{N_1(1-e^{-E_1/kT})v\sigma_1\xi_1'+N_2(1-e^{-E_2/kT})v\sigma_2\xi_2'+N_3v\sigma_3\xi_3'+N_4(1-e^{-E_4/kT})v\sigma_4\xi_4'} .$$

Intensities of luminescence H become

$$H_1=\frac{N_1}{N_c}(1-e^{-E_1/kT})nv\sigma_1\xi_1'$$

$$=\frac{N_1(1-e^{-E_1/kT})\sigma_1\xi_1'I}{N_1(1-e^{-E_1/kT})\sigma_1\xi_1'+N_2(1-e^{-E_2/kT})\sigma_2\xi_2'+N_3\sigma_3\xi_3'+N_4(1-e^{-E_4/kT})\sigma_4\xi_4'} ,$$

$$H_2=\frac{N_2(1-e^{-E_2/kT})\sigma_2\xi_2'I}{N_1(1-e^{-E_1/kT})\sigma_1\xi_1'+N_2(1-e^{-E_2/kT})\sigma_2\xi_2'+N_3\sigma_3\xi_3'+N_4(1-e^{-E_4/kT})\sigma_4\xi_4'} .$$

If $N_4=0$, H_1+H_2 would decrease monotonously.

The transition from H_1 to H_2 with temperature results in $E_1<E_2$ and $N_1\sigma_1\xi_1'\gg N_2\sigma_2\xi_2'$. $N_1\gg N_2$ has been satisfied here, and farther if thermal liberation of holes is important, we take next replacement,

$$\xi'=(1-e^{-E'/kT})n'v'\sigma'$$
$$(1-e^{-E/kT})nv\sigma=\xi ,$$

and we get the similar condition

$$N_1\sigma_1\xi_1'\gg N_2\frac{n'v'}{nv}\sigma_2'\xi_2$$

or

$$N_1\frac{n'v'}{nv}\sigma_1'\xi_1\gg N_2\sigma_2\xi_2' .$$

In either case we may satisfy the conditions represented by the experimental results.

The infrared quenching is also explained from the diagram. In silver chloride, the rate of excitation of holes by the infrared light is less effective than that of electrons, because the photoconductivity does not reduce in this case. Then, *a* centers are quenched liberating free electrons, which have no retiring places without original centers and cannot have remarkable effect in both of luminescence and photoconductivity. The retiring places may be offered by Fe^{+++} ions which protect from holes to recombine because of their charges, and the luminescence is considerably quenched while the photoconductivity is not quenched. On the other hand, *b* centers are electron traps and the infrared light liberates free electrons from other centers and enhances both the luminescence and the photoconductivity.

Now, we shall make some comments about the luminescence centers. We will not enter into the detail constitutions of *b* centers and *d* centers and are only satisfied to say that they are originated from Cd ions and Fe ions. In regard to *a* centers intrinsic to silver chloride, that small amount of Cd ions cancels the intrinsic luminescence may be inconsistent with that the luminescence centers are silver ion vacancies as mentioned by Wiegand. Moreover as the large amount of Cd ions enhances the luminescence though after quenching of Cd owns, the role of interstitial silver ions is excluded. Then we are forced to think of the existence of dislocations which are formed by heavy additions of Cd ions or any impurities accompanying stress fields, or think of more complex reasons as suggested by Rabin[13] in Ca doped sodium chloride.

The detailed discussions of these centers will be given with farther experimental results. We are also studying the effects of anion impurities and the results will be published later.

The authors wish to express their thanks to professor Teturo Inui for helpful criticism to the munuscript, and to Mr. Akira Ito and Mr. Susumu Horie for their untiring assistance throughout the experiments. The present investigation has been partly supported by the Scientific Research Grant from the Ministry of Education and by the Special Research Grant from Chuo University.

Internal Friction of Synthetic Quartz

By Yosio Hiki

The Government Mechanical Laboratory, Suginami-ku, Tokyo, Japan

(Received October 7, 1960)

Internal friction of twenty six specimens of synthetic quartz was measured at room temperature using the composite oscillator method. Specimens were cylinders, axes of which lay in the crystallographic YZ-plane and made various angles extending from $-35°$ to $+40°$ with the Y-axis. Synthetic quartz had usually smaller values of the internal friction than natural quartz. The internal friction of specimens parallel or nearly parallel to the Y-axis was almost independent of the strain amplitude, while that of specimens inclined to the axis at high angles showed noticeable amplitude-dependence. The orientation-dependence of the values of the internal friction could be well explained by the theory of dislocation damping. The dislocation density in synthetic quartz was estimated to be $10^2-10^3\,\mathrm{cm}^{-2}$, being about one hundredth of the density in natural crystals. Effect of X-irradiation on the internal friction of quartz was also studied for both synthetic and natural ones.

§1. Introduction

It is expected that the state of imperfections in crystals is generally different according as the crystals are grown in different ways. The internal friction measurement is one of the most powerful method to study about the crystal imperfections. There were few works which showed that the internal friction of synthetic quartz had somewhat different nature from that of natural one. King[1] measured the Q^{-1} of the synthetic and natural quartz oscillators at low temperatures and found that the synthetic quartz exhibited an extremely large mechanical absorption at 50°K with frequency of 5 Mc/sec. The absorption peak was almost two or three decades higher than that of the natural quartz. There appeared also a relaxation peak at 20°K both in synthetic and natural crystals. The author mainly studied the 50°K peak and considered that this might be originated from the vibration of the "nonbridging-oxygen defects", and scarcely noticed the 20°K peak which has assumed to arise from the movement of crystal dislocations[2].

In the present investigation, the internal friction of single crystals of synthetic quartz with various crystallographic orientations was measured as a function of the strain amplitude of the vibration at room temperature. The same kind of measurement about the natural crystals has been carried out and the results were already reported in the earlier paper[3] (hereafter called reference I). It was concluded from the results that the internal friction of quartz in the kilocycle range was mainly due to the vibration of dislocations in the crystals. The present study was intended to inspect the above conclusion in the case of synthetic quartz, and also to find the difference of the state of crystal imperfections in the synthetic and natural ones. The variation of the internal friction of both natural and synthetic quartz was also measured when they were annealed isothermally or irradiated with X-rays, because it was expected that they might have different behaviors.

§ 2. Experimental Procedures

The Marx's three-component piezo-electric oscillator was used to measure the internal friction of quartz specimens. The frequency of vibration used was about 64 kc/sec and the strain amplitude ranged from 0.5 to 5.0×10^{-5}. The detailed description of the experimental method is in the earlier papers.[3],[4]

Specimens were prepared from the synthetic quartz, being Y-bar crystals grown hydrothermally by the Sawyer Research Products, Inc. All crystals were free from electrical and optical twinning. The mother crystals were analyzed spectroscopically and it was found that they were purer than natural crystals and that the main metallic impurities were Al and Na. Their contents were considered to be smaller than 10 ppm although accurate determination was impossible. The specimens were of cylindrical form, 2 mm in diameter and about 40–50 mm in length. The length of each specimen l can be determined by the relation $l=(1/2f)\cdot\sqrt{E/\rho}$, where f is the frequency of the measuring oscillator, E the Young's modulus for the lengthwise direction, and ρ the density of the quartz. Using the values of E calculated from the elastic constants of quartz found in usual literatures, it was possible to get the frequency matching between the specimens and the oscillator better than 0.5%. The direction of the specimen axis was chosen to be in the crystallographic YZ-plane and made the angle θ with the Y-axis [cf. Fig. 1 in I]. Twenty six specimens with various orientations were prepared from three mother crystals, 'L', 'M' and 'N', the angle θ being chosen to range from $-35°$ to $+40°$ at an interval of 5°. Specimens inclined to the Y-axis at larger angles could not be prepared owing to the limitation in size and shape of the mother crystals. The specimen will be designated such as "L-$\overline{30}$-1", which refers to that "mother crystal is 'L', angle θ equals to $-30°$, and specimen number is 1".

§ 3. Results and Discussions

3.1 *Amplitude-dependence*

The internal friction, δ, of all specimens

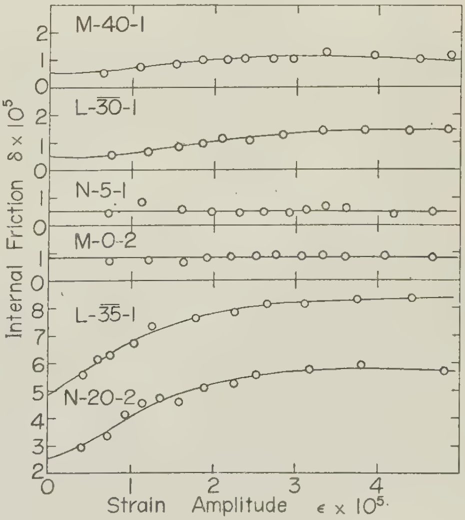

Fig. 1. Internal friction *vs* strain amplitude curves for various specimens.

was measured as a function of the strain amplitude of vibration, ε. Some of the typical results are shown in Fig. 1. In the case of specimens parallel or nearly parallel to the Y-axis, the values of internal friction are small and almost independent of the strain amplitude. Although the internal friction of specimens inclined to the axis at high angles is usually not so large as the case of natural quartz [Fig. 2 in I], the amplitude-dependence is noticeable in these specimens. Some crystals such as L-$\overline{35}$-1 and N-20-2 have larger values and more marked amplitude-dependence of internal friction than usual specimens. These anomalies are sometimes found in specimens with large values of the angle θ. There were four such specimens among seven 'L' specimens, one among seven 'N' specimens, and none among twelve 'M' specimens.

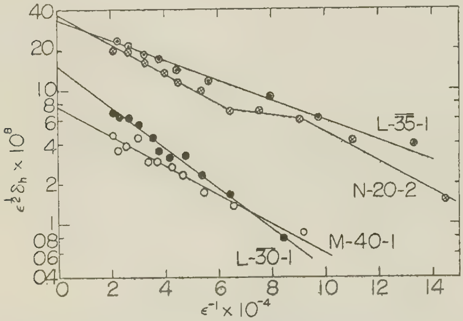

Fig. 2. Analysis of amplitude-dependence of internal friction for various specimens.

In ref. I, experimental results on the internal friction of natural quartz were analyzed using the theory of dislocation damping proposed by Granato and Lücke.[5] The internal friction of crystals due to dislocation damping can be given as[5),6)]

$$\delta=\delta_i+\delta_h=k_1B\omega+c_0\varepsilon^{-1/2}\exp(-c_1/\varepsilon)\,, \quad (1)$$

where ω is the angular frequency of the vibration, B the damping constant for the dislocation movement, and k_1, c_0 and c_1 contain the known quantities such as elastic constants of the crystals and the unknown quantities such as dislocation density in the crystals. The adaptability of this formula will be examined in the case of the synthetic quartz. From the experimental values of internal friction, δ, the amplitude-dependent part, δ_h, is obtained by subtracting the amplitude-independent internal friction which can be got by extrapolating the value of δ to $\varepsilon=0$. In Fig. 2, values of $\log\varepsilon^{1/2}\delta_h$ are plotted against ε^{-1} for four specimens. It is found that linear relationship usually holds between these two variables, which shows an evidence for the dislocation damping occuring in these crystals. Same plotting for the specimen N-20-2 shows anomalous behavior, which may be due to the abundant impurities in this specimen, as suggested in ref. I.

3.2 *Orientation-dependence*

The internal friction of twenty one specimens at strain amplitude equal to 3×10^{-5} are plotted in Fig. 3, where the abscissa is the angle θ. The figure attached to each point represents the specimen number. These values are considerably dependent on the crystallographic orientation of the specimen.

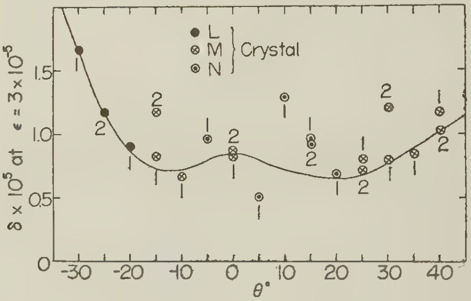

Fig. 3. Orientation-dependence of internal friction.

In the case of natural quartz, the dependence of the amplitude-independent and the amplitude-dependent internal friction on the specimen orientation was found to agree well with the theory of dislocation damping [section 3.4 in I]. In the present case, however, the amplitude-independent internal friction cannot be determined accurately for all specimens. Discussions must therefore be limited to the orientation-dependence of the internal friction at a constant amplitude. The experimental value of the internal friction will be rewritten as[3)]

$$\delta=K_1s^2E+K_2s^{3/2}E^{1/2}\exp(-1/sE)+\delta_0\,, \quad (2)$$

where s is the resolved shear stress factor, E the Young's modulus along specimen axis, δ_0 the internal friction caused from other origin than dislocation damping, K_1 and K_2 are constants independent of specimen orientation. When the dislocations in the crystal have the slip plane parallel to Y- or Z-axis, as assumed in the case of natural quartz, the factor s is proportional to $\sin\theta\cos\theta$. Inserting this into Eq. (2) and assuming that δ_0 has a constant value for all specimens, internal friction at a constant strain amplitude can be obtained as a function of θ. The solid curve in Fig. 3 represents the values calculated by such a method. Three constants δ_0, K_1 and K_2 were chosen so as the curve to pass three experimental points (points for M–40–2, L–$\overline{30}$–1, and midpoint of M–0–1 and M–0–2). The agreement of this curve with other experimental points is considered to be satisfactory. The scatter of some points may be mainly due to the inconstancy of δ_0. The origin of δ_0 may, for example, be the loss in the adhesive between the oscillator and the specimen or incorrectness of the shape of the specimen. Five specimens which have anomalously large internal friction are omitted in this plotting. These may have dislocation density larger than usual specimens, which is verified in the next section.

3.3 *Estimation of dislocation density*

As in the case of natural quartz, the dislocation density, Λ, the mean distance between pinning point, L_c, the maximum binding force between pinning defect and dislocation, F, and the concentration of the pinning points on dislocation, $C=b/L_c$, were calculated with regarding the network length, L_n, as a parameter. The most probable value of L_n was assumed to be $5\times10^{-4}-1\times10^{-3}$ cm [section 3.6 in I]. The results for three specimens, M–40–1, L–$\overline{30}$–1 and L–$\overline{35}$–1, are listed in Table I. The values for a natural crystal, A–45–1, are also shown in the table for the purpose of comparison. The last line represents those for A–45–1 annealed at 500°C for 150 hours, which are reproduced from Table II in ref. I.

Table I.

Specimen	L_n cm	L_c cm	Λ cm^{-2}	F dyne	C
M–40–1	5×10^{-4}	2.0×10^{-4}	1.1×10^{3}	1.2×10^{-4}	2.5×10^{-4}
(Syn.)	1×10^{-3}	3.0×10^{-4}	2.0×10^{2}	1.9×10^{-4}	1.6×10^{-4}
L–$\overline{30}$–1	5×10^{-4}	1.8×10^{-4}	1.4×10^{3}	2.3×10^{-4}	2.8×10^{-4}
(Syn.)	1×10^{-3}	2.6×10^{-4}	2.6×10^{2}	3.4×10^{-4}	1.9×10^{-4}
L–$\overline{35}$–1	5×10^{-4}	2.3×10^{-4}	4.4×10^{3}	1.5×10^{-4}	2.2×10^{-4}
(Syn.)	1×10^{-3}	3.4×10^{-4}	8.3×10^{2}	2.3×10^{-4}	1.4×10^{-4}
A–45–1	5×10^{-4}	1.2×10^{-4}	2.6×10^{5}	0.8×10^{-4}	4.1×10^{-4}
(Nat.)	1×10^{-3}	1.7×10^{-4}	5.0×10^{4}	1.1×10^{-4}	2.9×10^{-4}
A–45–1	5×10^{-4}	2.4×10^{-4}	1.2×10^{4}	1.5×10^{-4}	2.0×10^{-4}
(Ann.)	1×10^{-3}	3.6×10^{-4}	2.3×10^{3}	2.3×10^{-4}	1.4×10^{-4}

The dislocation density in usual synthetic quartz specimens such as M–40–1 and L–$\overline{30}$–1 is of the order of 10^2–10^3 cm^{-2}, which is about one hundredth of that in natural quartz. The density in specimen L–$\overline{35}$–1, which has large values of internal friction as shown in Fig. 1, is several times as large as the density in usual crystals. Synthetic quartz may contain the part with high dislocation density here and there in the crystal. The concentration of the pinning points on the dislocation lines in synthetic quartz seems to be lower than that in natural crystal. This agrees with the fact that synthetic quartz generally contain smaller amount of impurities than natural one. The maximum binding force between pinning defect and dislocation is of the same order of magnitude in synthetic and natural quartz. It may be possible that similar kind of defects, namely, some aggregates of impurities [section 3.7 in I], are pinning the dislocations.

Recently, Nielsen *et al.*[7] observed the etch pits in quartz crystals developed by concentrated hydrofluoric acid, and found that the pit density in synthetic quartz was about three decades lower than that in natural quartz. The authors suggested that the pits might be caused from the etching of impurities precipitated along dislocation line. Accordingly, the dislocation density and impurity concentration in synthetic crystal are conceivable to be lower than those in natural crystal. The results obtained from the internal friction measurements agree with this expectation from etching experiments.

3.4 *Effect of annealing*

The internal friction of a specimen L–$\overline{35}$–1 annealed at 500°C for 5, 10, 20, 50 and 100 hours successively, was measured as a function of the strain amplitude for each state during annealing. The relative values of the concentration of pinning points on the dislocation line, C, were determined through analyzing the ampitude-dependence of the internal friction. The variation of C/C_0 with annealing time is shown in Fig. 4, where C_0 is the initial value of C. The result for the natural quartz specimen, A–45–1, is also drawn in the figure which is reproduced from Fig. 9 in I. In the case of natural quartz, C/C_0 decreases monotonously with annealing time. On the contrary, the value for synthetic quartz increases at first and then decreases.

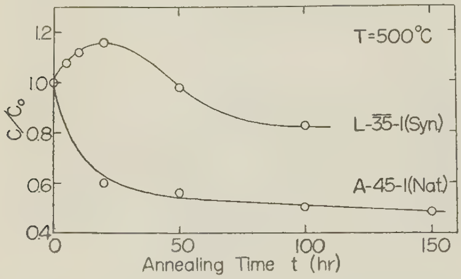

Fig. 4. Variation of C/C_0 for two specimens annealed at 500°C.

The different behaviors of natural and synthetic quartz may be explained as follows. As discussed in section 3.7 in I, the defects pinning down the dislocations in quartz crystals are assumed to be aggregates of impurities near dislocation lines. Natural quartz are considered to have grown very slowly at temperatures 200–350°C and maintained for long time under the ground. The concentration and mean size of impurity aggregates near dislocations may have reached to their equilibrium values at such temperatures. When the crystal is annealed at higher temperatures, some of the aggregates grow larger absorbing small ones on dislocation lines. The number of breakable pinning points may be diminished and C/C_0 be decreased apparently, because external applied stress cannot break dislocations away from the aggregate larger than the possible displacement of the dislocation segment. In the case of synthetic quartz, the concentration of aggregates near dislocations may not reach to the equilibrium value, because the crystals have been growth rapidly. When the specimen is annealed, impurity atoms in crystal are further gathered to the dislocation lines and form new aggregates, and some of the aggregates become large. Accordingly, the apparent number of pinning points may be increased firstly and then decreased.

3.5 *Effect of X-irradiation*

Quartz specimens with different crystallographic orientations were irradiated with X-rays and their internal friction was measured at room temperature. All specimens were annealed at 500°C for 100 hours and then exposed to the X-rays at a definite position separated by 30 cm from the window of the tube with Cu target operated at 40 kV and 20 mA. The results for three natural quartz specimens A–0–3, A–45–2, D–90–1, and a synthetic quartz specimen L–$\overline{30}$–2 are shown in Fig. 5, where the ordinate is the internal friction measured at a constant strain amplitude and the abscissa is the irradiation time. The horizontal line drawn in the left part of

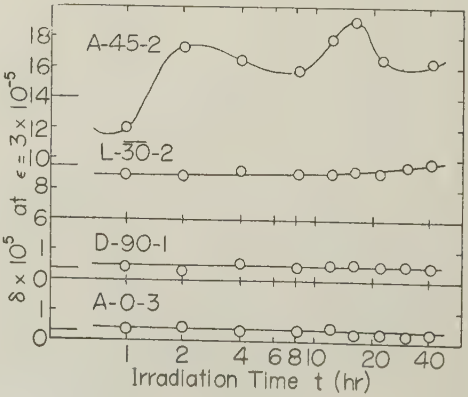

Fig. 5. Variation of internal friction with irradiation time for various specimens.

each curve represents the internal friction for the annealed specimen. The values of internal friction of the specimens A–0–3 and D–90–1 are almost unaffected by the X-irradiation, while that for A–45–2 is changed markedly although its variation with irradiation time is not simple. The internal friction of the synthetic specimen L–$\overline{30}$–2 is increased only slightly by the irradiation.

The above results can be interpreted as follows. When quartz are irradiated with ionizing radiation, the states of lattice defects are somewhat altered. The internal friction originated from the dislocation damping may be varied if the defects are able to act as the pinning points. The internal friction of specimen A–0–3 and D–90–1, which are parallel to Y- and Z-axis, respectively, is not affected by the irradiation because the dislocations in these specimens are inactive for the longitudinal vibration. The value for specimen A–45–2 is changed extremely by irradiation, because the contribution of dislocation damping to the internal friction is most remarkable for specimens with such orientations. The complex feature of the irradiation curve may be originated from the gradual growth of the impurity aggregates which pin down the dislocations. It may be possible that metallic aggregates are grown near dislocation lines promoted by irradiation, as observed in the case of X-irradiated NaCl.[8] Further experiments are desired to understand these phenomena. The synthetic quartz crystals usually contain smaller amount of impurities than natural ones, which is verified by the emission analysis[9] and the experiment of irradiation coloring.[9],[10] Annealed synthetic quartz may contain a few impurity atoms in crystal to grow into the pinning aggregates even when irradiated with X-rays.

§ 4. Reconsideration about Internal Friction of Quartz

It is worthwhile to take into consideration again about the adaptability of the theory of dislocation damping to the internal friction of quartz. The remarkable dependence of the internal friction on the crystallographic orientation was considered to be the most powerful evidence for the dislocation damping in quartz. Some other possible mechanisms which may cause the orientation-dependence of the mechanical damping will be examined:

1) Elastic waves of pure compressional mode can be propagated only in definite directions in an anisotropic medium. Compressional waves excited in other directions are partly converted into transverse waves.[11] Such an effect produces losses dependent on the orientation of the propagation, which must be taken into account in the attenuation measurement using the ultrasonic pulse method. In the case of the resonance method with the composite oscillator, the loss originated from the above effect may be ignored. This may be presumed from the fact that the actual resonant frequencies of all quartz specimens were not so depart from those calculated for the longitudinal vibration.

2) In the interior of the vibrating solid, local thermal flows are generated by the nonuniformity of temperature associated with the stress distribution. These flows originate the thermoelastic damping, the magnitude of which is usually dependent on the crystallographic orientation of the specimen. The thermoelastic damping in quartz is, however, very small, being estimated to be of the order of 10^{-9} in the kc frequency range.[12]

3) Some investigators considered the mechanical damping caused from the vibration of interstitial metallic ions in the " tunnels " of the quartz lattice.[13] The tunnels were considered to be parallel to the Z-axis since the conductivity and dielectric loss were found to be greatest in this direction. The orientation-dependence of the internal friction of natural quartz reported in ref. I cannot be explained by such a mechanism, because the internal friction of the specimens parallel to either the Y- or Z-axis are smaller than those inclined these axes at high angles.

4) It may be possible that the trains of the low temperature peaks[1],[2] contribute to the orientation-dependence of the internal friction at room temperature, although various crystals with different orientations have not been investigated thoroughly at low temperatures. Both peaks are those of relaxation type, which cannot yield the amplitude-dependent internal friction such as observed in the present experiment.

There remains some other questions about the internal friction of quartz crystal. Mason considered the relaxation peak at 20°K (5 Mc) as the Bordoni peak and obtained the result that the Peierls' stress for the dislocation in quartz was rather small.[2] Then dislocations can vibrate easily at room temperature and the theory of Granato-Lücke may be applied to the internal friction of quartz. The same author, however, proposed a new theory about acoustic wave attenuation caused from the viscosity of phonons in crystals, and discussed that the low temperature peak in quartz can be attributed to the phonon relaxation effect.[14] It was also shown that the vibration of dislocations could contribute to the internal friction at higher temperatures, where the damping of the moving dislocations was mainly due to the viscosity of the dragging phonons behind them. The measured value of the damping constant, B, for the dislocation movement was rather coincide with the value calculated by the phonon viscosity theory. The value of B calculated by the phonon scattering theory of Leibfried,[15] which has been used by the present author in the analysis of the experimental results, was about one tenth of the above value.

In conclusion, the large part of the kc-range internal friction of both natural and synthetic quartz crystals may be attributed to the motion of dislocations, because the amplitude-dependence and the orientation-dependence of the internal friction can be well explained through the theory of the dislocation damping. The obtained values of the dislocation density and other quantities concerning these crystals may also be reliable in order of magnitude, although the true origin of the damping force against the motion of dislocations in quartz has not been well understood.

Acknowledgement

The author wishes to express his sincere gratitudes to Dr. T. Kawada for his continued encouragement. He is also greatly indebted to Professor Y. Tomono for his kind instruction and advices. Thanks are also due to Mr. K. Takahashi at the Geological Survey of Japan for his kindness to carry out the spectroscopic analysis of the specimens.

The Crystal Structures of $KMnF_3$, $KFeF_3$, $KCoF_3$, $KNiF_3$ and $KCuF_3$ above and below their Néel Temperatures

By Atsushi OKAZAKI and Yasutaka SUEMUNE

Department of Physics, Faculty of Science, Kyusyu University, Fukuoka, Japan

(Received November 7, 1960)

The crystal structures of the antiferromagnets $KMnF_3$, $KFeF_3$ $KCoF_3$, $KNiF_3$ and $KCuF_3$ have been determined above and below their Néel temperatures (T_N) by X-ray diffraction using single crystals. At room temperature (above T_N) the structures of these compounds are of the ideal perovskite type (cubic) except for that of $KCuF_3$ which crystallizes as a tetragonal modification ($a>c$) of the perovskite type. At 78°K (below T_N) the lattice symmetries of $KMnF_3$, $KFeF_3$ and $KCoF_3$ are monoclinic, rhombohedral ($\alpha<90°$) and tetragonal ($a>c$), respectively, while $KNiF_3$ and $KCuF_3$ retain their own symmetries at room temperature. The lattice constants have been determined between these temperatures and their changes near the transition temperature were closely followed. This temperature region was extended up to 670°K for $KCuF_3$.

§ 1. Introduction

The crystal structures of the antiferromagnets KMF_3, where M indicates the $3d$ transition group elements; Mn, Fe, Co and Ni, have been investigated at room temperature by many researchers. The works performed by these researchers were summarized by Martin, Nyholm and Stephenson[1]. All these works have been done with powders and it is perhaps for this reason that the results on the crystal structures of these compounds are rather ambiguous. That is, some have reported as the perovskite structure with cubic symmetry, and others as the pseudo-perovskite structure with lower symmetry for the same compound.

Since the magnetic ions in the perovskite structure form a simple cubic lattice, the magnetic properties of ABO_3 compounds with this structure have been extensively investigated. Therefore it may be interesting to investigate in detail the crystal structures and the magnetic properties of KMF_3 compounds including $KCuF_3$ for which the lattice distortion according to the Jahn-Teller effect may be expected even above the Néel temperature.

The work described herein mainly deals with structural changes of KMF_3 compounds accompanied by their magnetic transitions. The structures at room temperature and at 78°K have been reported shortly[2]. The detailed structure analysis of $KCuF_3$ at room temperature has also been reported[3]. Recently Beckman and Knox[4] have reported a full account of the crystal structure of $KMnF_3$ in the temperature region between 15 and 293°K, and Scatturin et al.[5] have investigated the magnetic structures of KMF_3 compounds including $KCrF_3$ by neutron diffraction.

§ 2. Experiments

These compounds, prepared by Hirakawa, Hirakawa and Hashimoto[6] of our laboratory, crystallized in rectangular forms, their volume being mostly a few mm³. At every step of crystal preparation of each compound—after precipitation, crystallization and additional treatments—the crystal structure was examined by X-ray powder photographs, and almost always the pattern corresponding to the cubic perovskite structure was observed except for $KCuF_3$.

Single crystals were used throughout this work. The specimens on which the X-ray work was performed were formed into nearly cylindrical shape, 0.4∼1.2 mm in length and 0.05∼0.15 mm in diameter, by cutting with a razor blade and grinding with sand paper. Since it was easy to break along the the {100} planes, specimens elongated along the ⟨110⟩ were used without grinding.

At room temperature oscillation and rotation photographs were obtained by using cylindrical cameras, the diameters being 9 cm (Straumanis-Ieviņš arrangement of film mounting) and 10 cm (Bradley-Jay arrangement).

Above and below room temperature, oscilla-

Table I. Constructional details of high-

	Furnace or cooler	Temperature measurement
High-temperature camera	Cylindrical Ni-foil furnace (0.018 mm thick) described by Dent and Taylor[8]. Current was about 20A for 670°K. Controlled manually.	Chromel-Alumel thermocouple was placed 1 mm above specimen. Calibration was made by measuring the melting point of In, Sn, Bi, Pb and InSb. Accuracy: within ±2°C and stability during exposure: within ±0.5°C.
Low-temperature camera	Cooling gas from a liquid nitrogen Dewar was transferred by a double walled glass tube. Temperature was controlled by changing the rate of gas flow, which is regulated by the current through a resistor dipped into liquid nitrogen. The lowest temperature attained was 86°K.	Copper-constantan thermocouple was placed 2 mm above specimen (Fig. 1). Homogeneous temperature destribution was obtained by means of an attachment to the nozzle (Fig. 1). Accuracy within ±0.5°C and stability during exposure within ±1°C.

tion and rotation photographs were obtained by using the high- and low-temperature cameras having a multiple-film carrier which can be moved axially to give a series of 7 to 10 exposures for the equatorial reflexions. Their details are given in Table I. A part of the low-temperature camera (gas cooling type) is shown in Fig. 1. In order to attain 78°K liquid cooling method described by Lonsdale and Smith[7] was used.

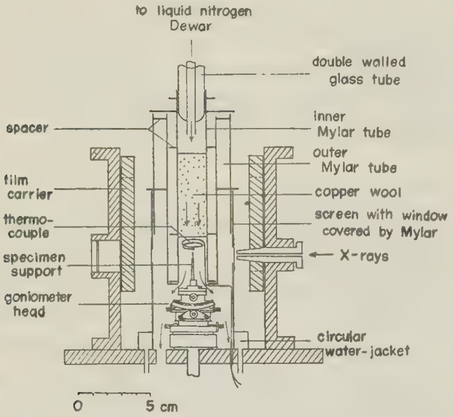

Fig. 1. A part of low-temperature camera using gas cooling method.

§ 3. Structure Determination

a) *at room temperature*

The oscillation photographs about the [100] as rotation axis were obtained for $KMnF_3$, $KFeF_3$, $KCoF_3$ and $KNiF_3$ with Fe$K\alpha$, Co$K\alpha$, Co$K\alpha$ and Cu$K\alpha$ radiations, respectively. In spite of the heavy exposure there was no evidence for superstructure reflexions similar to those observed for $KCuF_3$[3]. Moreover, since these four compounds are cubic and the observed intensities are in good agreement with those calculated by assuming that the structures are of the perovskite type, it seems

Table II. Lattice constants of KMF_3 at room temperature with experimental data.

Compound	Lattice constants (Å) at 298°K	Rotation axis	Radiation	Highest angle reflexion and its Bragg angle
$KMnF_3$	$a=4.190\pm0.001$	[100]	Fe$K\alpha$ Cu$K\alpha$	(330) ~79° (510) ~70°
$KFeF_3$	$a=4.121\pm0.001$	[100]	Co$K\alpha$	(420) ~76°
$KCoF_3$	$a=4.069\pm0.001$	[100]	Co$K\alpha$	(420) ~80°
$KNiF_3$	$a=4.014\pm0.001$	[100]	Cu$K\alpha$ Co$K\alpha$	(510) ~78° (330) ~69°
$KCuF_3$	$a_0=4.140\pm0.001$*	[001]	Co$K\alpha$ Cu$K\alpha$	(420) ~75° (510) ~72°
	$c_0=3.926\pm0.002$ (tetragonal)	[100]	Co$K\alpha$ Cu$K\alpha$	(042) ~78° (034) ~74°

* a_0 and c_0 designate the fundamental structure, because $KCuF_3$ has a superstructure[3].

and low-temperature cameras.

Atmosphere	Film mounting	Windows	Specimen
Vacuum. Both furnace and camera unit were set in the vacuum chamber.	Straumanis-Ievinš type film mounting. Diameter: 9 cm.	Al-foil for inner radiation shield. Mylar sheet for window of outer vacuum chamber.	Cylindrically shaped single crystal was mounted on a quartz fibre by a small amount of potter's clay.
Air. Equipped with a device to prevent frosting of specimen (Fig. 1).	Same as above.	A thin film of Mylar.	Cylindrically shaped single crystal was mounted on a thin quartz rod by adhesive paste.

that these have the ideal perovskite structure.

The lattice constants were determined from high angle equatorial reflexions recorded on rotation photographs. The graphical extrapolation against $\cos^2\theta$ was used for each case. In order to increase the accuracy of the extrapolation, reflexions by two different radiations were recorded on the same film, if necessary. In Table II rotation axis of specimen, radiation used, the highest angle reflexion by the radiation and the approximate value of the Bragg angle θ for each compound are summarized together with the obtained lattice constants, where the errors indicate the maximum deviations at the extrapolations for several runs.

b) *at low temperatures*

The Néel temperature of each compound determined by Hirakawa, Hirakawa and Hashimoto[6] from the magnetic susceptibility measurements is shown in Table III. Below these temperatures $KNiF_3$ and $KCuF_3$ retain their lattice symmetries, but those of $KMnF_3$, $KFeF_3$ and $KCoF_3$ become monoclinic, rhombohedral ($\alpha<90°$) and tetragonal ($a>c$), respectively.

Table III. Néel temperatures (°K) of KMF_3*.

$KMnF_3$	$KFeF_3$	$KCoF_3$	$KNiF_3$	$KCuF_3$
88	113	114	275	243

* A few of these values are somewhat different from those previously reported[2].

Together with these deformations the single crystals are turned into the polycrystalline state which consists of the crystallites having their main crystallographic axis oriented along any of the three former cube axes (for monoclinic and tetragonal cases) or any of the four former body diagonals (for rhombohedral case) with equal probability. Therefore these symmetries can be determined from the splittings of the $\{h00\}$ and $\{hhh\}$ reflextions. The splittings of the $\{400\}$ with Fe$K\alpha$ around the $\langle100\rangle$ and the $\{222\}$ with Cr$K\alpha$ around the $\langle110\rangle$ at 78°K are represented schematically in Fig. 2.

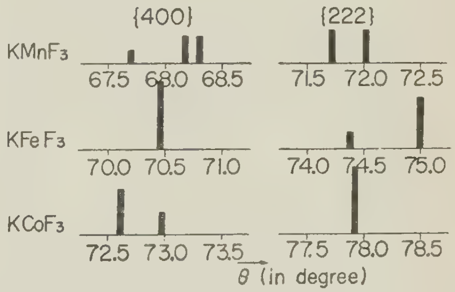

Fig. 2. $\{400\}$ and $\{222\}$ reflexions at 78°K. Abscissa is the Bragg angle. $K\alpha_2$-component of each reflexion is omitted for clarity.

The lattice constants were determined by the same extrapolation as at room temperature. The angles β of $KMnF_3$ and α of $KFeF_3$ were determined from the splittings of the $\{222\}$ with Cr$K\alpha$ and the $\{420\}$ and $\{330\}$ with Fe$K\alpha$, respectively. The results at 78°K are given in Table IV. Fig. 3 shows the temperature dependence of these constants.

Recently Beckman and Knox[4] have investigated $KMnF_3$ in detail down to 15°K. Their lattice constants are in good agreement with ours above 88°K (T_N). But they describe that the monoclinic phase observed by us at 78°K only appears when the crystal warms up from

Table IV. Lattice constants of KMF$_3$ at 78°K.

	Symmetry	Lattice constants (Å)
KMnF$_3$	monoclinic	(a,b,c) $=(4.168, 4.171, 4.185)$* $\beta=89°51'\pm1'$
KFeF$_3$	rhombohedral	$a=4.108\pm0.002$ $\alpha=89.51'\pm1'$
KCoF$_3$	tetragonal	$a=4.057\pm0.002$ $c=4.049\pm0.002$
KNiF$_3$	cubic	$a=4.001\pm0.002$
KCuF$_3$	tetragonal	$a=4.121\pm0.002$ $c=3.911\pm0.002$

* It can not be determined at present which of the three values in the parentheses corresponds to the letters a, b and c.

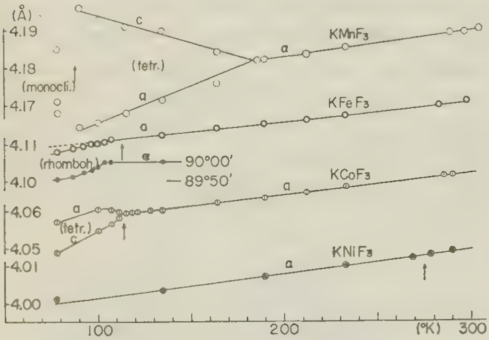

Fig. 3. Lattice constants of KMF$_3$ as a function of temperature. Arrows indicate T_N of each compound.

the antiferromagnetic state to 92°K, and that below T_N the crystal has orthorhombic symmetry with tetragonal pseudo-cell. Therefore reexaminations at 90°K and 78°K by liquid cooling were carried out when a special care was taken for sufficient cooling, and the previous results were confirmed as follows:

i) {222} splits into two components at 78°K but not at 90°K,

ii) {400} splits into three components at 78°K, but the pattern is rather unusual; three components have not the same intensity as shown in Fig. 2.

Therefore it may be true that the crystal becomes at least monoclinic at 78°K. The discrepancy below T_N may be attributed to the experimental method, that is, the temperature was not controlled continuously near T_N in our experiments.

c) lattice constants of KCuF$_3$

Up to 470°K in vacuum the crystal of KCuF$_3$ remains transparent and there is no change in appearance, but at 570°K it becomes opaque and dark. Nevertheless there is no significant change in the diffraction pattern up to 670°K.

The lattice constants of KCuF$_3$ up to 670°K are shown in Fig. 4. c_0/a_0 decreases linearly with increasing temperature and no anomaly can be found at T_N and in the temperature region between T_N and 370°K where an anomaly has been reported⁶⁾ on the magnetic susceptibility.

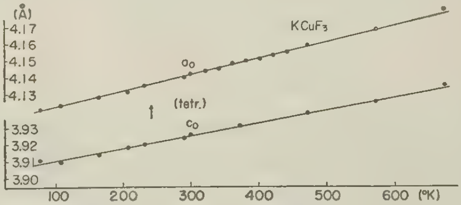

Fig. 4. Lattice constants of KCuF$_3$ as a function of temperature. An arrow indicates T_N.

An irreversible transition of the structure took place between 670 and 720°K, which would not be discussed farther.

§ 4. Discussion

Since the electronic orbital level (the $d\gamma$ level) of the Cu^{2+} ion is degenerate in the undistorted crystal structure, the tetragonal distortion of KCuF$_3$ which is observed even above T_N may be attributed to the Jahn-Teller effect arising from Cu^{2+} ion as discussed previously³⁾. The similar distortion of KCrF$_3$ observed by Scatturin et al.⁵⁾ may be attributed to the same origin.

In Table V the crystal distortions below T_N are compared with those of MO system⁹⁾ with rock-salt structure, which have been investi-

Table V. Crystal distortions of MO and KMF$_3$ compounds below T_N.

MnO	FeO	CoO	NiO
rhombo-hedral $\alpha>90°$	rhombo-hedral $\alpha<90°$	tetragonal $a>c$	rhombo-hedral $\alpha>90°$
KMnF$_3$	KFeF$_3$	KCoF$_3$	KNiF$_3$
monoclinic	rhombo-hedral $\alpha<90°$	tetragonal $a>c$	no distortion

The unit cells of MO compounds for rhombohedrally distorted cases are chosen differently from those in the original paper⁹⁾ for comparison with KMF$_3$ compounds gated theoretically by Kanamori[10]. It has also been pointed out by the same another[11] that the distortion in $KFeF_3$ and $KCoF_3$ seems to correspond to that in FeO and CoO.

Table VI. Tolerance factors of KMF_3 compounds.

$KMnF_3$	$KFeF_3$	$KCoF_3$	$KNiF_3$	$KCuF_3$
0.88	0.91	0.92	0.93	0.92

The ionic radii of Ahrens[12] are used.

In Table VI the Goldschmidt's tolerance factor t of KMF_3 system is given conventionally, which is defined by the following relation:

$$R_K+R_F=t\sqrt{2}(R_M+R_F),$$

where R_K, R_M and R_F are the ionic radii. It is known that while structures of the perovskite family occur for values of t down to about 0.8, the ideal cubic structure is found only if t is much closer to unity. The crystal distortion of $KMnF_3$ that occurs at 184°K (far above T_N) may be attributed to the low value of t.

The authors wish to express their hearty thanks to Prof. T. Okada for his continuous guidance and encouragement, to Dr. K. Hirakawa and Mr. T. Hashimoto for supplying the crystals and for discussions, to Mr. T. Fuchikami for collaboration at the beginning of this research, and to Miss K. Hirano for assistance. This investigation was partly supported by the Scientific Research Expenditure of the Ministry of Education.

Anomalous Diffusion at the Interface of Thin Bimetallic Film of Bi and Sb

By Ryōji SUGANUMA, Toshiho YOSHIDA* and Yoshibumi FUJIKI

Institute of Physics, Kyōto Prefectural University of Medicine

(Received November 7, 1960)

The intermetallic diffusion was studied by electron and X-ray diffraction and electrical resistance measurement on vacuum deposited thin bimetallic films of Bi and Sb. The formation of triple-layer, which consisted of two outer layers of Bi and Sb and the intermediate layer of solid solution of the definite composition, was observed in the course of heating in vacuum. Such an anomalous diffusion could not be expected from a usual diffusion couple of bulk specimens. It was found that the degree of such a triple-layer formation depended on the kind and deposition rates of secondary deposits, and the maximum thickness of the intermediate layer attaind by diffusion was confined to a certain limiting value. The defectiveness of films was deduced from electrical resistance measurements, the results of which were related to the triple-layer formation. Tentative explanation and discussions for this were proposed, assuming the existence of some strained intermediate layer of certain thickness where the diffusion rapidly took place.

§ 1. Introduction

At the interface between two metallic films, the interdiffusion and the formation of alloy such as an intermetallic compound or solid solution can be observed in some cases during the successive deposition of two metals[1),2)]. The concentration *versus* distance from the interface for such a bimetallic film immediately after deposition will be such as illustrated by the graph ($t=0$) shown in Fig. 1 (a). In the case where the two metals form a perfect miscible solution, the concentration *versus* distance graph at a time t' ($t'>0$) will follow the form such as shown in Fig. 1 (b) or (b′). The diffraction pattern of the last case will indicate broad bands with sharp edges which correspond to solid solutions of concentrations c_1 and c_2. There seem to be no special compositions other than c_1 and c_2. H. Cramer[3)], however, reported briefly that specimens prepared by the vacuum deposition of very thin layer of Cu on polished Au substrate showed the formation of a solid solution with a definite composition during heating, but no explanation and discussions were given. J. W. Menter[4)] also described that in some circumstances triple layers might be formed consisting of two outer layers of compositions approximating the pure metals and an intermediate layer with a well-defined alloy composition. C. Weaver and R. M. Hill[5)] also proposed the formation of some solid solution for the explanation of his adhesion experiment with thin bimetallic films.

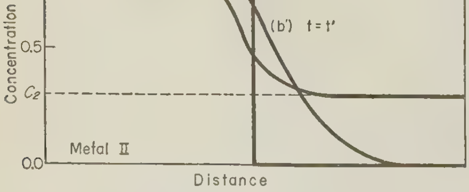

Fig. 1. The concentration *versus* distance curve.

The intermetallic reactions occurring at the interface as mentioned above will intimately be related to the structure and properties of the interface, and the present writers intended to investigate the process of diffusion in thin bimetallic films of Bi and Sb by electron and X-ray diffraction and electrical resistance measurement.

§ 2. Experimental Procedure and Aspects of Diffusion Observed by Electron Diffraction

The specimens were prepared by the successive deposition of Bi and Sb on Formvar

(b) After heating for 5 minutes at about 200°C.
(c) After heating for 10 minutes at about 200°C.
(d) After heating for 15 minutes at about 230°C.
(e) After heating for one hour at about 230°C.
(f) After heating for one hour at about 240°C.
(g) After heating for 6.5 hours at about 240°C.

film in vacuum (about 10^{-5} mmHg). The film thickness was measured by X-ray interference method⁶⁾, using Cu K_α radiation, with a film prepared on a microscopic slide glass at the same time as the specimens for electron diffraction. The thickness of Bi layers was 160∼380 Å and that of Sb 150∼500 Å.

Filaments for evaporation were cylindrical coils of about 15 mm in length and 3 mm in diameter made of W wire of 0.21 mm in diameter. The distance between the substrate and the evaporator was about 6 cm and a shutter of rotating disc-shape made of Al was used during preheating. The condition of vacuum and the geometry of deposition were maintained to be as constant as possible throughout the experiment. The rate of deposition, which had much influence on the results, was about 50∼100 Å/second (rapid deposition) or 0.5∼1 Å/second (slow deposition).

The degree of the formation of intermediate

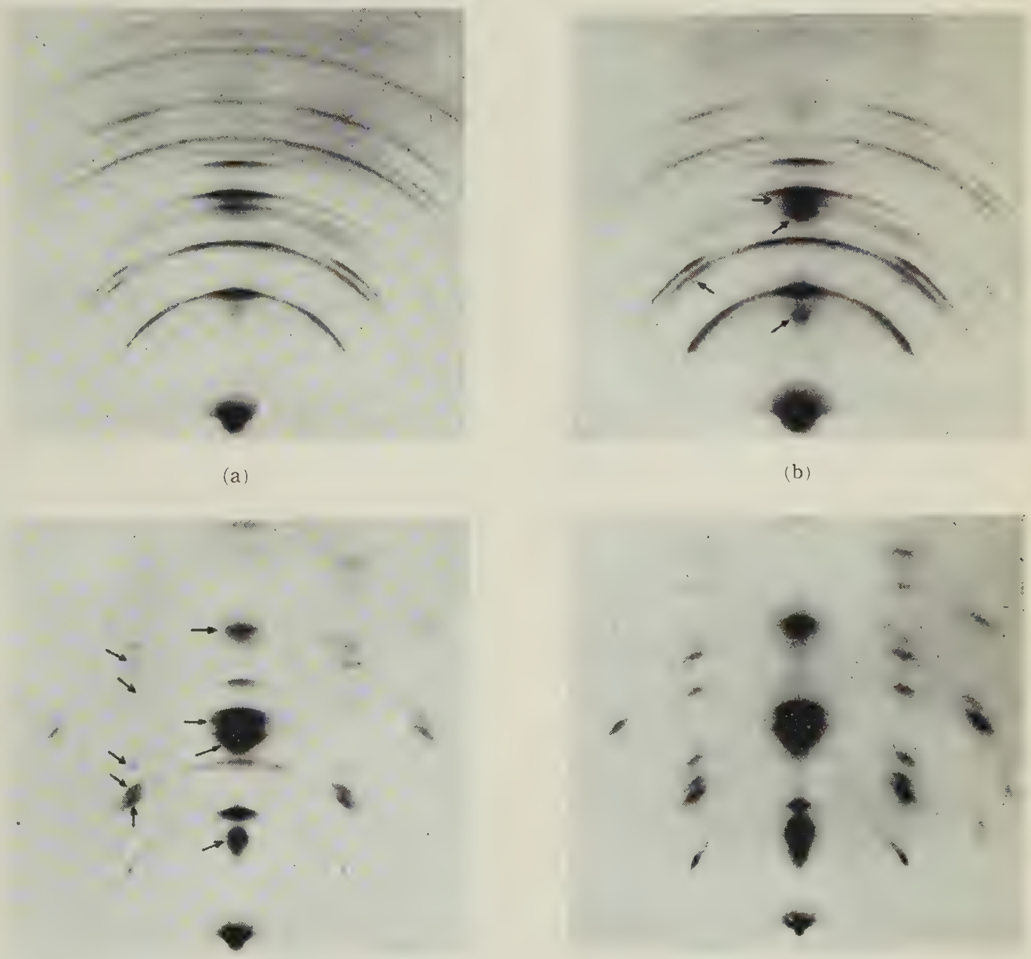
layer with a definite composition by heat-treatment subsequent to the deposition was influenced by the condition of evaporation, which would be described in detail afterwards. Here, the aspects of diffusion, where the triplelayers were formed by heating, will be described in the first place.

An electron diffraction pattern from a specimen prepared by the rapid deposition of Sb on a rapidly deposited Bi under-layer showed a fibre structure of Bi and Sb, whose {111} planes were parallel to the Formvar substrate, and in addition, very weak $\{20\bar{2}\}$ and $\{4\bar{2}\bar{2}\}$ rings of about 50 at. % Bi solid solution appeared as shown by arrows in Fig. 2 (a) (see also Fig. 3 (a)). This specimen did not show any change of its diffraction pattern even after the aging of about three weeks at room temperature. Then the specimen was heated in the diffraction camera and each stage of diffusion was photographed. The pattern did not show any appreciable change



(a) (b)

(c) (d)

Fig. 5. Electron diffraction patterns from the thin Sb film of about 100 Å thick deposited rapidly on the thick Bi layer of about 100 Å thick.

(a) At room temperature. The reflections due to the outer, thin Sb layer alone are observed.

(b) At about 190°C during heating. Weak reflections due to the intermediate layer of solid solution with a definite composition are superposed as indicated by arrows.

(c) After heating for 5 minutes at about 210°C. The reflections due to the intermediate layer are more intense than (b) as indicated by arrows.

(d) After heating for 20 minutes at about 210°C. The reflections due to the Sb layer disappear completely, and those due to the intermediate layer alone are observed.

even after heating for more than 5 hours at about 160°C, but the reflections corresponding to the solid solution of about 50 at. % Bi were sharpened and somewhat strengthened after heating for about 30 minutes at about 180°C.

To maintain the thermal history of all specimens as constant as possible, the heating process was controlled so that it took about 17 minuters for the heating up to about 200°C for all specimens.

After heating for about 5 minutes at about 200～210°C, the reflections due to the intermediate layer became more and more intense without any broadening, while those due to Bi- and Sb-rich solid solutions gradually decreased their intensity but showed no appreciable change of their lattice spacings (Figs. 2 (b), (c) and Fig. 3 (b)). Contrary to the expectation described briefly in § 1, the specimen at this stage is in the state of the triple-layer which is composed of the two outer layers of almost pure Bi and Sb and the intermediate layer of a solid solution with the definite composition.

After heating for about one hour at about 230～235°C, the diffuse scattering was superposed on the ring pattern, and at the same time, the appreciable changes of lattice spacings and intensity of the Bi- and Sb-rich solid solutions could be detected. While, those of the intermediate layer of about 50 at. % Bi solid solution did not show any appreciable change (Figs. 2 (d) and (e)). This indicates that the overall diffusion of usual type became pronounced at this temperature. The change of lattice spacing was greater for the Sb-rich solid solution than for the Bi-rich one, and therefore it was deduced that the diffusion of Bi into the Sb-rich solid solution was greater than that of Sb into Bi-rich one and consequently the net flow of atoms took place from Bi-rich solid solution side to Sb-rich one. Some considerations on this point will be given in § 6.

After the above-mentioned stage, the diffuse rings corresponding to the solid solution with varying lattice constants resulted from further heating (Fig. 2 (f)). Then, after heating for about 6.5 hours at about 235～240°C, the diffusion was almost complete and the diffraction pattern gave the sharp rings corresponding to the definite solid solution (Fig. 2 (g)).

§ 3. Effects of the Order of Successive Deposition and the Rate of Deposition on the Diffusion Process

The aspects of progress of diffusion during heat-treatment were greatly influenced by the

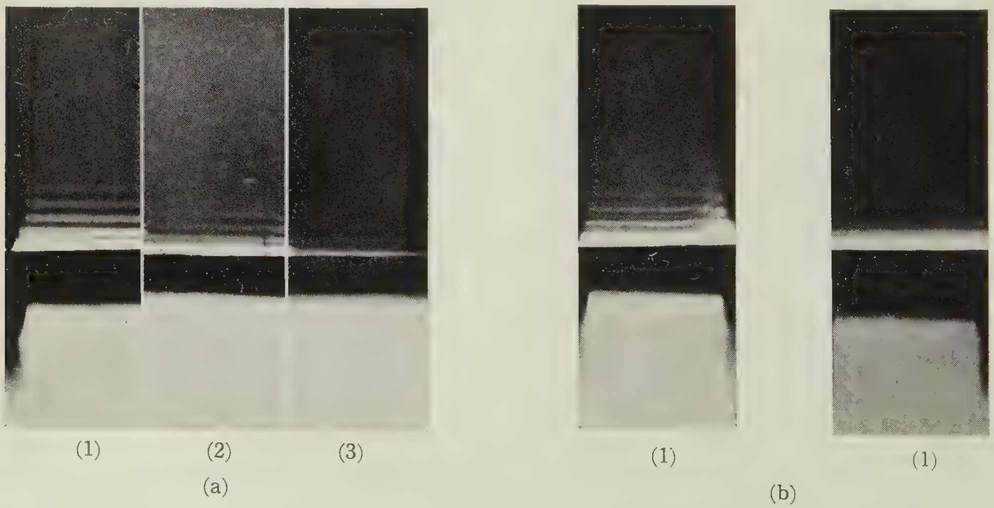


Fig. 6. Photographs obtained by X-ray interference.

(a) (1) Bi film of about 297 Å deposited rapidly.
(2) Sb film of about 302 Å deposited rapidly.
(3) Sb film of about 264 Å deposited slowly.
(b) (1) Double film of Sb (302 Å) deposited rapidly on rapidly deposited Bi under-layer (297 Å).
(2) Double film of Bi (256 Å) deposited rapidly on rapidly deposited Sb under-layer (240 Å)

Table I.

Type of specimen	Primary deposit		Secondary deposit		Temperature at which interdiffusion becomes most pronounced	Degree of triple-layer formation
	Kind	Deposition rate	Kind	Deposition rate		
I	Bi	rapid	Sb	rapid	∼200°C	most pronounced
II	Bi	slow	Sb	slow	∼240°C	
III	Sb	rapid	Bi	rapid	∼220°C	less than above two
IV	Sb	slow	Bi	rapid		
V	Sb	rapid	Bi	slow	∼245°C	not observed
VI	Sb	slow	Bi	slow		

order of successive deposition and the rate of deposition, and specimens are classified in several types. These are summarized in Table I.

(Type I) The results obtained for the specimens of this type were described in the previous paragraph.

(Type II) The specimens prepared by the slow deposition of Sb on the slowly deposited Bi under-layer also exhibited the formation of intermediate layer during heating, but its formation temperature was found to be about 240°C, which was higher than for the case of Type I (200∼210°C), and the considerable overall diffusion took place simultaneously.

(Type III) The Sb layer evaporated rapidly on Formvar film showed a strong perferred orientation as shown in Fig. 4 (a), and this orientation could not be destroyed by the rapid deposition of Bi on it. Examining the spotty arc pattern from the double films and the almost one-to-one correspondence of individual spots, it was supposed that the minute crystallites of Bi and Sb orientate parallel to each other not only in their crystallographic planes but also in their crystallographic directions (see Fig. 4 (b)). Further, many reflections due to double diffraction could be found in this case. The correspondence between individual spots in the reflections due to the intermediate layer of the definite solid solution and those of Bi- and Sb-rich solid solutions is not so perfect as that seen in the case of Bi and Sb. This means that the crystallites of the intermediate layer are not oriented perfectly parallel to those of Bi- and Sb-rich solid solutions. Considering, in addition, that the Debye rings due to the intermediate layer observed with the specimens of Type I are coarser than those due to Bi and Sb (Fig. 2), it will be recognized that the appreciable grain growth can arise in the process of the intermediate layer formation.

The heating at about 220°C for about 10 minutes of these specimens resulted in the formation of triple-layer as shown in Fig. 4 (b). This temperature was slightly higher than that for the films of Type I, and the maximum intensity of reflections due to the intermediate layer attained by heating was somewhat weaker than that for the cases of Types I and II. Further heating for about 20 minuites at about 240°C resulted in the superposition of diffuse lines, and subsequent change was almost the same as that for Type I.

(Type IV) When Sb was deposited slowly on Formvar film, the ring pattern was caused in most cases. After the rapid deposition of Bi on it and subsequent heating at about 220°C, however, the formation of triple layers could be observed just like in the case of Type III.

(Types V, VI) Whenever the secondary Bi deposits were slowly formed, the intermediate layer of the definite composition could never be detected independently of the deposition rate of primary deposits, and the usual overall diffusion as shown in Fig. 1 (b) took place at about 245°C.

The results described above may be summarized as follows:

(1) The specimens of Types I and II seem to indicate the initial alloy formation at the interface during the deposition of secondary

Sb metal, although, in the case of Type II, the reflections due to this initially formed alloy can be detected only occasionally. While, the specimens of any type other than Type I or II never show the existence of such an alloy before heat-treatments. However, it will be likely that there exists a very thin layer of alloy at the interface which cannot be detected by electron diffraction in these cases.

(2) The formation of triple-layer during heating is most pronounced for the specimens of Types I and II and less pronounced for those of Types III and IV, while Types V and VI do not show any triple-layer formation. This is the same sequence as for the initial alloy formation during deposition.

(3) From Table I, it may be deduced that the degree of triple-layer formation depends not on the kinds and deposition rates of primary deposits but on those of secondary deposits.

(4) The temperatures at which the interdiffusion becomes much pronounced can be classified into two groups with the deposition rate of Bi, namely, about 200∼220°C for the specimens of Types I, III and IV where Bi is rapidly deposited, and about 240∼250°C for those of Types II, V and VI where Bi is slowly deposited.

(5) In addition, contaminations of the surfaces of under-layers due to the adsorption of some impurities were found to hardly affect the aspects of diffusion, from the fact that the exposure to air before the second deposition had no effect.

Discussions on these results and some additional informations will be given in §§ 6 and 7.

§ 4. Effects of the Film Thickness on the Diffusion Process

4-1. *Effects of the relative thickness of double film*

To investigate whether the relative thickness of double layers affects the thickness of the intermediate layer formed by heating or not, observations with electron diffraction by the reflection method was carried out, because no appreciable effects could be found within the thickness range where the transmission method was applicable. The thick Bi layer of about 1000 Å in thickness was rapidly deposited on a glass substrate and then the thin Sb layer of about 100 Å was also rapidly deposited on it. The specimen exhibited only the reflections due to the outer, thin Sb layer at room temperature (Fig. 5 (a)), but the weak reflections due to the intermediate layer of about 50 at. % Bi solid solution were superposed on them by subsequent heating in vacuum (Fig. 5 (b)). The reflections due to this layer became more and more intense, while those of Sb-rich solid solution gradually diminished their intensity (Fig. 5 (c)) and finally disappeared after continued heating at about 210°C (Fig. 5 (d)). Again, the formation of the layer of the definite solid solution was seen in this case. This definite solid solution did not show any appreciable change in its lattice constant and intensity during the prolonged heating at about 230°C, and so it was deduced that in this stage the surface of thick Bi layer was covered by the thin layer of the solid solution of the definite composition and further diffusion was almost interrupted.

4-2. *Effects of the total thickness of composite film*

To investigate whether the thickness of the definite solid solution increases or not with the change of total thickness of bimetallic film, some additional experiment by X-rays was performed with the very thick films. The layer of Bi of about 5000 Å in thickness and that of Sb of about 6000 Å were rapidly deposited on a microscopic slide glass successively. The specimens sealed in Pyrex tube in vacuum were heated at various temperatures for various time intervals, and then they were examined by X-rays. The reflections due to Bi and Sb began to change positions after heating for about 10 minutes at about 210°C, showing the change of their lattice spacings, while those due to the layer of the definite composition could never be detected even after prolonged heating.

It is suggested consequently that the thickness of the intermediate layer of the definite composition is not so thick as it can be detected by X-rays but confined to some limiting value where the transmission electron diffraction can be applicable.

The results described in this paragraph will be discussed in § 7.

§ 5. Some Considerations on the Geometrical Structure of the Interface

In § 3, it was described that the formation of triple-layer was appreciably affected by the kinds and deposition rates of secondary deposits. What might be affected by these factors would be, in the first place, the geometrical structure[7),8)] such as grain size, boundaries or porosities etc., in the second place, the stress involved within thin films or defects such as various imperfections[7)]. In the present problem, it seemed very difficult to obtain direct informations about the metal-metal interface, so that we had no other means than to deduce the structure and properties of the interface from those of the individual layer. In this paragraph, some considerations on the first factor will be given.

Some qualitative informations could be obtained from the X-ray interference with thin films which was performed for the determination of film thickness. In the first place, the number of visible interference fringes may be considered to be a measure for the roughness of film surface if it is compared among the films of almost the same thickness. The number of interference fringes observed for the rapidly deposited Sb layer was much less than that for the rapidly deposited Bi layer of almost the same thickness (Figs. 6 (a) (1) and (2)), though the absorption of X-rays was less for the former than for the latter. Consequently, the roughness of the former surface should be greater than the latter. Comparing the slowly deposited Sb film with the rapidly deposited one, the roughness of the former surface seemed to be greater than that of the latter (Figs. 6 (a) (2) and (3)). This is consistent with the results of electron microscopy obtained by E. Cremer and E. Ruedl[8)]. While, the layer of Bi was found to be considerably smooth independently of their deposition rates. It was also found that the surface of outer layer of composite film, irrespective of their kinds and deposition rates, was always smooth even if the surface of under-layer was considerably rough. This was deduced from the facts that many, clear interference fringes could be observed for composite films.

In the second place, the smoothness of interface of composite films can be deduced from an anomalous intensity distribution of interference fringes detected for these composite films, because X-rays reflected partially at the smooth interface will modify the intensity distribution of interference fringes due to the double film as a whole. Considering that such an anomaly could always be detected for the films of Sb deposited on Bi irrespective of their deposition rates, the interface of Sb and Bi under-layer was considered to be smooth. While, the interface of the film of Bi deposited on the slowly deposited Sb under-layer would be considerably rough because the anomaly could never be found. The interface of the film of Bi deposited on the rapidly deposited Sb under-layer would be intermediate in its roughness between the above two cases, because the anomaly could be detected sometimes and the surface of rapidly deposited Sb under-layer was smoother than that of slowly deposited one as described above (Figs. 6 (b) (1) and (2)).

The roughness of interface deduced from these facts depends on the kinds and deposition rates of primary deposits, but not on those of secondary deposits on which the degree of triple-layer formation depends, as shown in § 3. Consequently, no direct relations can be found between the structure and the triple-layer formation.

§ 6. Electrical Resistance Measurement

The electrical resistance measurement was performed in relation to the second factor mentioned in the previous paragraph. The layer of about 400 Å in thickness of Bi or Sb was rapidly or slowly deposited on a microscopic slide glass cut in the dimension of about 30 mm in length and 3.5 mm in width. The leads of Cu foils were soldered on each end where Pt electrodes were prepared by the baking of platinium chrolide solution. The electrical resistance was measured in vacuum by the Wheatstone bridge during aging at room temperature or at subsequent isochronal annealing. The rapid heating and cooling were necessary for the isochronal annealing by pulse heating. The heating, therefore, was performed in vacuum by heat radiation from W coil placed at a distance of about 15 mm from the specimen. The heating coil was wound so carefully that the temperature gradient along the long dimension of specimen became as small as possible and consequently the temperature difference between each end and the mid point of specimen was estimated to be within 1～2°C. The temperature of specimen was measured by Chromel-Alumel thermocouple. The heating to appropriate temperatures could be done within 30 seconds～one minute by manual controlling of heater current. The time interval of about 10 minutes was necessary for the complete cooling to room temperature, but that required for the cooling to about 50°C was within about 2 minutes.

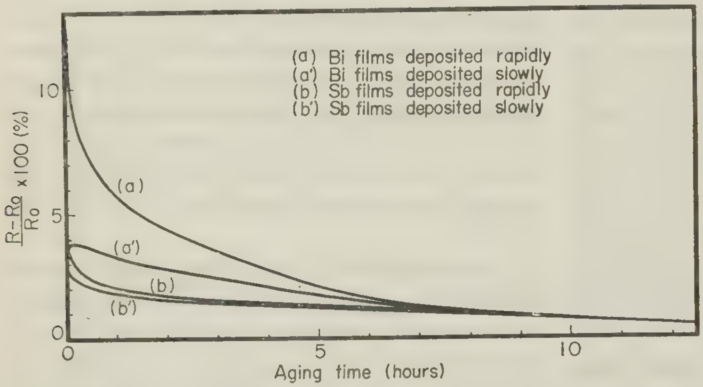

Fig. 7. The percentage decrease in electrical resistance of thin films during the room temperature aging.

The results obtained from the room temperature aging are shown in Fig. 7. The values of $100(R-R_0)/R_0$ are plotted against the aging time, where R is the measured resistance, and R_0 the resistance after the aging of about 24 hours, being nearly constant during subsequent aging. After these measurements, the isochronal annealing was made by the pulse heating for 5 minutes at each temperature. The electrical resistance after each pulse annealing was measured at room temperature and calibrated to the values at 30°C. These results are shown in Fig. 8, taking $100(R-R_0)/R_0$ as the ordinate and the annealing temperature as the abscissa, where R_0 is the same as shown in Fig. 7 and R the calibrated resistance at 30°C.

The percentage decrease in resistance during the room temperature aging shows a marked dependence on the deposition rate. The decay of electrical resistance of vacuum deposited thin films is usually considered to be due to the decay of imperfections[7),9)], and so the less percentage decrease in resistance for the slow deposition rate than for the rapid deposition rate seems to indicate that the decay of mobile imperfections in the slowly deposited films has already begun during deposition[9),10)]. More appreciable decay than the above is seen for the subsequent isochronal annealing as shown in Fig. 8. The decay for the Bi layer is greater for the rapidly deposited one than for the slowly deposited one, while the decay for the Sb layer shows almost the same tendency for both the rapidly and slowly deposited ones. Further, the decay for the Sb layer is much greater than for the Bi layer, which means that the lattice defects are much for the former than for the latter. This is consistent with the results obtained by H. D. Murbach and H. Wilman[11)] by means of stress measurement with thin films. The cause of resistance increase observed for Bi layers as shown in Fig. 8 is not clear in the present stage of investigation.

The results obtained from electrical resistance measurement may be summarized as follows:

(1) The results suggest that the rapidly deposited or slowly deposited Sb layer is most defective, the rapidly deposited Bi layer next defective and finally the slowly deposited Bi layer least defective. This sequence of defectiveness, applying to the secondary deposits of double films, agrees well with the sequence of initial alloy formation during deposition or triple-layer formation during heating as described in § 3.

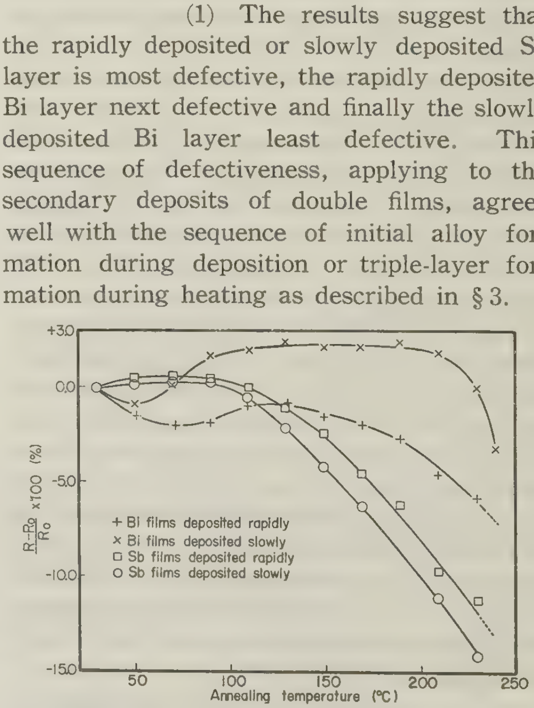

Fig. 8. The percentage decrease in electrical resistance of thin films during the isochronal annealing.

(2) If it is assumed that the interdiffusion in the present bimetallic films is influenced to some extent by vacancies, the net flow of such vacancies will be considered to arise from Sb side to Bi corresponding to the net flow of atoms from Bi side to Sb (§2). It is deduced from Fig. 8 that vacancies are richer in Sb layer than in Bi layer, and therefore, the concentration gradient responsible for such a flow can be expected.

(3) The temperature at which the mobility of imperfections is much increased is about 110∼120°C for the rapidly or slowly deposited Sb layer, about 140°C for the rapidly deposited Bi layer and about 200°C for the slowly deposited Bi layer (Fig. 8). These temperatures should be related to those at which the interdiffusion in double layers becomes much pronounced. The flow of vacancies from one layer to another is necessary for the interdiffusion to take place and the temperature for such a flow to occur may be determined by the temperature at which the vacancies begin to decay in Bi films, because this temperature is higher for Bi films than for Sb ones. Consequently the pronounced interdiffusion is expected to occur at about 140°C for the composite films of Sb and rapidly deposited Bi or about 200°C for those of Sb and slowly deposited Bi, independently of the deposition rate of Sb and the order of successive deposition. While, the temperatures determined by electron diffraction were about 200∼220°C for the former films and about 240∼250°C for the latter ones, as summarized in §3. The general tendency observed by electron diffraction such that the appreciable diffusion takes place at lower temperature for the former (200∼220°C) than for the latter (240∼250°C), coincides with the tendency deduced from the decay of resistance (140°C for the former and 200°C for the latter), but there exists quantitative disagreement between the observed and the deduced temperature in each of the two cases.

Discussions on these results will be given in the next paragraph.

§7. Discussions and Summary

(1) As mentioned in §1, Cramer[3)] observed the same phenomenon for the specimen of thin Au layer deposited on polished Cu as for the composite films of Bi and Sb. Menter[4)] also reported the observation of triple-layer formation in his experiment concerning the Moiré pattern. Although none of them gave any explanation or discussion on thier observations, this phenomenon seems to be a general tendency for thin bimetallic films prepared by vacuum deposition and not particular for the case of Bi and Sb.

(2) Though the clear-cut explanation seems to be difficult in the present stage, the triple-layer formation may be interpreted tentatively by the assumption that the intermediate layer of a certain thickness is separated from two outer layers by some condition, which may be realized by assuming the hightly strained intermediate layer. The very thin layer of solid solution, which was sometimes difficult to be detected, was already formed at the interface of double films during the successive deposition of constituent metals before heating as described in §§2 and 3. This initial alloy formation may be due to the defects in the evaporated metallic films and the latent heat of vaporization of secondary deposit as discussed in the previous papers[2)]. This initially formed layer, whose lattice constant is different from those of upper- or under-layer, may exert the stress on its surroundings and develop the strained layer of a certain thickness. It may be allowed to consider that the relative thickness of the upper and under strained layers is always constant irrespective of the total and the relative thickness of the bimetallic film as a whole, and further the diffusion takes place very rapidly in the intermediate layer including both the initially formed alloy layer and these strained layers, and therefore the state of homogeneous solid solution with the definite composition will be attained very rapidly in this intermediate layer in the early stage of heating. Consequently the triple-layer may be formed.

This assumption may be supported not only by the facts which will be described in (3) and (4), but also by the study of adhesion performed by C. Weaver[5)]. He reported that the values of adhesion obtained for two-layer films of Ag–Pb, Al–Pb and Ag–Cr, which had no miscibility in the solid state at room temperature, were only slightly greater than for the under-layer (Pb or Cr) alone, while the abnormally high adhesion was obtained for the bimetallic films of Cu–Cr and Au–Cr, in which the miscibility of two metals exists in Cu-, Au- or Cr-rich side. Explanation for this high adhesion was given by Weaver on the basis of the formation of a harder, strained intermediate layer at the metal-metal interface, which was due to the formation of a layer of solid solution of somewhat different lattice spacing, causing a resultant strain.

(3) If such a strained intermediate layer exists in the present case, its extent will depend upon the thickness of the alloy formed during deposition, but not upon the thickness of upper-or under-layer itself.

(a) Consequently, in the first place, the thickness of the intermediate layer formed by heating should be confined to such a strained layer of a definite thickness and not increased by the increase of total film thickness. This was actually confirmed by the X-ray diffraction with thick films and by the reflection method of electron diffraction with the specimen of thin Sb layer deposited on thick Bi film, as shown in § 4.

(b) In the second place, the maximum intensity of diffraction rings due to the intermediate layer attained by triple-layer formation should be related to the thickness of the initially formed alloy at the metal-metal interface during successive deposition. As described in § 3, the degree of triple-layer formation is classified into three cases by the kinds and deposition rates of secondary deposits, namely, the most pronounced degree for the films of rapidly or slowly deposited Sb with Bi under-layer (Types I and II), the less pronounced degree for those of rapidly deposited Bi with Sb under-layer (Types III and IV) and the never detected formation for those of slowly deposited Bi with Sb under-layer (Types V and VI). This sequence was found to be just the same as that of the degree of the initial alloy formation (§ 3) and also that of the degree of the defectiveness involved in secondary deposits (see (1) in § 6). These facts will support the assumption considered above.

(4) Finally, some additional support for the assumption stated in (2) may be obtained from the consideration on the discrepancy between the temperature at which appreciable diffusion actually occurs and that deduced from electrical resistance measurement. The former temperature was found to be about 200～210°C for the films of Types I, III and IV or about 240～250°C for those of Types II, V and VI from the results obtained by electron diffraction, while the latter one was estimated to be about 140°C or about 200°C in each case. The discrepancy of about 50°C can be found. If the vacancy mechanism is responsible for the interdiffusion in the present case, the facts that the interdiffusion doe not yet occur at 140° or 200°C though the imperfections such as vacancy in each upper- or under-layer are mobile at these temperatures will probably suggest that vacancies in the intermediate layer may be trapped, for example, at the concentrated dislocations which will be responsible for the structure of the highly strained layer connecting the initially formed layer of solid solution and the upper- or under-layer of pure metal[12]. The activation energy for such trapped vacancies may be greater than for those in upper- or under-layer, and therefore they can hardly decay at 140°C or 200°C. When the temperature is raised to about 200～210°C or about 240～250°C, the vacancies concentrated in the strained region become movable and appreciable diffusion occurs in this strained region, while most of the vacancies in the unstrained upper- and under-layers have already been decayed and the diffusion rate in these layers are much less than that in the intermediate layer. Consequently, the interdiffusion of metals will rapidly take place in the intermediate layer at these temperatures, resulting in the formation of triple-layer. Further, the fact that the appreciable grain growth can be observed in the formation process of the intermediate layer with the definite composition as described in § 3 seems to suggest that the strained intermediate layer mentioned above will play an important role for the triple-layer formation.

For the specimens of Types V and VI, such a triple-layer formation could not be detected. However, these specimens may be considered to be the simple double-layer formed by the superposition of two metals without any intermetallic reactions at the metal-metal interface and to resemble rather the sintering of fine powders of Fe and Cr[13], or the usual diffusion couple of bulk specimens. Accordingly, the strained intermediate layer in these cases, even if it exists, would be confined within the metal-metal interface itself and sufficiently thin for the detection by electron diffraction.

Electrical Properties of Heavily Doped *n*-Type Germanium

By Yoshitaka FURUKAWA
The Electrical Communication Laboratory,
Musashinoshi, Tokyo

(Received November 12, 1960)

Experimental studies were made on electrical resistivity, Hall coefficient and magnetoresistance of *As*- *Sb*- and ($As+Sb$)-doped germanium in the electron concentration range of (10^{18}～$3\times10^{19}\,\mathrm{cm}^{-3}$). The mobility difference between *As*- and *Sb*-doped germanium has been observed at room temperature. This difference seems to be related with the difference in the ionization energy of group V elements. From the present experiment, it has been concluded that in heavily doped germanium, interaction between electron and ionized impurity should be treated as short range force instead of Coulomb force owing to the fairly large screening effect, and as the result the nature of the core of impurity influences directly upon the impurity scattering.

§1. Introduction

Electrical properties of non-degenerate *n*-type germanium containing shallow impurities such as *P*, *As*, *Sb* have been investigated extensively by many authors. One of their result is that the ionization energy of the impurities depends on the impurity concentration as well as the specific element. Therefore the impurity dependence of electrical properties of germanium containing these impurities was observed clearly at low temperatures. However in temperature range where all donors are ionized completely and scattering is mainly due to lattice vibration, the electrical resistivity of germanium is independent substantially on the specific element in group V.

On the other hand, many investigations have been made on heavily doped *n*-type germanium. Lark-Horovitz[1] measured resistivity ρ (ohm-cm) and carrier concentration n (cm^3) at low temperatures and found the approximate validity of the relation $\rho=6270\,n^{-1/3}$ which was deduced from Conwell-Weisskopf formula taking into account Fermi statistics. Bowers[2] measured magnetic susceptivility and Pollack[3] measured piezoresistance. They concluded that four-ellipsoid model is accepted in heavily doped n-type germanium and there is no substantial change in curvature of the conduction band for energies up to 0.08 eV above the band minimum. Goldberg[4] measured magnetoresistance and showed that the symmetry condition $b+c=0$ is satisfied with uncertainty of 30%. These experiments were made on *As*- and *P*-doped germanium.

However, in recent years Esaki-diode was discovered and in its current-voltage characteristics at low temperatures, phonon assisted tunneling[5] was observed in *Sb*- doped junctions of germanium, but not in *As*- and *P*-doped junctions. In addition, the author[6] observed the mobility difference between *As*- and *Sb*- doped germanium at room temperaperature. These results indicate that specification of the kind of impurity is necessary for discussing the electrical properties of heavily doped n-type germanium at room temperature even for the elements in group V.

This paper describes the experimental studies on the impurity dependence of the electrical properties (resistivity, Hall coefficient, and magnetoresistance) of heavily doped n-type germanium.

§ 2. Sample Preparation and Experimental Method

As-, *Sb*- and (*As*+*Sb*)- doped single crystals were grown by pulling from the melt in [100] direction, using the pulling rate of about 7 μ/sec and rotation of about 50 r.p.m. The crystals were sliced perpendicular to the long axis of the single crystals and the bridge shape samples were prepared by using a ultrasonic tool. The samples suitable for making magnetoresistance measurements were prepared by cutting thin plates as shown in Fig. 1. In these samples, the current direction deviates from [100] axis to [010] axis by 22.5°. In cutting the samples, crystal axis was determined optically and confirmed by electron diffraction analysis.

A conventional D.C. method was used for the measurements of resistivity, Hall coefficient and magnetoresistance. The magnetoresistance constant b, c and d are defined in Eq. (1).

$$\frac{\Delta\rho}{\rho H^2}=b+c\frac{(\boldsymbol{I}\cdot\boldsymbol{H})^2}{I^2H^2}+d\frac{\sum_{i=1}^{3}I_i^2H_i^2}{I^2H^2}\,. \qquad (1)$$

In this equation ρ is the resistivity and $\boldsymbol{I}$ and $\boldsymbol{H}$ are the current density and magnetic field respectively. When the angle θ is measured as shown in Fig. 2, Eq. (1) is expressed in the following form.

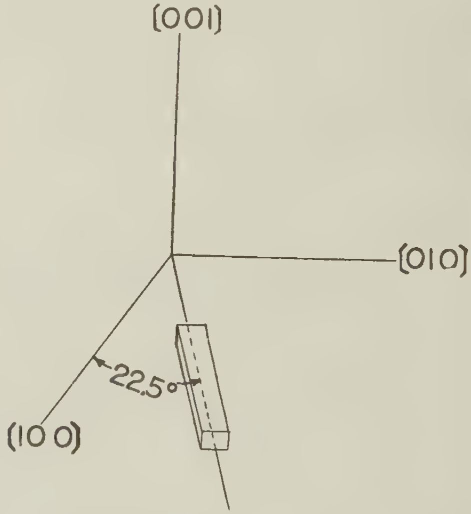

Fig. 1. Cutting direction of samples for measurement of magnetoresistance effect. The crystals were pulled in [001] direction in this figure.

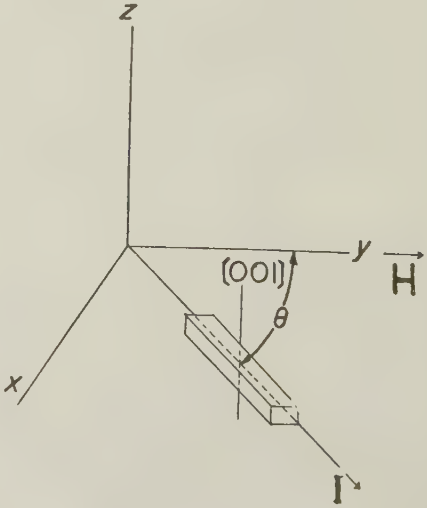

Fig. 2. Position of the samples in magnetic field for the measurement of magnetoresistance.

$$\frac{\Delta\rho}{\rho H^2}=\left(b+\frac{c+d}{2}\right)+\frac{1}{2}\left(c^2+cd+\frac{d^2}{2}\right)^{1/2}\cos(2\theta+\alpha)$$

$$\tan\alpha=\frac{d}{2c+d}\,. \tag{2}$$

Therefore the amplitude, the mean value and the angle $\theta_{\min}$ for the minimum of $\Delta\rho/\rho H^2$ determine b, c and d. This method[7] has the following advantages in the present experiment. (1) All magnetoresistance constants are determined by one rotation of samples in magnetic field. (2) $\theta_{\min}$ is related directly with the ratio c/d so that comparison of magnetoresistance constants of *As*- and *Sb*- doped germanium is made easily.

§ 3. Experimental Results

(a) *Resistivity, Hall Measurements*

Resistivity and Hall measurements were made at 300°K. Magnetic field of 5000 oersteds was used for the Hall measurements. Electron concentration n (cm^{-3}) was calculated by using the relation $n=1/Re$. Where R is the Hall coefficient and the factor[8] arising from the band structure *etc* was neglected in this relation.

Fig. 3 shows *n versus ρ* curves for *As*- and *Sb*- doped germanium. Electron mobility in Sb- dopted germanium is higher than that in *As*- doped germanium. In this figure the experimental points for samples with higher *As* concentration deviate from this straight line to high resistivity side. Such deviation has not been observed in *As*- doped crystals pulled in [111] direction[6] and in *Sb*- doped crystals pulled in [111] or [100] direction. This may be due to anomalous precipitation of *As* or other lattice defects.

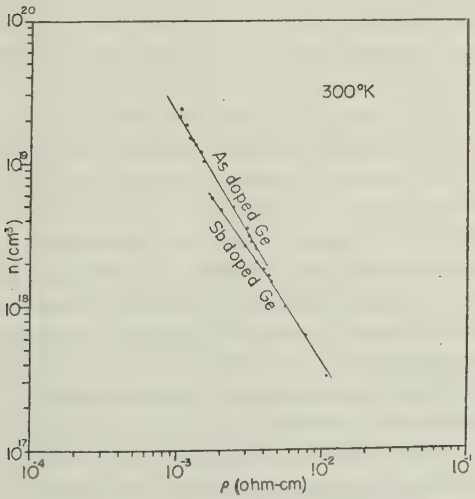

Fig. 3. Resistivity *versus* electron concentration curves for *As*- and *Sb*- doped germanium at 300°K

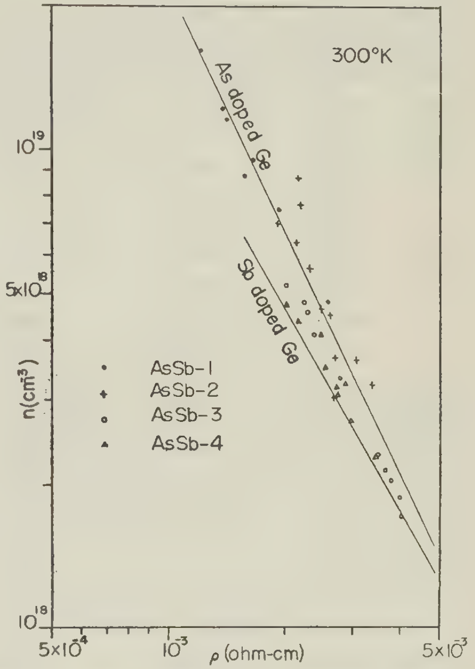

Fig. 4. Resistivity *versus* electron concentration relations for (*As*+*Sb*)- doped germanium at 300°C.

Fig. 4 shows *n versus ρ* relations for the samples containing *As* and *Sb* simultaneously. The straight lines in this figure are the same shown in Fig. 3. Concentration of each impurity in the samples was estimated as follows. In the first place, *As*- doped single crystals were grown and *As* concentration at several points along the pulling direction was determined by measuring the Hall coefficient. Then the crystals were re-melted with *Sb*. Again single crystals of nearly equal size as the original crystals were pulled in [100] direction. Distribution of *As* in the crystals thus obtained was assumed to be same as in original crystals. As concentration estimated at the top of the crystals (seed side) and at the tail where single crystal breaks is shown in Table I.

Table I. *As* concentration estimated from distribution of *As* in the original crystals.

Crystal	*As* Concentration at the top (cm^{-3})	n at the top (cm^{-3})	*As* Concentration at the tail (cm^{-3})	n at the tail (cm^{-3})
AsSb-1	$\sim 2\times 10^{18}$	4.8×10^{18}	$\sim 10^{19}$	1.6×10^{19}
AsSb-2	$\sim 5\times 10^{17}$	3.0×10^{18}	$\sim 3\times 10^{18}$	8.7×10^{18}
AsSb-3	$\sim 10^{17}$	1.7×10^{18}	$\sim 10^{18}$	5.2×10^{18}
AsSb-4	$\sim 2\times 10^{17}$	2.3×10^{18}	$\sim 6\times 10^{17}$	4.7×10^{18}

	No 5	2.37	4.0	1.2	3.6	0.25	0.24
	No 11	3.78	2.0	0.5	1.6	0.24	0.35
	No 17	3.93	1.7	0.4	0.9	0.31	−0.1
AsSb-4	No 6	3.47	2.3	0.36	2.1	0.15	0.31
	No 12	2.54	3.5	0.62	4.4	0.12	0.16
	No 14	2.50	4.1	0.69	4.4	0.14	0.54
	No 16	2.19	4.4	0.78	3.6	0.18	0.2

Impurity concentration was also determined by spectroscopic analysis. Procedure of this analysis is as follows. Standard samples with different electron concentration were selected from *As*- and *Sb*- doped crystals. Using the standard samples working curves for *As* and *Sb* were drawn by plotting blackness of *As* and *Sb* spectrum lines on the photographic plate against electron concentration determined from the Hall measurements. Concentration of each impurity in $(As+Sb)$-doped samples was determined by measuring the blackness of *As* and *Sb* spectrum lines and comparing it with the working curves. Result is shown in Table II. However this result is not so accurate because the assumption that the impurity concentration is equal to the electron concentration was used in drawing the working curves. The sum of *As* and *Sb* concentration shown in Table II is almost always higher than electron concentration obtained from the Hall measurement. This difference may be due to the precipitation of impurities in the samples.

In Fig. 4 the experimental points for samples with large r, where r is defined by $r=$ *As* concentration/sum of *As* and *Sb* concentrations, lie on *As*- doped line while those for samples with small r lie on *Sb*- doped line. The behavior of transition of experimental points from *Sb*- doped line to *As*- doped one with increasing r will be clearly observed if $(\rho-\rho_{Sb})/(\rho_{As}-\rho_{Sb})$, where ρ_{As}, ρ_{Sb} and ρ (hereafter) are the resistivity of *As*- *Sb*- and $(As+Sb)$- doped germanium, is plotted against r for a fixed electron concentration. However in the present experiment it is difficult to draw such curve because of lack of data for fixed value of n.

In Fig. 5 $(\rho-\rho_{Sb})/(\rho_{As}-\rho_{Sb})$ is plotted against

r for specimens with various electron concentration. Though the dotted curve in this figure will have no physical meaning unless $(\rho-\rho_{Sb})/(\rho_{As}-\rho_{Sb})$ is independent on n, it is shown clearly that the transition of experimental points occurs sharply at $r \approx 0.2 \sim 0.5$ in the concentration range of $n > 10^{18}\,\mathrm{cm}^{-3}$.

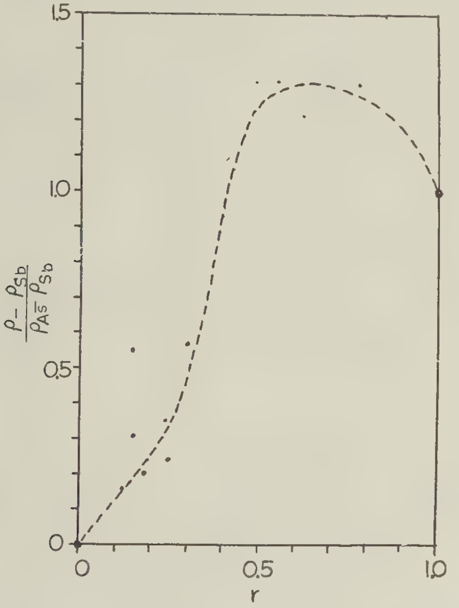

Fig. 5. $(\rho-\rho_{Sb})/(\rho_{As}-\rho_{Sb})$ *versus* r relations.

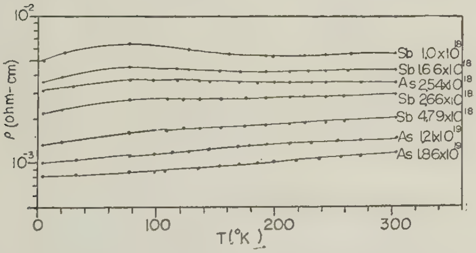

Fig. 6. Temperature dependence of the resistivity for *As*- anp *Sb*- doped germanium.

Fig. 6 shows a typical example of temperature dependence of resistivity of *As*- and *Sb*-doped germanium. The resistivity of the samples with $n > 3\times10^{18}\,\mathrm{cm}^{-3}$ decreases monotomously with decreasing temperatures, while the resistivity of the samples with $n < 3\times10^{18}\,\mathrm{cm}^{-3}$ has a maximum in measured temperature range (4.2°K~300°K).

(b) *Magnetoresistance Measurements*

Magnetoresistance effect of heavily doped germanium was so small that magnetic field of 8500 oersteds was used for this experiment. This magnetic field strength satisfies still the weak field condition. Accuracy of this measurement is lower than that of resistivity and Hall measurements because of appearance of fairly large noise in voltage drop across the resistivity probes.

Fig. 7 shows a typical example of angular dependence of magnetoresistance for *As*- and *Sb*- doped germanium at 300°K Results for $(As+Sb)$- doped germanium are shown in Fig. 8. The minimum of magnetoresistance appears at about 60° for *As*- doped samples

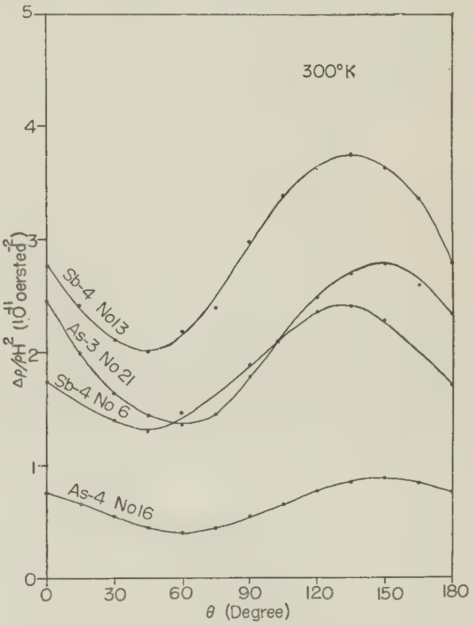

Fig. 7. Angular dependence of magnetoresistance for *As*- and *Sb*- doped germaninum at 300°K. Magnetic field of 8500 oersted was used.

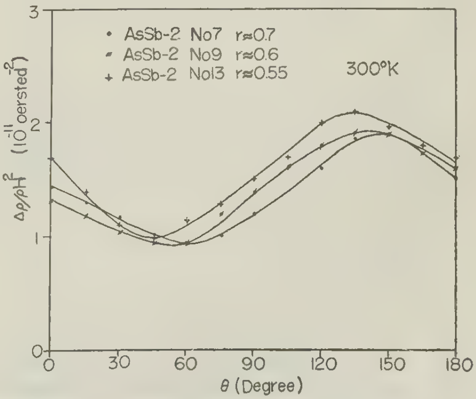

Fig. 8. Angular dependence of magnetoresistance for $(As+Sb)$- doped germanium. $\theta_{\min}$ increases with increasing r from about 45° to about 60°.

Table III. Magnetoresistance of n-type germanium at 300°K.

Crystal	Sample	Resistivity (10^{-3} ohm-cm)	Electron concentration (10^{18} cm^{-3})	Magnetoresistance constant		
				b	c (10^{-11} oersted^{-2})	d
As-3	No 21	3.67	2.4	1.13	−0.51	2.41
As-4	No 16	1.44	12	0.31	−0.18	0.85

	No 19	2.68	3.0	1.27	−1.15	2.3

and at about 45° for *Sb*-doped samples. For (*As*+*Sb*)- doped samples $\theta_{\min}$ is equal to about 45° for the samples with small r, increases with increasing r, reaches about 60°. However the transition of $\theta_{\min}$ does not occur simultaneously with the transition of $(\rho-\rho_{Sb})/(\rho_{As}-\rho_{Sb})$ when r is varied. Magnetoresistance constants are listed in Table III.

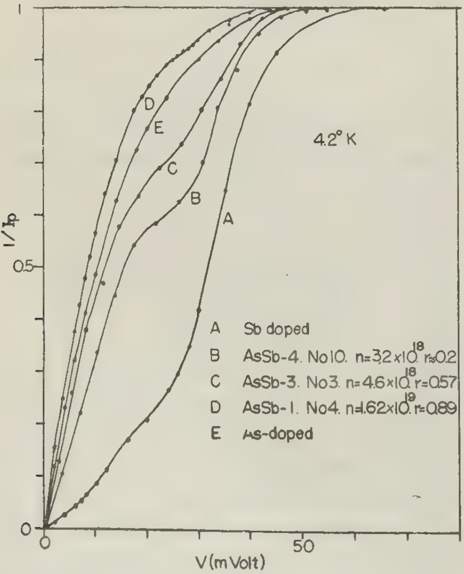

Fig. 9. V–I characteristics for *As*-, *Sb*- and (*As*+*Sb*)- doped junctions at 4.2°K. Phonon assisted tunneling associated with transverse acoustic phonon was quite ambiguous for all (*As*+*Sb*)- doped junctions.

(c) *Observation of Phonon assisted Tunneling*

Fig. 9 shows current-voltage characteristics for *As*-, *Sb*- and (*As*+*Sb*)- doped junctions of germanium at 4.2°K. Phonon assisted tunneling assosisated with longitudal acoustic phonon was observed at about 27 mv, but tunneling associated with transverse acoustic phonon which was observed clearly at about 7 mv for *Sb*- doped junctions was quite ambiguous for all (*As*+*Sb*)- doped junctions.

§ 4. Discussion and Acknowledgement

n versus ρ curve for *P*-doped germanium has been measured only in the electron concentration range of ($1.8\times10^{19}\sim4.5\times10^{19}$ cm^{-3}) and coincided with *As*-doped line shown in Fig. 3 within the experimental error. The observed mobility difference between *Sb*- and *As*- or *P*-doped germanium cannot be expected from Conwell-Weisskopf or Brooks-Herring formula, and seems to be related to the fact that *Sb* has the smallest ionization energy of the group V elements. In havily doped germanium, short range force acts between electron and ionized impurity, and as the result the nature of the core of impurity influences directly upon the impurity scattering.

Another explanation for the mobility difference is as follows. The conduction band structure is modified by heavy doping of impurity in *P*- and *As*-doped germanium, but this is not the case in *Sb*-doped germanium. This assumption[5)] was first proposed for the explanation of the direct tunneling in *P*- and *As*-doped junctions of germanium. However, if the transition of experimental points shown in Fig. 5 is assumed to be due to the band modification, it is difficult to explain the observed phonon assisted tunneling in $(As+Sb)$-doped junctions which were made of the samples with $r>0.5$ (See Fig.9).

The sharp transition shown in Fig. 5 is an unexpected result. As a limiting case of short range force, if the ionized *As* and *Sb* atoms in germanium behave as fixed elastic spheres of radii R_{As} and R_{Sb} respectively, relaxation time τ obtained from classical treatment is as follows.

$$\frac{1}{\tau}=\frac{1}{\tau_{As}}+\frac{1}{\tau_{Sb}} \qquad (3)$$

$$\tau_{As}=\frac{1}{NrR^2_{As}v}$$

$$\tau_{Sb}=\frac{1}{N(1-r)R^2_{Sb}v}\,.$$

Where v is velocity of electrons and N is the sum of *As* and *Sb* concentrations $(N_{As}+N_{Sb})$. Lattice scattering is neglected in above expression.

In this case, the relation $r=(\rho-\rho_{Sb})/(\rho_{As}-\rho_{Sb})$ holds for any value of n. This relation is approximately satisfied for the samples obtained from *AsSb*–3 and *AsSb*–4 crystals. In these samples electron concentration estimated by Hall measurement is nearly equal to the sum of *As* and *Sb* concentrations estimated by spectroscopic analysis. For the samples obtained from *AsSb*–1 and *AsSb*–2 crystals, n differs apprecibly from the sum of the impurity concentrations and the above relation does not hold entirely.

The sharp transition of experimental points shown in Fig. 5 is related with the depature of n from $(N_{As}+N_{Sb})$, therefore it may be due to precipitation of impurities. However, the reason why precipitation of impurity occurs easily in $(As+Sb)$-doped germanium at relatively low impurity concentration and the reason why precipitation occur at $r>0.2$ is not known.

It may be probable that there exists some interaction between *As* and *Sb* atom and as the result a new scattering mechanism is introduced together with ordinary lattice and impurity scattering. Teltow[9)] has suggested that a pairing between two donor ions like P^+ may form in silicon in analogy to hydrogen molecule. Though no evidence of such pairing between donors of the same kind has been reported, pair formation between *As* and *Sb* atom may be expected from the consideration of tetrahedral covalent radii of these impurities. Radius of *Sb* atom is larger than that of germanium, while Radius of *As* atom is smaller than that of germanium. If this is the case in $(As+Sb)$-doped germanium, pairing, hence additional scattering will appear markedly at $r\approx0.5$.

As for the magnetoresistance measurement the symmetry condition $b+c=0$ is satisfied fairly well for *Sb*-doped germanium and also for $(As+Sb)$-doped germanium with small r. The results for *As*-doped germanium show departure from this condition. However more acculate determination of $\theta_{\min}$ is required for discussing the symmetry condition since a slight change in $\theta_{\min}$ affects appreciably on the ratio c/d, therefore on the symmetry condition. However considering the experimental error in the present experiment it may be said that the symmetry condition is sutisfied in *As*- and *Sb*-doped germanium.

On the other hand, $|c/d|$ for *Sb*-doped germanium is obviously larger than that for *As*-doped germanium. This difference in $|c/d|$ may be due to the difference in relaxation time because magnetoresistance constants b, c and d are the functions of relaxation time and the shape of the energy surface, and conduction band structure seems to be the same in both *As*- and *Sb*- doped germanium. Moreover, $|c/d|$ depends only on the specific impurity, but not on the electron concentration (See Table III). So that, the difference in $|c/d|$ may be due to anisotropic character of impurity scattering. In the case of spherical energy surface, $|c/d|$ increases with decreasing anisotropy. If this tendency in $|c/d|$ is true even for germanium, scattering by *Sb* atom will be more isotropic as compaired with *As* atom. This conclusion seems to be related with the fact that electron spin resonance of *As*-doped germanium shows singlet and triplet, while *Sb*-doped germanium shows only singlet.

The author wishes to thank Dr. Z. Kiyasu, Dr. T. Niimi and Prof. Dr. T. Okada for their continual encouragements, Mr. T. Shimozaki for spectroscopic analysis, Mr. K. Ono for electron diffraction analysis and Mr. T. Takahashi for preparation of heavily doped crystals. He is also indebted to Dr. W. Sasaki of the Electrotechnical Laboratory for his helpful discussions.

Paramagnetic Resonance of Mn^{++} Associated with Impurities in Alkali Chlorides

By Yasaburo YOKOZAWA

Research Institute of Applied Electricity,
Hokkaido University, Sapporo

and Yukio KAZUMATA

Department of Physics, Faculty of Science,
Hokkaido University, Sapporo

(Received November 18, 1960)

The paramagnetic resonance absorption of Mn^{++} ions associated with the impurities of fluorine or divalent anions has been investigated in the single crystals of NaCl and LiCl. A resolved fine structure was observed in a "not quenched crystal" and it did not fade into a broad single line in contrast with the spectra of Mn^{++} ions which had been usually observed in alkali halides. The ground level splitting parameters have been determined in the spin Hamiltonian $DS_1^2+E(S_2^2-S_3^2)$ as follows: $D=(-420\pm1)\cdot10^{-4}\,\mathrm{cm}^{-1}$, $|E|=(65\pm1)\cdot10^{-4}\,\mathrm{cm}^{-1}$ for $Mn^{++}-F^-$, $D=(-511\pm5)\cdot10^{-4}\,\mathrm{cm}^{-1}$, $|E|=(25\pm5)\cdot10^{-4}\,\mathrm{cm}^{-1}$ for $Mn^{++}-X^{--}$, a manganese divalent anion pair, in NaCl, and $D=(-672\pm5)\cdot10^{-4}\,\mathrm{cm}^{-1}$, $|E|=(12\pm3)\cdot10^{-4}\,\mathrm{cm}^{-1}$ for $Mn^{++}-X^{--}$ in LiCl, the principal axes of the spin Hamiltonian being in nearly agreement with the cubic axes of the crystal. The large value of D suggests the existence of the strong attractive force between Mn^{++} and impurity ion.

§1. Introduction

As the electron spin resonance of paramagnetic ions is affected sensitively by their environment, the state around the paramagnetic ions may be investigated by the structure of the resonace lines. When divalent cations, such as Mn^{++}, are introduced in a monovalent ionic crystal, an equal number of positive ion vacancy may be produced by the principle of charge compensation, or the extra negative charges of divalent anion impurities such as O^{--} or S^{--}, if exist, may be compensated by the extra positive charge of the cations. Then, a Mn^{++} and vacancy may tend to pair with each other experiencing a Coulomb attraction. It may be also possible that a Mn^{++} ion attracts a divalent anion forming a manganese-anion pair, $Mn^{++}-X^{--}$, when the attractive force between them is strong. These circumstances will be investigated by paramagnetic resonance.

The fine structure of Mn^{++} ions in the single crystal of NaCl was observed by Schneider and Caffyn[1], for the first time, quenching the crystal from high temperature, although only a broad single line with a half-width of 400 gauss was observed before quenching[2]. Watkins[3] observed the several types of resonance spectrum with increasing temperature. He classified the spectra according to their appearance and studied the transformations among them. Spectrum I is a broad single line appearing before quenching, arising from Mn^{++} ions in an aggregated state. Spectrum II consists of 6 lines which become conspicuous above 250°C. This arises from isolated Mn^{++} ions which are free from any vacancy. Spectrum III is complex and observable in the temperature around 200°C, or at room temperature after quenching. This spectrum was successfully analyzed by Watkins and Walker[4], and Morigaki, Fujimoto and Itoh[5], assuming Mn^{++} ions associated with a vacancy bound in one of the near cation sites. This can be further divided into two types, one from the Mn^{++} ions with a positive ions vacancy at one of their nearest neighbor cation site, and the other with a vacancy in the next nearest neighbor cation site, designated by spectrum III_1 and III_2, respectively. It was found that spectrum III faded into I in several days after quenching at room temperature. Spectrum III was also observed for Mn^{++} ions in KCl and LiCl single crystals by Watkins[3] and Fukuda, Uchida and Yoshimura.[6],[7] Besides these spectra, Watkins observed spectrum IV, complex one which had lower intensity and larger splitting. He showed that this spectrum arised from Mn^{++} ions associated with a divalent negative impurity ion such as O^{--} for each Mn^{++} ion.

In the present work, different spectra from those described above were observed for Mn^{++} ions in NaCl and LiCl single crystals grown from a melt. All these spectra had fine structure before quenching and were stable at room temperature. The Mn^{++} ions responsible to these spectra are considered to be trapped on some special positions in the crystal, such as a nearest neighbor site with respect to impurities, forming Mn^{++}-impurity pairs. The spectrum from Mn^{++}-F^- pairs is reported in the previous paper[8]. In this report the details of analysis of this spectrum together with others will be given.

§ 2. Experimental Procedure

Mesurements were carried out by a conventional spectrometer, using a rectangular reflection cavity and a barretter for detection. A klystron 2K25 was frequency stabilized to the sample cavity at about 9 kMc/sec working at room temperature. The modulation frequency of the magnetic field was 260 c/s, and the detected signal from the barretter was amplified with a 260 c/s narrow band amplifier and then detected by a lock-in amplifier and recorded as the first derivative of the absorption curve. The magnetic field was produced by an electromagnet with a pole face of 12 cm diameter, 4 cm gap, and a exciting coil of about 10 ohms in D.C. resistance. The exciting current, about 5.5 amperes for 5000 gauss, was supplied through a current-regulator after the rectification of A.C. 100 volts by a semiconductor rectifier. The regulator consisted of power transistors and a chopper amplifier designed similar to that of Garwin[9], where the exciting current was regulated to within 10^{-4}. The magnetic field could be swept from 300 gauss to 6500 gauss continuously, and was measured by proton resonance; g vaule was determined by the comparison of the spectra with the resonance of di-phenyl picryl hydrazil in which $g=2.0036$.

The crystals studied were grown in air by the Kyropulos method from a melt into which about 0.001 mole fraction of $MnCl_2$ or MnF_2 had been added. The starting materials were of reagent grade purity of Kanto Chemical Company. The crystal was attached to the bottom of the cavity and an external magnetic field was rotated in the (001) plane of the crystal. Since LiCl was very hygroscopic, an evacuated cavity was employed.

§ 3. Analysis of the Spectrum

The Mn^{++} spectrum has been discussed in detail in many papers[10]. The spin Hamiltonian of Mn^{++} in a crystalline field can be written, including the hyperfine interaction, as

$$\mathscr{H}=g\beta \boldsymbol{H}\cdot\boldsymbol{S}+\mathscr{H}_{\rm cry}+\boldsymbol{I}\cdot A\cdot\boldsymbol{S}+\sum_j \boldsymbol{I}_j'\cdot A'S\,. \tag{1}$$

Here g is the spectroscopic splitting factor, β the Bohr magneton, $\boldsymbol{H}$ the external magnetic field and $\boldsymbol{S}$ the electronic spin of Mn^{++}. The third and forth terms represent the hyperfine interactions, where $\boldsymbol{I}$ is the nuclear spin of Mn^{++}, $\boldsymbol{I}_j'$ that of the j-th anion, A and A' are h.f. coupling tensors, and the summation is taken over the anions surrounding Mn^{++}. The effect of the crystalline field on Mn^{++} is described by $\mathscr{H}_{\rm cry}$ which can be written as

$$\mathscr{H}_{\rm cry}=DS_1{}^2+E(S_2{}^2-S_3{}^2)\,, \tag{2}$$

neglecting the terms quartic in S.

The crystalline field splitting caused by Eq. (2) can be calculated by a perturbation method and the results up to the second order calculation are given in the literature[10]. In this work, D was so large that a higher order approximation was necessary. The field strengths for resonance up to the third order approximation are given by next expressions.

$$\left.\begin{array}{lll}
\multicolumn{3}{l}{\text{For } \boldsymbol{H}/\!/\text{axis 1}}\\
\quad M=\pm 5/2\rightleftarrows\pm 3/2 & H=H_0\mp 4D+4E^2/H_0\pm 6DE^2/H_0{}^2\,, & \\
\quad M=\pm 3/2\rightleftarrows\pm 1/2 & H=H_0\mp 2D-5E^2/H_0\pm 33DE^2/H_0{}^2\,, & \\
\quad M=+1/2\rightleftarrows -1/2 & H=H_0\qquad -8E^2/H_0\,, & \\
\multicolumn{3}{l}{\text{For } \boldsymbol{H}/\!/\text{axis 2}}\\
\quad D \text{ should be replaced by} & \tfrac{1}{2}(3E-D)\,, & \\
\quad E \qquad\qquad\qquad\quad \text{by} & -\tfrac{1}{2}(D+E)\,, & \\
\multicolumn{3}{l}{\text{For } \boldsymbol{H}/\!/\text{axis 3}}\\
\quad D \qquad\qquad\qquad\quad \text{by} & \tfrac{1}{2}(-D-3E)\,, & \\
\quad E \qquad\qquad\qquad\quad \text{by} & \tfrac{1}{2}(D-E)\,. &
\end{array}\right\} \tag{3}$$

Here M is the component of the electronic spin in the direction of the applied magnetic field, and H_0 is $h\nu/g\beta$, ν being the klystron frequency.

The third term of Eq. (1) adds to these expressions a hyperfine structure. The anisotropy in A is small and A can be treated as a scalar quantity. Then the hyper-fine structure to be added to Eq. (3) is for the $M\rightleftarrows M-1$ transition,

$$-Am-\frac{A}{2H_0}\{I(I+1)-m^2+m(2M-1)\}\,, \tag{4}$$

m being the component of the nuclear spin of Mn^{++}.

The last term in Eq. (1) splits each line in a complex way. For example, 6 chlorine ions surrounding Mn^{++} which form a octahedron split a resonance line into $7^3=343$ components with $I'=3/2$ and these components may not be resolved, contributing only to the line width[11]. But for fluorine ions, as they have nuclear magnetic moments of 3 times larger than those of chlorine ions and $I'=1/2$ for their nuclear spins, the super-hyper-fine structure is so widely splitted and simple as to be observable. Tinkham[12] calculated the shifts and splittings of resonance lines due to this interaction, yielding the result,

$$A_s\sum_j I_{jz}+\mathrm{A}_p\sum_j I_{jz}(3\cos^2\theta_j-1)\,. \tag{5}$$

Here I_{jz} is the component of nuclear spin of F^-, $\pm\frac{1}{2}$ and θ_j the angle between the external magnetic field and the σ-bonding axis of Mn^{++}-F^-. A_s represents the contribution from the admixed fluorine $2s$ orbit and A_p that from $2p$ orbit and also a direct dipole-dipole interaction between Mn^{++} and F^-.

§ 4. Experimental Results

1) *The spectrum of Mn^{++}-F^- pair in NaCl.*

As reported in the previous paper[8], the complex spectrum of Mn^{++} was observed in the single crystal of NaCl which was grown from a melt into which about 0.001 mole fraction of $\mathrm{MnF_2}$ had been added. Each line of the spectrum was a doublet, coming from the super-hyperfine structure of a fluorine ion. This indicates, from Eq. (5) that there exists only one fluorine ion near a Mn^{++} ion, forming a Mn^{++}-F^- pair. The principal axes, 1, 2 3, were found to coincide with the cubic axes of the crystal, one of which was considered to be the direction of Mn^{++}-F^- bond. Although finely resolved doublet structures appeared when an external magnetic field was directed to [100] or [110], no resolved structures could be observed in other directions. This fact is explained by assuming the existence of two types of doublets which correspond to the plus and minus signs of E. $2\times3\times30=180$ doublets appear in the spectrum, 30 being the number of lines for each Mn^{++} ion.

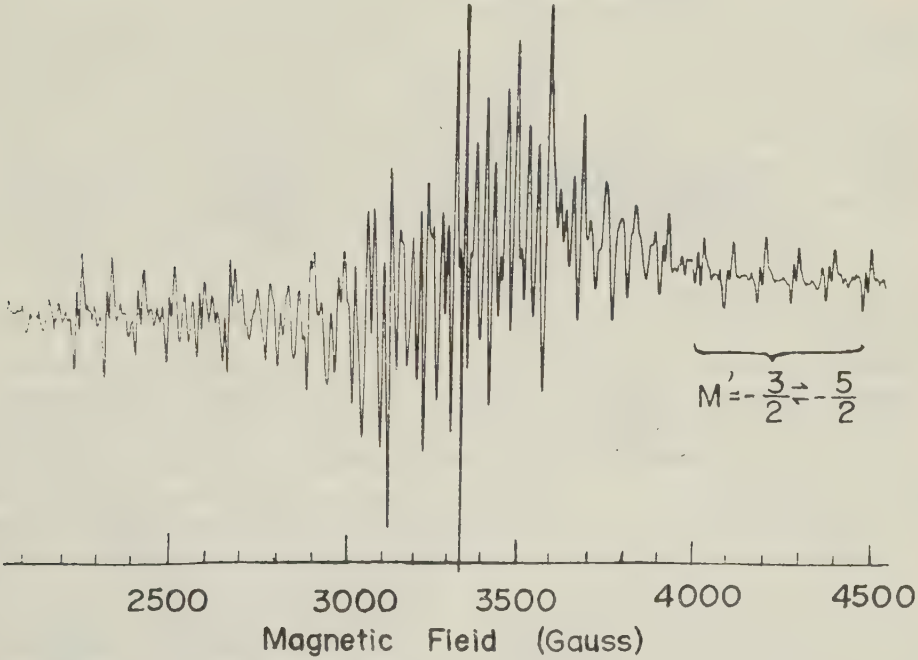

Fig. 1. The spectrum of $Mn^{++}-F^-$ in NaCl, the direction of an external magnetic field being parallel to [110] of the crystal. The transition $M'=-3/2\rightleftarrows-5/2$ for which $Mn^{++}-F^-$ direction is perpendicular to the magnetic field is designated in the figure, where M' is the magnetic quantum number of Mn^{++}. For the spectrum with $\boldsymbol{H}$//[100], see Fig 1 of the previous paper.[8]

The spectrum in [100] direction was already shown in Fig. 1 of the previous report[8]. Fig. 1 of this paper shows the spectrum in [110] direction. In this direction,

$$M'^{*}=(-3/2)\leftrightarrows(-5/2)$$

transition lines of Mn^{++} for which Mn^{++}-F^- bond is perpendicular to the external magnetic field appear separately from other lines as are designated in the figure. The designation of the quantum transitions of the spectrum lines in [100] direction shown in the previous paper was possible with the help of the spectrum in Fig. 1 of this paper. Spin Hamiltonian constants g, D, E and A were determined by the use of Eqs. (3) and (4). Super-hyper-fine coupling constants As and Ap were determined from both spectra of Fig. 1's of two papers.

2) *The Spectrum of Mn^{++}-X^{--} in NaCl.*

Most crystals of NaCl grown from a melt added with $MnCl_2$ had the same resonance spectra as the types I, II and III given in introduction. Among these crystals, there were some in which a different kind of spectrum appeared beside them. The intensity of this spectrum is different from crystal to crystal and in some crystals it is much stronger than those of the other types. Fig. 2 (a) shows the spectrum of this conspicuous one. The condition of the appearance of this spectrum is not yet clear, but it may have some relation with the time of melting before pulling up, the longer the time the stronger the intensity of this spectrum.

Spin Hamiltonian constants of this spectrum are determined as shown in Table I. As

---

[*] M' designates the magnetic quantum number of Mn^{++} for which $Mn^{++}-F^-$ bond is perpendicular to the external magnetic field, using the same notation as in Fig. 1 of the previous paper.[8]

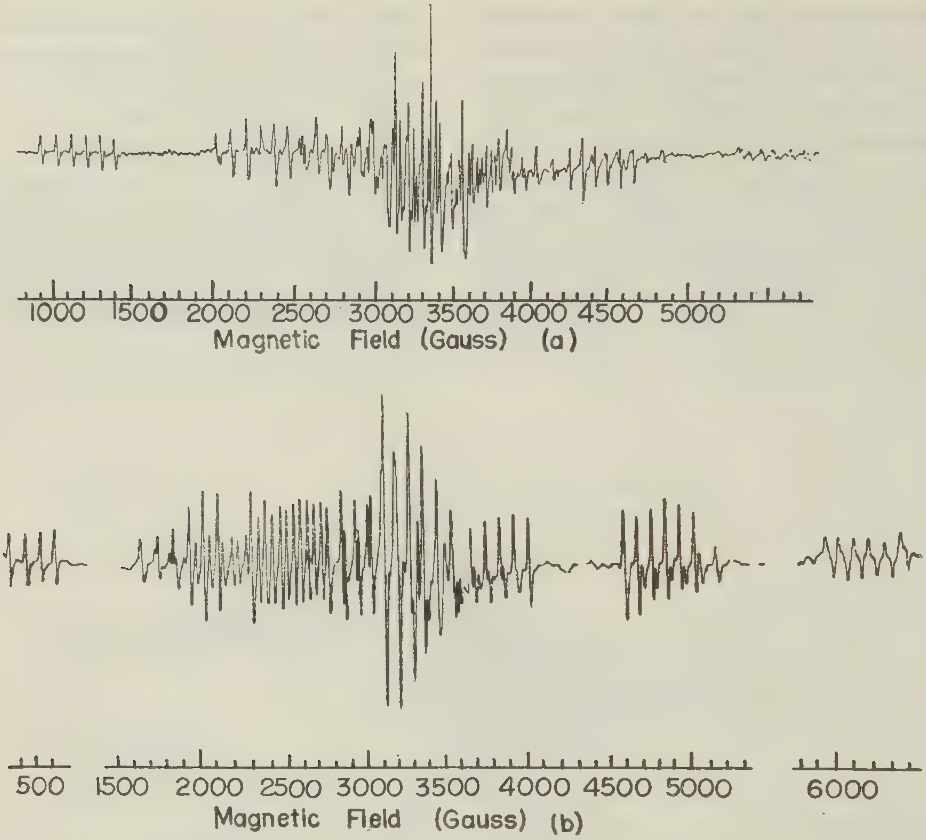

Fig. 2. The spectra of $Mn^{++}-X^{--}$ in the single crystals of (a) NaCl and (b) LiCl. In (a), the magnetic field is slightly misoriented from the principal axis of the spin Hamiltonian, distorting the resonance lines in the group on the highest field side. In (b), the sensitivity is about 3 times larger on the highest field side than on the other side of the spectrum.

these are in good agreement with those of spectrum IV, Mn^{++}-X^- pairs will be responsible to this spectrum.

3) *The spectrum of* Mn^{++}-X^{--} *in LiCl*

Although the spectrum of Mn^{++} ions in LiCl grown from a melt added with $MnCl_2$ was the same as that of type III, that from a melt added with MnF_2 had a different type, as shown in Fig. 2 (b). The principal axes of the spin Hamiltonian are nearly parallel to the cubic axes of the crystal respectively, and splitting parameters are given in Table I. The resonance lines in the group on the highest field side were always weaker than those on the lower field side and disappeared when the magnetic field was rotated from the direction corresponding to Fig. 2 (b) over 1 degree. This is similar to the spectrum discussed in (2), and is explained assuming that the principal axes make a small angle with the cubic axes of the crystal, the angular variation of the positions of resonance lines in the highest field group being larger than that in the lower field. As D is large in this spectrum, the third order perturbation terms of $\mathscr{H}_{\text{cry}}$ make the same order contribution to the second order terms and Eq. (3) is insufficient for the determination of the splitting parameters. However fortunately, as E is small, Eq. (3) is sufficiently accurate for the positions of the resonance lines of Mn^{++} for which the direction of Mn^{++}-F^- bond coincides with the direction of the magnetic field, and D can be calculated. On the other hand, the positions of the lines of other Mn^{++} for which Mn^{++}-F^- is perpendicular to the magnetic field are necessary for the determination of E. However, for this purpose the accurate positions of resonance lines themselves are not necessary but only the difference of positions of two kinds of lines are sufficient, so E can be determined also using

* Watkins[3)] determined the angle between the principal axes of the spin Hamiltonian and the cubic axes of the crystal to be 1.3° for $Mn^{++}-X^{--}$ in NaCl.

Eq. (3).

As will be discussed in the next paragraph, the small value of E is the evidence of the absence of a vacancy near a Mn^{++} ion. Therefore, the Mn^{++} ion is considered to locate near a divalent anion, forming a Mn^{++}-X^{--} pair.

Watkins considered that the most probable divalent negative ion X^{--} is oxygen negative ion.

The results are summurized in Table I.

§ 5. Discussions of the Results

1) *Mn^{++}-F^{-} pair in NaCl*

As described in § 4, Mn^{++}-F^{-} bond is considered to direct to one of the cubic axes of the crystal. Then a question arises why E is so large, in spite of the equivalence of axes 2 and 3. This can be answered assuming the existence of a vacancy locating in the next nearest neighbor cation site of a Mn^{++} ion perpendicular to the Mn^{++}-F^{-} direction as shown in Fig. 3 (a). The assumption of this model will be supported as follows. The fluorine ion as well as the chlorine ion locating between a Mn^{++} ion and a vacancy may be attracted to the Mn^{++} ion, yielding the quadratic terms in the electrostatic potential at the Mn^{++} ion site which reflect D and E of the spin Hamiltonian. Now, the quadratic part of the potential from a fluorine ion alone and that an from an attracted chroline ion plus a vacancy are represented by φ_1 and φ_2, respectively as follows,

$$\left.\begin{aligned}\varphi_1&=D_1X_1{}^2-(1/3)D_1\cdot r^2\,,\\ \varphi_2&=D_2X_2{}^2-(1/3)D_2\cdot r^2\,,\end{aligned}\right\}\tag{6}$$

where X_1 and X_2 are the components of r with respect to 1 and 2 axes respectively [see Fig. 3 (a)], r being the distance from Mn^{++}. Therefore, the total potential φ is represented as,

$$\varphi=\varphi_1+\varphi_2=D'X_1{}^2+E'(X_2{}^2-X_2{}^2)-(D'/3)r^2\,,\tag{7}$$

where

$$D'=D_1-\tfrac{1}{2}D_2\,,$$
$$E'=D_2/2\,,$$

D' and E' correlate to D and E of the spin Hamiltonian.

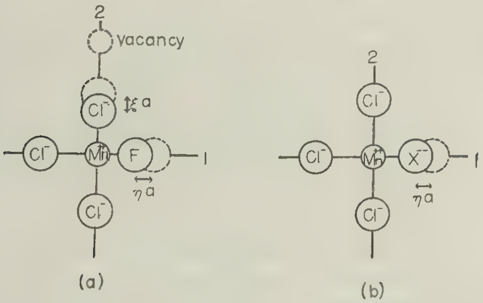

Fig. 3. The arrangement of the anions surrounding a Mn^{++} ion. The displacements of a foreign anion and chlorine ions around a vacancy are shown.

If F^{-} is absent, this model reduce to spectrum III_2. In this case, as $D_1=O$, $D_2=2E'$ corresponding to $\pm2\times65\times10^{-4}\,cm^{-1}=\pm130\times10^{-4}\,cm^{-1}$ and it is in good agreement with the value of spectrum III_2, in which $D=131\times10^{-4}\,cm^{-1}$,[3)] taking only the plus sign of E. In the case of the existence of a vacancy on axes 3, the sign is reversed.

The large value of D suggests the strong interaction between Mn^{++} and F^{-}. This interaction was estimated by Watanabe's theory[14)], following the similar procedure employed by Watkins[3)]. Watanabe calculated the splitting parameter D of Mn^{++}, when an axial crystalline field $V_{\mathrm{axl}}=cr^2Y_2{}^0\ (\theta\varphi)$ existed around a Mn^{++} ion, as follows,

$$D=-9.90\varDelta^2\times10^{-10}+3.62M'\varDelta10^{-5}\,cm^{-1}\,,\tag{10}$$

$$M'=(1/4)(5/\pi)^{1/2}c^2\langle r^2\rangle=-eD'\langle r^2\rangle/3hc\,,\tag{11}$$

Here $\langle r^2\rangle$ is the average value of r^2 for Mn^{++}

ions, that is $\langle r^2\rangle=0.4\times10^{-16}$ as determined from Hartree functions and M' complex expression depending upon the overlap of the wave functions, for which we take the value $0.2\,\mathrm{cm}^{-1}$ as it does not affect the results largely. Now, D' is calculated on the stand-view of a point charge model shown in Fig. 3 (a), ξ and η being the fractional displacements of anions,

$$D_1=-9e\eta/2a^3\cdot\alpha\,, \tag{12}$$

$$D_2=-(3+72\xi)e/16a^3\cdot\beta\,. \tag{13}$$

Here, α and β are corrections to the point charge model and represent the magnitude of the effectiveness of the crystalline field due to the covalency of the ions or the overlapping of the wave functions.

At first, we will consider the case when a F^- ion is absent. In this case, the splitting parameter is expressed by $D=2E=130\cdot10^{-4}$ cm^{-1}, corresponding to $\Delta\sim3500\,\mathrm{cm}^{-1}$ by Eq. (10). On the other hand, Eqs. (11) and (13) give $\Delta\sim280\beta$, taking $\xi=0.048$, the same value as Watkins[3)] employed in his explanation of spectrum III_2, β becomes the order of 12, the same result as Watkins. Now, we will proceed to D. As As and Ap of this spectrum are nearly equal to that of the Mn^{++} in NaF single crystal[13)], the Mn^{++}-F^- distance is considered to be close to the Na^+-F^- distance in NaF, resulting $\eta=0.17$*. Then, from Eqs. (8), (11) and (12), Δ is calculated as $400\alpha-3500/2$, where the result mentioned above is used for D_2. Observed value of D, $-460\times10^{-4}\,\mathrm{cm}^{-1}$ on the other hand, gives $\Delta\sim11000$ by Eq. (10). Thus $\alpha\sim30$, showing the existence of the strong atractive force between Mn^{++} and F^-.

2) *Mn^{++}-X^{--} pair in NaCl and LiCl*

The model of a Mn^{++}-X^{--} pair is shown in Fig. 3 (b), η being the fractional displacement of a X^{--} ion. This model gives

$$\left.\begin{array}{l} D'=-3e/2a^3(1/(1-\eta)^3+3\eta)\cdot\alpha\,, \\ E'=0\,, \end{array}\right\} \tag{14}$$

α having the same meaning as that in the case (1). If the Mn^{++}-X^{--} distance is 2.20 Å, the sum of the radii of both ions where X^{--} is assumed to be oxgen negative ion, then $\eta=0.22$ for NaCl and $\eta=0.14$ for LiCl, a similar calculation as above gives for Mn^{++}-X^{--} in NaCl $\alpha\sim4$, and in LiCl $\alpha\sim7$. On the contrary, if the ion is assumed not to displace at all, $\eta=0$, as assumed by Watkins[3)], the calculation gives $\alpha\sim11$ for NaCl and $\alpha\sim9$ for LiCl. As a Mn^{++}-X^{--} pair is probably considered to make a union which is independent of circumstances, η may not differ largely for both crystals, so the fractional displacement may be small, giving $\eta\sim0$.

§ 6. Concluding Remark

The results of the paramagnetic resonance of Mn^{++}-Impurity in NaCl and LiCl have been described. The splittings of resonance spectra are large, indicating that there exists a strong attractive force between Mn^{++} and impurity ions. Moreover, the resolved fine structure is observed in a " not quenched crystals " and is stable in the room temperature, in contrast to the spectra of Mn^{++} not associated with a impurity as obserbed by other investigators[1)–7)].

The present authors wish to express their sincere thanks to Drs. H. Watanabe and S. Ogawa for their valuable discussions and to Mr. Y. Nakano for the construction of the current regulator for the electromagnet.

Ferromagnetic Resonance Absorption of Single-Crystal Thin Films of Nickel

By Masao KURIYAMA, Hirokage YAMANOUCHI and Sukeaki HOSOYA

The Institute for Solid State Physics, University of Tokyo,
Shin-Ryudo-cho, Minato-ku, Tokyo, Japan

(Received November 26, 1960)

Single-crystal thin films of nickel having the (100) and the (111) orientations were epitaxially grown by deposition in vaccum onto heated rock salt and zincblende. By electron diffraction, these films were examined to be 100 A to 500 A in size of crystallites without appreciable strain.

By the experiment of ferromagnetic resonance absorption at room temperature, three magnetic quantities were measured at the same time: the saturation magnetization, the crystalline anisotropy and the Landé splitting factor. The first quantity was found to be almost independent of the thickness of films (100 A to 1000 A) and its magnitude was 350 or 400 in gauss, respectively for the (111) or the (100) orientation. This difference may be ascribed to the stress in films. The second one varied in the range between -2×10^4 and -5×10^4 erg/cm^3 and the third was 2.2 in average.

The crystalline anisotropy causes the shift of resonance line as the film is rotated in its plane. Besides, it was found that the more perfect orientation a film has, the narrower is the resonance line.

§ 1. Introduction

There have been a number of experimental works on the magnetic properties of ferromagnetic polycrystalline films. Polycrystalline films, however, give the complicated magnetic properties, which have not yet been completely explained. These properties generally are closely related to both the crystalline anisotropy and the magnetostriction due to the stress in films. Single crystal films, therefore, were used in the present work.

The epitaxial growth of single crystalline films was reported for nickel and iron deposited in vacuum onto the heated cleavage face of rock salt by Shirai[1], and for nickel onto that of zincblende by Miyake and Kubo (Takagi)[2]. Recently Boyd[3] has prepared single-crystal films of Ni, Fe, Ni-Fe and Ni-Co alloys and measured their magnetic crystalline anisotropy with a torque meter. The experiment of ferromagnetic resonance absorption, however, has not so far been carried out for single crystalline films.

In the present work, from the measurement of ferromagnetic resonance absorption three magnetic quantities, such as the saturation magnetization, the cubic crystalline anisotropy constant and the Landé splitting factor, could be obtained at the same time. Single crystal films always give a reproducible and sharp resonance line in spite of the possible contamination and of the unavoidable inhomogeneity such as film granularities, defects and the non-uniformity of thickness.

§ 2. Experimentals

a. *Preparation of specimens*

Nickel films were prepared by deposition in vacuum onto heated single crystal surface of NaCl and ZnS by the method similar to that of previous workers[1),2)]. Rock salt and zincblende crystals were cleaved parallel to the (100) and the (110) planes respectively and placed in a chamber which was evacuated to a pressure of about 3×10^{-6} mm Hg. The substrate was heated to about 550°C for NaCl and to about 400°C for ZnS and held there for about an hour and then cooled slowly to a certain temperature between 430° and 530°C for NaCl and between 230° and 380°C for ZnS. Then nickel was evaporated from a tungsten filament on which nickel was coated by electroplating[4]. In this case, pure nickel (99.99%) supplied from the Sumitomo Mining Co. was used as an electrode. In order to examine whether the impurities appearing in an electroplating process influence the resonance field, other portions of the pure nickel could manage to be evaporated from a tungsten filament in the usual way applicable to metals which are not apt to be alloyed with tungsten. But this way of evaporation gave the same results in resonance absorption as the former way. The former method, therefore, was used throughout the whole experiment.

Evaporation was made in a pressure of 3×10^{-6} mm Hg with the speed of less than 2 A/sec. A polished quartz plate was placed in a chamber as a thickness monitor. The thickness of the evaporated film was measured by an optical multi-beam interference method of Tolansky. Films used for measurements were 20 A to 1300 A in thickness.

b. *Microwave apparatus*

The microwave apparatus of a standard type for X-band was used. With a phase sensitive detector, the differential curve of absorption was automatically recorded at room temperature.

Two types of cavities were used for the two different geometrical settings of a crystal as will be shown in Fig. 3: a. the static field is applied parallel to the surface of a specimen and b. the static field perpendicular to the surface, while the microwave field is in the surface.

The strength of the magnetic field was measured by a flux meter which was calibrated by NMR. The frequency of microwave was determined in each measurement by a sample $MnSO_4\cdot H_2O$, as a standard which has the Landé splitting factor of 2.00[5)]*.

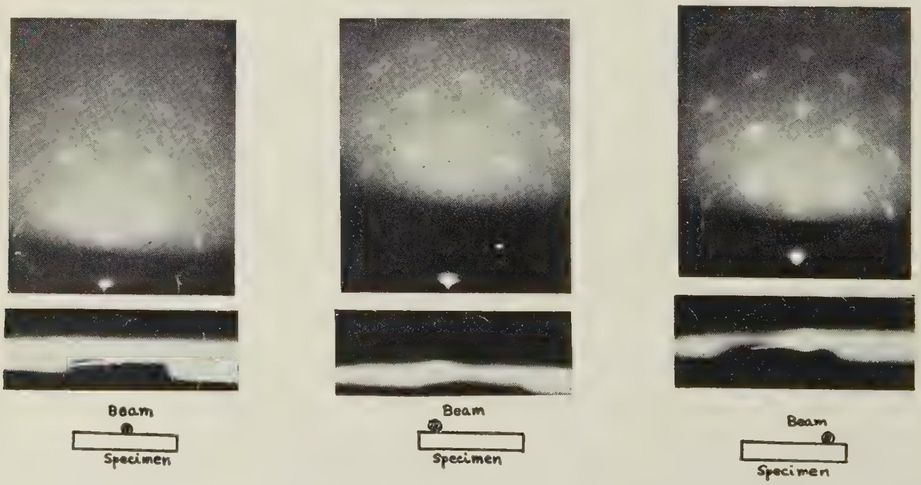

Fig. 2. Electron diffraction patterns from the surface at different positions. Reflection patterns are shown above, and the shadows of specimen with a trace of incident beam are shown in the middle, and the schematic figures of the shadows are shown at the bottom.

---

* In the precise measurement of g value, DPPH should be used as a standard, which has the width of about 3 gauss. As $MnSO_4\cdot H_2O$ has the width of about 300 gauss, Δg can be estimated to be ±0.03 at most. In the present experiment, however, such a magnitude of error is too small to be discussed.

§ 3. Crystal Structure of Thin Films

Films were all examined by electron diffraction: Portions of nickel film on NaCl were removed from a substrate by floating them onto a water surface and were studied by transmission method. Some of them were also studied by reflection method as they were on the substrate. Films on ZnS were all examined by reflection method.

As shown in Fig. 1, films on rock salt have the (100) plane parallel to a substrate surface and either the [100] axis or the [110] axis parallel to the cube edge of the substrate. On the other hand, films on zincblende show the (111) plane parallel to a substrate face with the [110] axis parallel to the [100] axis of the substrate, as also shown in Fig. 1.

In the case of nickel on rock salt the diffraction patterns often show the twin spots due to the microtwins in the (111) planes of the crystal. Magnetic measurements were done for the specimens which were considered to be slightly twinded at worst.

If electron beams deflected by a few minutes impinge the crystal surface at different positions, as shown in Fig. 2, the diffraction patterns show that, exactly speaking, films should consist of many crystallites having slightly different orientations. Applying the line breadth analysis method[6] to the transmission patterns such as Fig. 1, it is found that these crystallites have the crystal size (coherent size) of 100–500 A and no appreciable strain. These results, therefore, implies that a film consists of " mosaic " blocks of a few hundred angstroms having the mis-orientation of at most a few minutes of arc.

A lattice constant agrees well with that of bulk material.

§ 4. Results of Ferromagnetic Resonance

In a ferromagnetic resonance experiment of a single crystal, resonance conditions are given as follows[7),8)]:

a. When the plane of specimen is (100), namely in the case of films on rock salt,

$$\omega_a{}^2=\gamma^2[H_a+4\pi I_s+(K/2I_s)3 \\ +\cos 4\theta)][H_a+(2K/I_s)\cos 4\theta]\ , \qquad (1)$$

$$\omega_b{}^2=\gamma^2[H_b-4\pi I_s+2K/I_s]^2\ , \qquad (2)$$

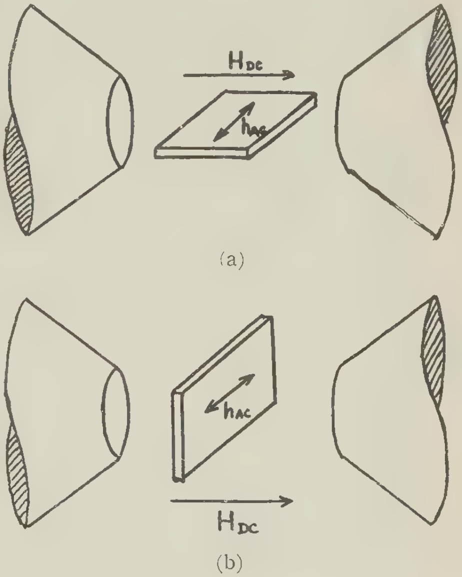
Here θ is the angle between the [001] axis and the applied dc field.

b. When the plane of specimen is (111), namely in the case of films on zincblende,

$$\omega_a{}^2=\gamma^2[H_a+4\pi I_s-K/I_s]H_a\ , \qquad (3)$$

$$\omega_b{}^2=\gamma^2[H_b-4\pi I_s-4K/3I_s]^2\ . \qquad (4)$$

In the above expressions the subscripts a and b correspond to the two different geometrical positions shown in Fig. 3a and b. ω is the frequency of the microwave and γ is related to the Landé splitting factor g as $\gamma=ge/2mc$. I_s is a saturation magnetization, K, the first order anisotropy constant and H, the resonance field for each case. The second order anisotropic effect and the magnetostriction effect are both neglected here. The latter effect will be discussed later in § 5.



(a)

(b)

Fig. 3. Two different geometrical settings of a crystal.

a. The static field is applied parallel to the surface of film.

b. The static field is applied perpendicular to the surface of film.

In order to obtain three quantities such as the saturation magnetization, the anisotropy constant and the Landé splitting factor at the same time, single crystal films are all measured in two positions as shown in Fig. 3.

Being rotated around the normal of a film in the static magnetic field, the (100) film deposited onto rock salt clearly gives the shift of resonance line, which has the four-fold symmetry as shown in Fig. 4a. Such a symmetry is explained by a term of crystalline anisotropy in equation (1). This phenomenon

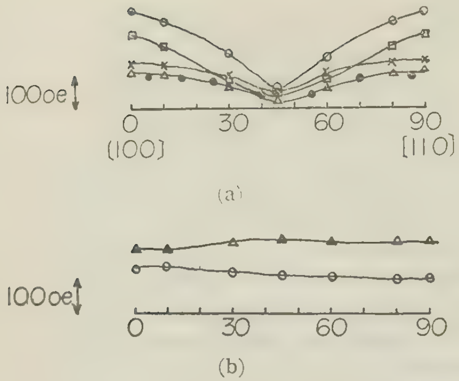


Fig. 4. Shift of the resonance field. Ordinate represents the field direction referred to the crystallographic axis. Frequency of microwave is about 9000 Mc, and the resonance field are about 1000 and 1600 oe. in strength, respectively for (100) and (111) films. Various marks correspond to the specimens with different thickness.

a. (100) Ni on NaCl.
b. (111) Ni on ZnS.

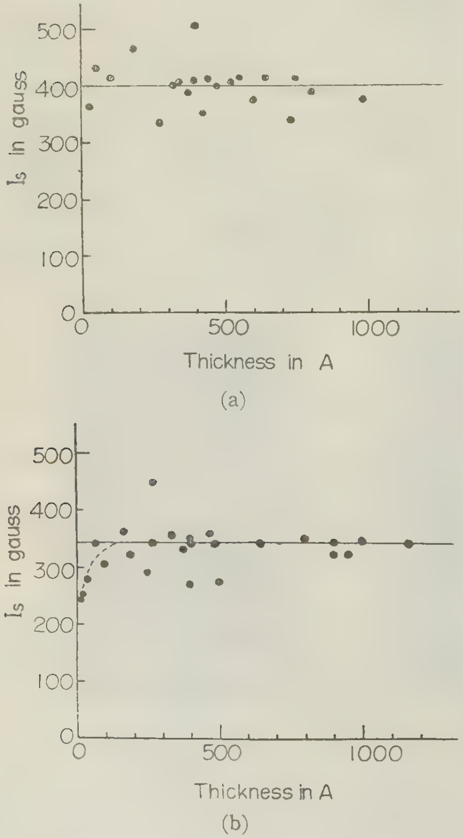

Fig. 5. Variation of the saturation magnetization with the thickness of films.

a. (100) Ni on NaCl.
b. (111) Ni on ZnS.

may be considered to provide the evidence that, even if in some cases the twin crystals exist as a minor part in film, not only the anisotropy constant but also the other magnetic quantities can be regarded as those from a single crystal having, as a whole, the (100) orientation. From the amplitude of the periodic change of field shift, the anisotropy constant is estimated to be -2×10^4 to -5×10^4 erg/cm^3, assuming the magnetization of 400 gauss, and agrees with the values obtained below. On the other hand, the (111) film made on zincblende gives no appreciable shift of the resonance line, as shown in Fig. 4 b.

According to either a pair of (1) and (2) or that of (3) and (4), respectively for the (100) and the (111) films, the magnitudes of the saturation magnetization, the cubic crystalline anisotropy constant and the Landé splitting factor can be obtained from the observed fields in two positions and are plotted against the thickness of films in Figs. 5, 6 and 7. The

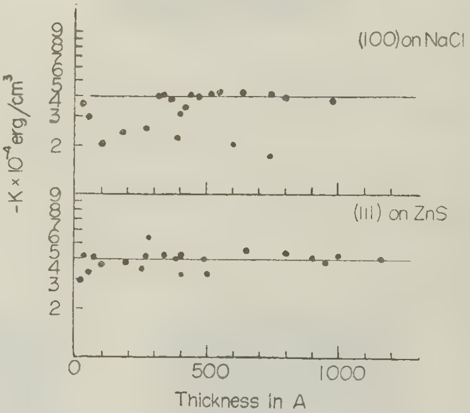

Fig. 6. Variation of the anisotropy constant K with thickness of films.

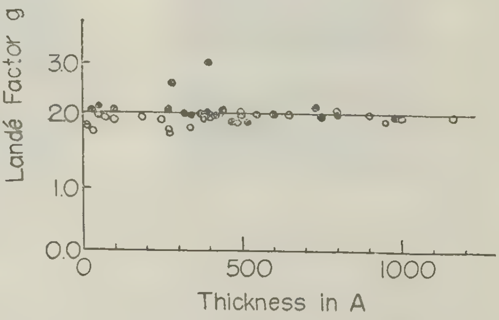

Fig. 7. Variation of the Landé splitting factor g with the thickness of films. Open circles stand for (111) Ni on ZnS, and solid circles for (100) Ni on NaCl.

magnitude of the first is almost constant for various thickness of films, but is found to be 350 and 400 in gauss, respectively for the (111) and the (100) orientations. This difference may be attributed to the stress induced in films as will be discussed in § 5. The anisotropy constant varies in the range between -2×10^4 and -5×10^4 erg/cm³. The value of the Landé splitting factor is obtained to be 2.2 in average.

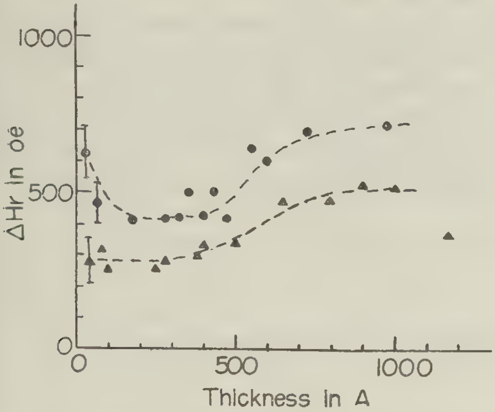

Fig. 8. Half value width of the resonance field against the thickness of films. Circles stand for (100) Ni on NaCl, and triangles for (111) Ni on ZnS.

The half value width of the resonance line is also plotted against the thickness of films in Fig. 8. Usually the polycrystalline film gives broader line (above 700 oe.) than the present specimens do. From the viewpoint of the epitaxial growth, it can be said that crystals grow well if they are not so thick, and moreover, that they give better orientation on zincblende than on rock salt. In fact, the line width of resonance is larger on rock salt than on zincblende and is smaller in the range of thickness of 100 A to 500 A for films on both substrates. It is, therefore, concluded that the broadening of the resonance line depends on the perfectness of orientation in films and hence an observed line consists of many lines shifted by the anisotropy in crystallites with different orientations.

§ 5. Discussions

As described in § 4, the stress in a film may be responsible for the difference of the values of magnetization between films on rock salt and those on zincblende. Since the equations in § 4 contain neither the second order anisotropy effect nor the magnetostriction effect which is more important, the contribution should be discussed of the latter to the resonance field.

If a stress exists in a film, the correction due to magnetostriction must be taken into consideration for the equations in § 4. Since real films may be under stress in a rather complicated way, this correction cannot be estimated exactly. Here we will simply assume that the stress is radially symmetric in the plane of film, and will roughly calculate the order of magnitude of the correction terms, using the general formulae by Macdonald[8].

For the (100) film, the correction term with the order of magnitude of $+\lambda_{[100]}T/I_s$ is inserted in the left side bracket in (1), and $-\lambda_{[100]}T/I_s$ is in (2). For the (111) film, $+(\lambda_{[100]}-\lambda_{[111]})T/I_s$ is inserted in the left side bracket in (3) and $-\lambda_{[111]}T/I_s$ is in (4). Here $\lambda_{[lmn]}$ is the magnetostriction in the $[lmn]$ direction and T, the stress. If T is positive, the stress is tensile.

With these corrections of magnetostriction, the field of resonance becomes larger for the parallel field case and smaller for the perpendicular field case than for those cases without magnetostriction. In other words, if the equations in § 4 without magnetostriction corrections are used for the films with magnetostriction, the magnitude of the saturation magnetization becomes smaller than the true value. Of course, the value of the splitting factor also changes.

If the difference between the value of magnetization obtained from the bulk material and that from the present thin film can be attributed entirely to the magnetostriction effect and besides the magnetostriction constants are assumed to be the same as those for the bulk material, it is derived from the above mentioned calculation that the stress with the order of magnitude of $+10^7$ to $+10^9$ dyne/cm² should be present in films on both kinds of substrates. Such a stress in the film yields the elastic strain of 10^{-5} to 10^{-3}, for Young's modulus of nickel is the order of 10^{12} dyne/cm².

Because the present stress is tensile, the spots in the electron diffraction patterns should be not only broadened but also shifted to one side. Even the elastic strain of 10^{-3}, however, cannot be detected by the electron diffraction camera available at present, because the shift falls within the experimental error.

If the strain in the film could be found by a high resolution electron diffraction camera, the values of the saturation magnetization could have become larger than the values obtained in § 4 and the difference caused by the kinds of substrates would have vanished. The origin of such stress was not investigated in the present work, because we did not try to measure the variation of the resonance field after stripping a film from a substrate and annealing.

The authors wish to express their sincere thanks to Prof. H. Abe and Miss H. Shirai for the use of the microwave equipment.

Specific Heat of Ti_2O_3

By Shoichiro NOMURA, Tatsuyuki KAWAKUBO
and Taketoshi YANAGI

Physics Department, Tokyo Institute of Technology
Oh-okayama, Meguro, Tokyo

(Received December 5, 1960)

A measurement of the specific heat of Ti_2O_3, prepared by the method of powder metallurgy, was carried out in the temperature range from 50° to 250°C, under the pressure of 10^{-4} mm Hg. A modified method of measurement by the conduction-type calorimeter was adopted, and its reliability of measurement was described in connection with the method of calculation. A broad anomaly of specific heat was observed near 180°C and the amount of anomalous heat was 36 cal/mol, which was smaller than Naylor's result. Some discussions about the anomaly of specific heat were presented.

§ 1. Introduction

Several investigations have been reported about an anomalous behavior of Ti_2O_3 in the temperature range from 160° to 200°C. The lattice parameters of this crystal, which has the corundum-type structure, change markedly in this temperature region,[1),2)] but no symmetry change is observed[3)]. An abrupt change in the magnetic susceptibility,[1),4),5)] accompanied by a marked change in the electrical conductivity, has been observed near the transition temperature[6)].

It has been suggested from the result of measurement of magnetic susceptibility that an antiferromagnetic ordering would be present below the transition temperature. Shirane and coworkers, however, concluded from their neutron-diffraction data that the antiferromagnetic ordering seems to be excluded[7)]. A new model, recently proposed by Goodenough, is favourable to this anomaly in Ti_2O_3[8)].

An anomalous specific heat has been detected by Naylor using the drop method[9)]. This method is not considered to be suitable to give the temperature dependence of heat capacity and so Naylor did not show any explicit curve of the anomalous specific heat near the transition temperature. We have, therefore, examined the temperature dependence of the specific heat of Ti_2O_3 by using a conduction-type calorimeter. In this paper, our measuring method and the results on the specific heat of Ti_2O_3 will be described.

§ 2. Experimentals

a) *Specimen*

The specimen was prepared by the method of powder metallurgy. A mixture of fine powder of highly purified Ti and $3TiO_2$ was pressed into a pellet. This was placed in a graphite crucible, inside of which was covered with a molybdenum sheet, and fired at 1500°C under the pressure of 10^{-4} mm Hg for six hours in a graphite-resistor vacuum furnace. After firing, the pellet was crushed into powder and this was sintered again by the same process. The final product was dark violet in colour. In order to examine the completion of the solid-state reaction, the X-ray powder diffraction photograph was taken by using CuK_α at room temperature. Fig. 1 shows the obtained pattern, where the indices are referred to the hexagonal structure. This pattern coincides with that of the corundum-type structure and the lattice parameters obtained from our data are in good agreement with the former results[1),2)]. In the case that the specimen was fired at 1200°C, the X-ray diffraction pattern showed a few extra-lines in addition to the broad Ti_2O_3 diffraction lines.

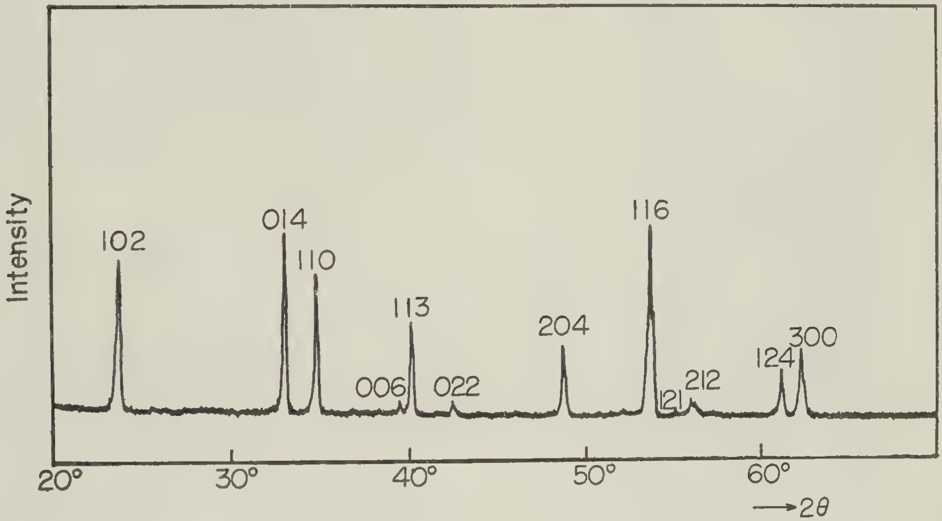

Fig. 1. X-ray diffraction pattern of Ti_2O_3.

b) *Apparatus for the specific heat measurement**

The adopted method was of the conduction type, in which the thermo-electromotive force of the differential thermocouple was recorded when the current of the furnace was varied in a definite manner[10)]. The main part of the calorimeter is shown in Fig. 2. The powder sample is put in a container S, which is made of a thin sheet of nickel. This container is surrounded by a thick outer case C made of a nickel block, and separated from the latter by fine alumina rods R. T_1 is a Pt-Pt 13%Rh thermocouple of 0.2 mmϕ for measuring the temperature of the sample and T_2, T_3 for measuring the temperature difference between the container S and the outer case C. To get a good thermal contact between T_2 and S, T_2 is bound to S at a definite position on its surface with a fine Pt wire. T_3 is inserted into a narrow hole bored in the outer case C. F is a nichrome-resistor furnace to supply heat to the sample and the case C. The heat capacity of the furnace is large owing to its thick alumina tube. In our conduction-type method, however, the temperature difference between S and C is not necessary to be kept constant, and so the large heat capacity is rather favourable for the stable measurement. Surrounding the furnace F, a set of cylindrical sheets of stainless steel D₁, D₂ are used for thermal shields. The pressure in the vessel V is kept under 10^{-4} mm Hg during the measurement in order to prevent the sample from oxidation. The rate of heating of the sample is kept nearly constant, about 1°C/min, by a program control of the furnace input-voltage.

---

* An automatic recording of the measurement was carried out by Y. Murakami and its details will be reported in future.

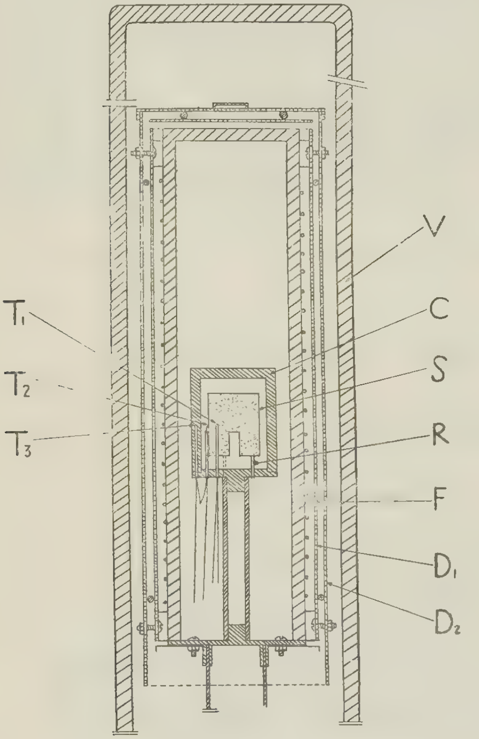

Fig. 2. The main part of the apparatus for the specific heat measurement.

c) *Measuring method*

The masses and the specific heats of the sample and the container S are denoted by m, m_0; $C(\theta)$, $C_0(\theta)$ respectively, where θ represents the absolute temperature. If θ_e is the temperature of the outer case C, the amount of heat which is transfered from C to S during the time interval Δt, can be represented by a function of θ and $\theta_e-\theta$, as $Q(\theta, \theta_e-\theta)\Delta t$. Then a following relation holds between them.

$$\{mC(\theta)+m_0C_0(\theta)+\delta(\theta)\}\frac{\Delta\theta}{\Delta t}=Q(\theta,\theta_e-\theta)\,, \quad (1)$$

where $\Delta\theta$ is the temperature increase during the time interval Δt; $\delta(\theta)$ is a correction term, which is responsible for the heat capacity of the holding rods, the parts of the themocouples inside the outer case C, and the heat conduction through them. The function Q may generally be written as $K(\theta)\{(\theta_e-\theta)-(\theta_e-\theta)_0\}$, where the suffix zero means the value obtained in thermal equilibrium and $K(\theta)$ is a coefficient of thermal transfer between the container and the outer case[10]. Supposing the thermal transfer is mainly due to the radiation, $K(\theta)$ will be proportional to θ^3 [11]. Now Eq. (1) becomes to

$$mC(\theta)+m_0C_0(\theta)+\delta(\theta)$$
$$=K(\theta)\frac{\Delta t}{\Delta\theta}\{(\theta_e-\theta)-(\theta_e-\theta)_0\}\,. \quad (2)$$

Here let us consider the measurement are carried out three times as follows; the first one is for the sample concerned, the second for a standard sample, of which the specific heat is well known in the present temperature range, and the third for the container alone. If the successive experiments are denoted as 1, 2, 3 respectively, the following equations are obtained:

$$m_1C_1(\theta)+m_0C_0(\theta)+\delta(\theta)$$
$$=K(\theta)\left[\frac{\Delta t}{\Delta\theta}\{(\theta_e-\theta)-(\theta_e-\theta)_0\}\right]_1\,, \quad (3)$$

$$m_2C_2(\theta)+m_0C_0(\theta)+\delta(\theta)$$
$$=K(\theta)\left[\frac{\Delta t}{\Delta\theta}\{(\theta_e-\theta)-(\theta_e-\theta)_0\}\right]_2\,, \quad (4)$$

$$m_0C_0(\theta)+\delta(\theta)=K(\theta)\left[\frac{\Delta t}{\Delta\theta}\{\theta_e-\theta)-(\theta_e-\theta)_0\}\right]_3\,. \quad (5)$$

Subtractions (5) from (3) and (4) give

$$m_1C_1(\theta)=K(\theta)A_1\,,$$
$$A_1=\left[\frac{\Delta t}{\Delta\theta}\{(\theta_e-\theta)-(\theta_e-\theta)_0\}\right]_1$$
$$-\left[\frac{\Delta t}{\Delta\theta}\{(\theta_e-\theta)-(\theta_e-\theta)_0\}\right]_3\,, \quad (6)$$

$$m_2C_2(\theta)=K(\theta)A_2\,,$$
$$A_2=\left[\frac{\Delta t}{\Delta\theta}\{(\theta_e-\theta)-(\theta_e-\theta)\}_0\right]_2$$
$$-\left[\frac{\Delta t}{\Delta\theta}\{(\theta_e-\theta)-(\theta_e-\theta)\}\right]_3\,. \quad (7)$$

From these equations, we get $C_1(\theta)$ as follows;

$$C_1(\theta)=\frac{m_2A_1}{m_1A_2}\cdot C_2(\theta)\,. \quad (8)$$

For the relations (3), (4) and (5) to hold simultaneously, the conditions in each measurement

1, 2, 3 should be kept as same as possible; for example, the pressure in the vessel V, the mounting situations of the container and the thermo-couples, the increasing rate of the temperature, etc..

To see how these situations are realized, the measurements for two alumina samples different in mass were carried out, and the relations (6) and (7) were checked. In this case the substances denoted by the suffixes 1 and 2 are both alumina and $m_1=12.75$ g, $m_2=14.02$ g. Fig. 3 shows the values of $A_1/C_1(\theta)$ and $A_2/C_2(\theta)$ in an arbitrary scale and their ratio obtained from the measurements. Provided the conditions stated above are satisfied, this ratio should be constant, m_2/m_1, in the whole range of the temperature. Our result shown in Fig. 3 is just like that. Further, $K(\theta)$ is seemed to vary as θ^{-3} above 90°C. The deviation from θ^{-3} below 90°C seems to be due to the predominance of the heat conduction through the rods and the thermocouples.

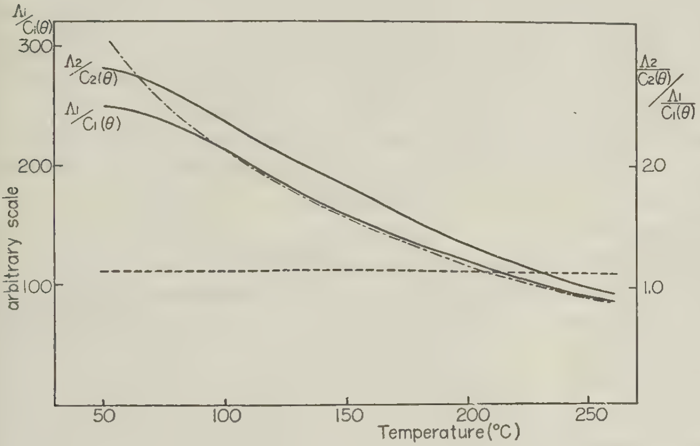

Fig. 3. The calibration characteristics for Al_2O_3 powder. The full lines show the temperature dependences of $A_1/C_1(\theta)$ and $A_2/C_2(\theta)$, the dashed line their ratio, which is nearly constant and equal to $m_2/m_1=1.102$. The hyphenated line represents θ^{-3} curve which is plotted so as to coincide with curve at 100°C.

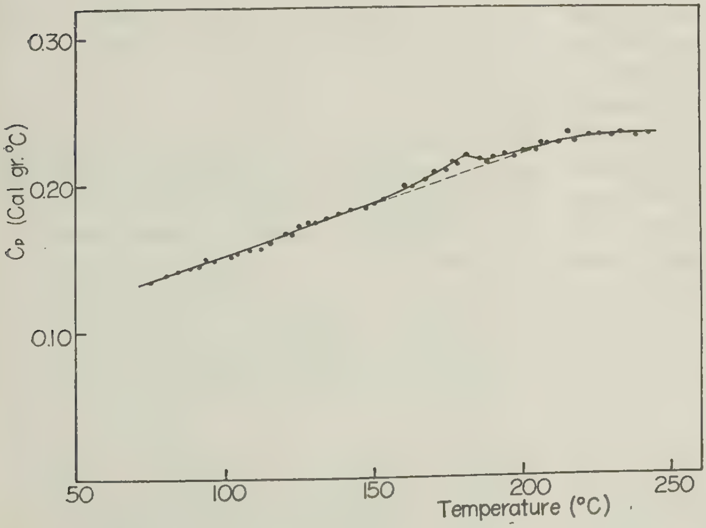

Fig. 4. Specific heat of Ti_2O_3.

§ 3. Results and Discussions

The specific heat of Ti_2O_3 in the temperature range from 50° to 250°C is shown in Fig. 4. A small anomaly is observed near 180°C, the anomalous heat being calculated as *ca* 36 cal/mol. The measurement was carried out under the pressure of 10^{-4} mm Hg. When the pressure was of the order of 10^{-2} mm Hg, a rather large amount of anomaly, over 100 cal/mol, could be observed. The samples, which had extra lines in addition to those of Ti_2O_3 itself in the X-ray analysis, also showed a large specific heat anomaly. These facts suggest that the heat of oxidation might additively be observed in the measurement of the specific heat, if one did not take care of the removal of oxygen in the vessel.

Naylor[9] made the heat-content measurement of Ti_2O_3 by the drop method at temperatures as high as 1750°K. The sample used was prepared by the carbon-reduction of titanium dioxide (the chemical analysis showed 99.4% Ti_2O_3). In his method, the sample was enclosed in a platinum-rhodium alloy capsule during the measurements. The capsule, after being filled with the sample, was evacuated free of air, filled with helium, and sealed-off with platinum. In his paper, he stated that he had found an anomalous heat of about 215 cal/mol near 473°K, but the determination of the transition temperature was difficult and considered to be accurate only to about 20°K.

Comparing our result with Naylor's, following points are noticed;

(1) Naylor's method is considered to be rather superior than ours for determining the mean absolute value of the specific heat, but our method is considered to superior for observing temperature dependence of the specific heat near the anomalous point.

(2) In our case the anomalous heat spreading over the temperature range from 160° to 200°C was observed. This fact corresponds to Naylor's remark that the selection of the transition temperature was difficult in his heat-content measurement. The absolute values of the specific heat in two cases agree well at 200°C, but the amounts of the anomalous heat at the transition show a large discrepancy. This discrepancy may be due to the effect of oxidation of the sample. The small contents of the impurities, further, may play a large role for it, as in the case of the electrical conduction phenomena.

Hitherto, many investigations have been carried out for the properties of Ti_2O_3, and it is supposed that the transition should be caused not by the magnetic ordering but by a change of the bonding character between the cations Ti^{3+} near the transition temperature. In recent papers about oxides[8], Goodenough has pointed out that the electron-pair-bond formation between cations Ti^{3+} plays an important role for the transition of Ti_2O_3 and that only a non-cooperative transition can occur. Any quantitative estimation about the specific heat anomaly of Ti_2O_3 can not be made from Goodenough's model, because of its qualitative nature. But it may be supposed that a large anomoly would not be expected for this substance, because of the lack of the magnetic ordering, the non-cooperative character of the transition and the small lattice deformation by the electron-pair-bond formation. It may be considered that the specific heat anomaly is composed of the electronic term, which is due to the thermal excitation of electrons between fairly splitted levels t_{2g} which would contribute to the semiconducting character below the transition, and the lattice-vibration term which is affected by the electron-pair-bond formation. As Ti_2O_3 is still semiconducting above the transition, a large electronic specific heat anomaly would not be expected near the transition. Noticing that the specific heat anomaly is only about 47 cal/mol even in barium titanate[12], in which the change of the lattice parameters is the same order as that of Ti_2O_3 and the cooperative transition takes place, our results on Ti_2O_3 seems to be reasonable for the electron-pair-bond model.

The authors wish to express their sincere thanks to Prof. S. Sawada for helpful discussions and continual encouragement.

Regrowth of Germanium from Molten Indium or Lead

By Masami Tomono

Central Research Laboratory, Hitachi, Ltd., Kokubunji, Tokyo

(Received December 21, 1960)

A single crystal of n-type germanium was alloyed with indium on its (111) plane and the resulting regrown layer of p-type germanium was observed. When the specimen was cooled at an intermediate speed, dendritic crystal is produced on the flank of the pan-shaped regrown layer. In the case of cooling at very low speed, steps bounded by (111) plane are produced also on the flank. Any of these may be indicative of the growth due to screw dislocation. On the other hand, when the specimen was cooled rapidly, growth due to surface nucleation takes place on the bottom while dendritic growth due to screw dislocation is produced on the flank. As to a specimen made by alloying $Pb-As$ alloy on a p-type germanium pellet and subsequently cooled at low speed, several layers of striations are observed on its cross-section. By this method, it is possible to make observations on the state in which misfit grain boundary is formed in the course of regrowth and also on the anomaly of regrowth produced around a blowhole and other foreign materials.

§ 1. Introduction

Many studies have been made on the shape of regrown germanium crystal produced when the germanium substrate is alloyed with indium, lead or other low-melting-point metal[1),2),3),4)]. As to the cooling process of the temperature cycle during alloying, if the cooling speed is high, uniform regrown layer is produced whether the solid-liquid interface coincides to the (111) plane or not. In the case of intermediate speed, jagged regrowth surface results and inclusion of solvent metal is present in the regrown layer. For a lower speed, it is known that the regrown layer is again uniform[2)]. The author made detailed observations on the regrown germanium layer obtained by alloying indium to an n-type germanium crystal. In an earlier report[5)], the results of the observations were presented on the regrowth pattern on the flat and smooth bottom area of the pan-shaped regrown layer obtained by the rapid cooling of specimen during alloying. Subsequently cooling speed was varied and the corresponding changes in regrowing state of p-type germanium were observed on the sloping flank of the pan-shaped regrown layer. Further, cross section of the regrown layer was made at the bottom of the pan and the layer was made at the bottom of the pan and the layered structure was examined. Finally, $Pb-As$ alloy was alloyed to a p-type germanium single crystal and the resulting distinct layered structure was examined, then the state in which grain boundary is formed by misfitting in the regrown germanium or the growing state of crystal around a blowhole was observed.

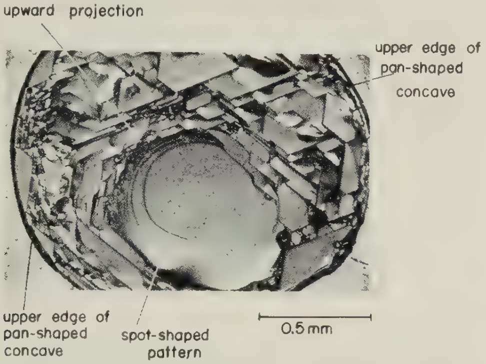
§ 2. Experiment

2.1 *Dendritic regrowth*

A single crystal of n-type germanium was heated at about 590°C with a small piece of indium on it, and subsequently cooled at a speed of about 20 deg/sec. The resulting regrowth of the germanium is shown in Fig. 1. In the flat and smooth area on the bottom seen slightly below the center of the figure there exist many spot-shaped patterns, and these correspond to the abnormal regrowth pyramids described in the earlier report[5)]. On the sloping surface of the pan-shaped concave, the dendritic lamellae grow, each of which is bounded by a straight line parallel to [110] axis. In the vicinity of the lamella edge, there exists an upward projection and with this as a center an upward growth takes place. Fig. 2 shows relatively large dendritic lamella appeared on the upper edge of the pan-shaped concave of the specimen which was made by alloying indium at 540°C and subsequently cooling at an intermediate speed—about 60 deg/sec. On the large lamella parallel to the (111) surface of the germanium substrate, there exist in a large number the so-called abnormal regrowth pyramids described in the earlier report[5]. From this, it is known that the regrowth in the direction perpendicular to the lamella has taken place. A specimen obtained under nearly the same condition in the case of Fig. 1 was cleaved with a pincette, and the cleaved surface is shown in Fig. 3. Initially, the dendrites grow along the direction nearly perpendicular to the (111) plane of the substrate surface, but after some progress of the growth, a lateral growth parallel to the same (111) plane takes place dominantly. The hexagonal plates seen layered in Fig. 1 correspond to the latter. Further at the root of the dendrite, it is possible that indium is left pent up in the regrown layer when the adjacent growing dendrites unite together[2]. At the end of the regrown layer located slightly left to the center, upward projections are observed. They may be the same as those on the edges of lamellae of Fig. 1. Fig. 4 shows the cross-sectional view of a specimen which was cooled at a speed as low as 0.3 deg/sec and cleaved again with a pincette. In this case, stepped regrown layers, each bounded by the {111} planes, exist on the sloping flank. At the boundary between the flat area on the bottom and the steps on the flank, there exists a moat which was formed by the delay of the growth as is already known[6]. We see in Fig. 1 that such a moat is also formed by the cooling at a higher speed. When a specimen is kept at 520°C and subsequently cooled rapidly by pouring oil, an extremely thin p-type regrown layer is produced. This specimen was ground at an angle of 18° with its surface and the cross section was etched for about 1 minute with the etchant composed of 40% concentrated nitric acid (48%) and 20% deionized water. The result is shown in Fig. 5. In parallel to the (111) plane of the substrate single crystal surface, regrown layer about 2.7 μ thick is produced. In this case, a striation exists in the regrown layer in parallel to the p-n boundary on the bottom. The regrown lawer on the sloping surface seen in the right-hand part grows in parallel to the p-n boundary at first, but from the part corresponding to the striation on the bottom fine dendritic growth takes place. At the part where the regrown layer on the bottom and that on the sloping surface meet each other, no regrown layer exists at all. The dendritic regrowth pattern on the sloping surface observed under an electron microscope is shown in Fig. 6. The specimen was prepared by rapid cooling by pouring oil as in the case of Fig. 5. In the present example, it is assumed that the temperature was lowered down to below the melting point of the indium within about 0.1 sec. The observations by the electron microscopy were made by replica method using the platinum-palladium shadowing. On the surface of each lamella fine regrowth patterns are seen and they are indicative of the progress of layered growth around some growth centers and in the direction approximately perpendicular to the photograph. From the width of shadow, it was ascertained that the height of these fine growth steps is about 200Å. At the part where the upper and lower adjacent lamellae unite with each other, the growth pattern of the upper lamella overflows and spreads over the lower lamella. Fig. 7 shows the dendritic growth pattern on the less sloped area of the specimen which was prepared by the similar rapid cooling. The photograph shows clearly that the upper and lower steps unite with each other to make the growth pattern continuous. The black irregular pattern is caused by the collapse of replica at the part where intricate structure exists. This area may be a valley caused by the delay of crystal growth due to some obstacles. Blowholes or impurities attached to the crystal surface may be such obstacles. In Fig. 8, the photograph of the part at which the flat and smooth surface on the bottom and the sloping surface of the regrown layer meet together is shown on a specimen prepared similarly by rapid cooling. From the area where the end of the growth step of the lamella in the upper right and the flat and smooth surface on the bottom come in contact with each other, fine concentric growth steps develope locally. In the other part on the bottom it is distinctive that the growth pattern due to the surface nucleation described in the earlier report[5] appears unlike the case of Fig. 1. At the part where the stepped crystal and the bottom surface meet together there is a gap and this gap corresponds to the part which lacks regrown layer on the edge of the flat and smooth surface of Fig. 5.

2.2 *Striation*

In Fig. 5, an example was given to show the striation appeared on the germanium layer regrown from the indium melt. The author prepared a specimen by alloying 97%*Pb*−3%*As* alloy to a *p*-tpye germanium pellet at about 800°C and subsequently cooling the system at a low speed of 0.2 deg/sec. The specimen was then cut and the cross-section was etched with an etchant of 60% concentrated nitric acid and 40% fluoric acid (48%) and observed under a microscope. By this method, it was possible to observe the striation in the regrown germanium layer. An example of this case is



upward projection
upper edge of pan-shaped concave
upper edge of pan-shaped concave
spot-shaped pattern
0.5 mm

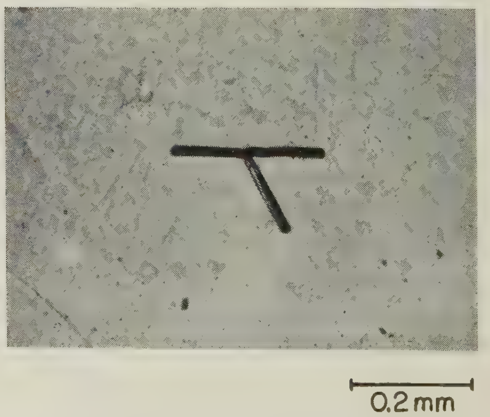

Fig. 12. Special defect in the single crystal grown from germanium melt

given in Fig. 9(a) and (b). (b) is close-up of the central part of (a). A striation in the lower *n*-type regrown layer develops in parallel to *p-n* boundary and the formation of regrown layer is relatively complete. On the contrary, many imperfect structures are seen in the upper regrown layer. In the early stage of the alloying, the molten $Pb-As$ alloy had arrived just at the point A in the figure. At the time when the surface tension decreased due to somewhat elevated temperature, drop of the melt spread to a position B. It is for this reason that the quantity of *p*-type germanium dissolved into the $Pb-As$ melt is smaller in the part between A and B than A and J, and hence stepped structure is caused in the *p-n* boundary at A. The *p-n* boundary between A and J is parallel to the (111) plane. A *p-n* boundary on the flank crossing at J aslant with the above-mentioned boundary will be another {111} plane. On the other hand, the sloping parts of the step at A and B are deviated from such {111} plane macroscopically. At the beginning of the regrowing process, regrowth had taken place nearly in parallel to the *p-n* boundary also in the neighborhood of A, but due to the presence of such a slight non-uniformity as point C (which is probably a fine blowhole or foreign material), difference in growing state had been caused between the right- and left-hand sides and from this part a misfit plane CD had developed. On the right of CD, the slope of the growing surface increases gradually and approaches the {111} plane which makes an angle of 70°32′ with the (111) plane on the bottom.

Further on the right, another misfit plane EF is present against the (111) plane parallel to the bottom. In the part where a fine blowhole G exists, the growth is markedly delayed at first compared with the surrounding part, but once passing over that blowhole the growth makes up the delay resulting in the flat and smooth striation. In the neighborhood of such a large blowhole as H, distinct non-uniformity in growth is seen. At the part neighboring to the bottom of the blowhole, growth of crystal is badly delayed as shown by the striations FHI similarly to the case of G. But, thereafter the growth is made so rapidly that at KL it is rather protruding than in the other part. One end of the *n*-type regrown layer B, in the left-hand part of the figure has grown to have the same height as other parts, but the other end J in the right-hand part is poor in growth and makes a concave.

2.3 *Regrowth in the neighborhood of a blowhole*

We found in Fig. 9 that in the neighborhood of a blowhole the growth is more distinct than in the other areas. To examine this in more detail, Fig. 10 is presented. The specimen was prepared in nearly the same way as in the case of Fig. 1. In the part around a relatively large blowhole, frequently the growth is more advanced than in the other. Some of the growth patterns are developed from a part around the blowhole as a center. Fig. 11 shows an example of the growth patterns developed around a blowhole. The specimen in this case was prepared also in nearly the same way as in the case of Fig. 1.

A terrace seen on the right of the blowhole represents the top surface surrounded by [110] axes of the abnormal growth pyramid described by the author in the earlier report[5]. With at least two centers around the blowhole, two groups of growth patterns are seen. Similar growth patterns are present also in the left-half neighborhood of the blowhole where the growth is delayed compared with the terrace. This suggests that the growth of the terrace and the concentric growth arround the blowhole are independent of each other.

2.4 *Special defect in the single crystal grown from germanium melt*

In Fig. 12, the special defect frequently found in the single crystal which was grown from the germanium melt is shown.

As described in the earlier report, this defect badly affects the electric characteristics of the *p-n* junction[7]. The cause for the formation of this defect will be discussed later.

§ 3. Discussion

3.1 *Regrowth of germanium*

The author pointed out in the earlier report that the regrowth of *p*-tpye germanium from the indium melt is due to the screw dislocation in some cases and the surface nucleation in the others. From the results of that study it follows presumably that for the growth rate exceeding some 20 μ/sec the crystal growth can be caused by the surface nucleation but in the case of lower rate screw dislocation is responsible for the growth[5]. With reference to the experimental results discussed in §2, when the heated specimen of Fig. 5 was cooled rapidly by pouring oil, its temperature might be lowered down to below the melting point of the indium within 0.1 sec. Since the flat and smooth bottom area of the p-type regrown layer is 2.7 μ thick, the growth rate is roughly 30 μ/sec and therefore there is a possibility of growth due to the surface nucleation. In Fig. 5, there is a great difference in the growth patterns between the flat and smooth surface of the bottom and the sloping surface of the flank. Referring to Fig. 8 for the similarly prepared specimen, a planar growth pattern not clear in symmetry exists in the lower left part of the photograph. This is probably indicative of the growth caused by the surface nucleation as described in the earlier report[5]. On the other hand, the growth in the sloping part of Fig. 5 is dendritic clearly. Referring to Fig. 6, each dendritic lamella has some growth centers clearly. In this case, it is assumed that the growth takes place with several very adjacently existing screw dislocations as a center. In the case of Fig. 5, which of the surface nucleation or screw dislocation is responsible for the growth may be dependent on the condition of the substrate crystal surface. In the present case, the flank area is deviated from the (111) plane macroscopically, but it seems microscopically to be formed by bunching together of a great number of fine growth steps surrounded by two {111} planes crossing at an angle of 70°32′ with each other. At the begining, the growth progresses with the concave corner of the step as center and consequently, the regrown layer develops in parallel to the sloping surface of the substrate[2] as seen from Fig. 5, but after a while the new crystal planes thus grown from the adjacent concave corners meet with each other at the convex corner and cause the misfit boundary there. It is quite possible that by the repetition of such process many screw dislocations are produced. It is known that the dendrite is liable to be produced if the temperature gradient from inside the solid towards the solid-liquid interface is larger than that from the interface towards inside the the liquid, especially if the gradient inside the liquid is negative[8],[9],[10]. This condition will be satisfied in case the specimen was cooled rapidly by pouring oil. When the abovementioned two conditions are satisfied simultaneously, the dendritic growth may take place due to the screw dislocations. On the other hand, on the flat and smooth (111) plane of the bottom relatively uniform growth occurs and therefore, the screw dislocations are not produced so much. It is probably for this reason that even when the cooling speed was made extremely high at the end of the cooling period the dendrite due to the screw dislocation is difficult to grow and rather the surface nucleation is responsible for the growth. In comparison with the above, the growing speeds in the cases of Figs. 1, 3, 4, 10 and 11 are extremely small and for these cases it will be doubtless that the growth is effected by the screw dislocation. It has been known that under the special conditions lamellar dendrite is produced[8], and the large lamellar crystal grown on the upper edge of the panshaped concave of Fig. 2 will be a dendritic lamella caused by the presence of twin planes[11],[12]. The growth of this lamella to its thickness direction is effected surely by the screw dislocation because the abnormal growth pyramids described by the author in the earlier report[5] are present in a large number on the surface of the lamella. The mechanism with which dislocation array is produced on such a lamella has already been described[13], and the array conceivably plays the role as the center of the abnormal regrowth. Finally, the discussion on the case of Fig. 9 will be given as follows: For such a markedly slow cooling, it is quite easy to consider that the crystal growth is effected by the screw dislocation[5]. The heat of melting of germanium into the molten indium is 11.9 kcal/mol[14],[15], while that of germanium into lead is 19.2 kcal/mol with reference to the phase diagram G_e-P_b system[16]. Generally, the activation energy for nucleation, ΔF_c, is given by[17].

$$\Delta F_c=\left(\frac{\Delta H}{2N}\right)^2\frac{1}{kT\ln\alpha} \qquad (1)$$

where ΔH is the heat of melting, N is the Avogadro's constant, k is the Boltzmann's constant, T is the absolute temperature and α is the saturation ratio of germanium in the melt. Denoting by I the rate of formation of critical nuclei, we have[17].

$$I=I_0\exp(-\Delta F_c/kT) \qquad (2)$$

I_0 is a constant, and for the growth of germanium from the indium melt, it is expressed as:

$$I_0 \approx 10^{25}\ \mathrm{cm}^{-2}\ \mathrm{sec}^{-1} \qquad (3)$$

As the saturation ratio α exceeds 1.4, the growth due to surface nucleation becomes prominent as described in the earlier report. The growing speed of the crystal in this case is about 20 μ/sec[5]. While, in the case of lead the heat of melting is extremely large compared with indium as described above, and consequently, for the crystal growth to be effected mainly by the surface nucleation, the saturation ratio must be larger than in the case of indium. From this, it follows probably that the possibility of the germanium crystal being grown by the surface nucleation from the melt having lead as its main component is badly poor, especially when the specimen was cooled at considerably low speed as in the case of Fig. 9. On this ground, it is conceived that the regrowth of n-type germanium in the case of Fig. 9 had been effected by the screw dislocation. But, it seems difficult to find the reason why the screw dislocations cause the several layers of striation patterns as seen in Fig. 9 to be presented. In the earlier report[5], the author assumed that the so-called abnormal growth pyramid might be caused, when the pair of the clusters of adjacent screw dislocations with equal sign were present and the clusters had different sign each other. In the course of growth of germanium crystal from the lead melt, because some of the regrown germanium lattice sites are substituted by the larger atom of lead, a great number of lattice defects may be caused at the beginning of growth of n-type germanium on the substrate[10]. As a consequence, there will also be a possibility of producing many pairs of adjacently existing screw dislocation clusters as described above. Denote by ρ_c the radius of critical nucleus and by A the spacing between the adjacent screw dislocation clusters of the same number of dislocations but with different signs each other respectively. Then, if the supersaturation of germanium in the melt is not so high, it is possible that ρ_c is large enough to meet the relation $2\rho_c > A$. In such case, the screw dislocation clusters with different signs interefere with each other and do not participate in the growth. Thus, the crystal growth is effected mainly by the single screw dislocation existing at random on the substrate crystal surface. The growing speed in this case is relatively small, but as the specimen is cooled down gradually, the supercooling becomes large accordingly and hence ρ_c becomes small. And when $2\rho_c < A$ is reached the screw dislocation clusters with different signs begin to act as the centers of of growth independently of one another. This causes the growing speed to be increased and as a result, the supercooling becomes again small. At the same time, heat of solidification is generated so much that the temperature of the solid-liquid interface is raised, thus the the supercooling becomes smaller. Since this is the case, ρ_c becomes again large, thereby the growth due to the above-mentioned screw dislocation clusters being completely stopped and the growing speed considerably reduced. This process is possibly repeated several times before the regrowth of germanium is completed if the specimen was cooled at extremely low speed as in the pressent example. In case the crystal growth is advancing at high speed, effective segregation coefficient of As will be larger and in the regrown layer at that part a larger amount of As is contained. Thus, the growth at high speed and that at low speed will be repeated alternately, probably thereby enabling the several layers of striations to be produced. As to the variation in the effective segregation coefficient with the growing speed of the germanium crystal, it has been well known that in general the donor impurity is liable to be changed[18].

3.2 *Striation*

From the striation patterns of Fig. 9 it is possible to know much about the regrowth. In the lower part of the figure, the n-type regrown layer extends in parallel to the p-n boundary. This is probably because both of bottom and flank areas of the p-n boundary were composed of the single (111) plane respectively, no blowhole was present in the melt during the regrowth, and the cooling was made at a very low speed. In this case the delay of the regrowth at the periphery of the bottom surface as seen in Figs. 4 and 5, at the part J of Fig. 9 and in many other cases cannot be observed. At the part J of Fig. 9, the first striation has grown to nearly the same degree as other parts, but the second, the third, .. etc. have attained very poor growth.

This indicates that in the cooling process the regrowth at the periphery is effected on both the bottom and flank parts simultaneously, and the supply of germanium from the melt is apt to be insufficient. This trend becomes distinct as the regrowing process progresses. Our explanation for such difference between two parts is as follows: In the lower part, molten *Pb—As* maintained nearly the same shape throughout the whole process of alloying, while in the upper part, drops of the molten *Pb—As* collapsed and spread over the region A∼D of the figure in the course of the heating process as described in 3.2. This made the difference in the shape of the drop between the heating and cooling processes, and especially at the periphery reduced the thickness of the molten layer. Next, as to the part A∼B of the photograph, to which the molten *Pb—As* spread at the later time as described above, the solid-liquid interface produced in the course of the heating process was substantially deviated from the single (111) plane though the growth at the beginning was made in parallel to the interface. As the growth progresses, the interface shows a trend to approach the most stable {111} planes, and once encountered with such a disturbance as blowhole C, the left part of C approaches the (111) plane parallel to the bottom and the right part approaches the other {111} plane which makes an angle of 70°32′ with the bottom, and at the same time grain boundary due to misfitting is produced as shown by CD. Further, on the immediately right of CD, as the regrowth progresses the angle between the interface and the bottom plane become large gradually, and then another grain boundary EF is produced. On the other hand in the neighborhood of B, the slope of growth plane with respect to the (111) plane is relatively small and no misfit boundary is produced. At the part neighboring to a small blowhole G, supply of germanium from the melt is less than other parts at first and apparently the growth is delayed. But, once passing over the blowhole, the growth becomes more rapid compared with the other parts, thus resulting in the flat and smooth growth pattern after a while. It is apparent that in the case of such slight uneveness being present on the growth plane a trend to produce flat and smooth growth plane exists. On the other hand, in the case of such a large blowhole as H being present, the growth is badly delayed in that part at first as shown by FHI, but as the specimen is cooled down, the blowhole contracts gradually and fresh melt is pushed and collected in the place from above, thereby possibly starting the growth newly around the blowhole. Then, if any two growth surface which progressed along the blowhole collide with each other anywhere around it, then screw dislocation arrays will be produced with a high possiblility. With this array as a center, rapid abnormal growth takes place resulting in the swollen growth at the area around the blowhole as shown by the parts K and L compared with the other parts. Similarly, in the case of regrowth from the indium melt, swollen growth is produced as shown in Fig. 10 frequently at the area around the blowhole, and many growth centers exist around the blowhole as shown in Fig. 11. Further in Fig. 11, the growth pyramid swollen in a terrace on the right of the blowhole represents the abnormal growth pyramid described in the earlier report[5], and the growth patterns developing from several growth centers around the blowhole are seen to exist also in the delayed growth area on the left of the above-mentioned terrace. This fact will be easily understood on seeing that the growth at K and L of Fig. 9 developed independently of the other areas at the end of the regrowth period.

3.3 *Defect accompanying the dendritic growth*

When the specimen was cooled rapidly, dendritic crystal growth took place in the sloping area deviated from the (111) plane, and each dendritic lamella grows due to screw dislocation as seen in Figs. 6 and 7. In these figures it will be seen how a crystal growth occurs from the upper lamella towards the lower one at the part where the both lamellae unite with each other. As seen from Fig. 3, in this case indium is left at the root of the projection[2]. Such a defect will be possible to occur if the solid-liquid interface is inclined somewht with the (111) plane when the single crystal is grown from the germanium melt containing a trace of impurity. In such case, the impurity in the germanium melt is concentrated there gradually, so that its melting point is lowered down to such value that after the surrounding has been solidified completely and a rapid solidification occurs there. The special defect found frequently in the germanium single crystal as shown in Fig. 12 is considered to be created by such cause. Sometimes, such defect appears as the layered structure independent on the surrounding single crystal at all, and this will be reported by Y. Sugita[19].

Acknowledgement

The author is indebted to Mr. Y. Sugita for his supply of many data and cooperation in experiment.

Low-Temperature Electrical Breakdown in Germanium

By Jiro YAMASHITA

Institute for Solid State Physics, University of Tokyo, Tokyo

(Received December 26, 1960)

The low-temperature electrical breakdown effect in n-type germanium which was observed by Sclar and Burstein, and Koenig and Gunther-Mohr, is discussed from viewpoint of the hot electron theory. At first, we assume that the energy loss of conduction electrons comes only from the acoustic scattering, while the mobility is determined by ionized- and neutral impurity scatterings besides the acoustic scattering. We evaluated the electron temperature as a function of applied field and then estimated the rate of ionization of donors and the thermal recombination coefficient. By using these values we estimated the breakdown field of some specimens and compared it with the experiment. The result of the theory seems to be in good agreement with the experiment, when the concentration of donors and acceptors is fairly small. The theoretical result is, however, inconsistent with the experiment, when specimens contain donors above $10^{15}/\text{cm}^3$. It seems to be other mechanisms of the energy loss which work more effectively than the acoustic scattering does, when the concentration of the donors is above $10^{15}/\text{cm}^3$. Further, we proposed a mechanism of the energy loss at compensated germanium which leads to the negative resistance.

§ 1. Introduction

Recently the low-temperature electrical breakdown effect in germanium has been actively investigated.[1] Although some aspects of the phenomenon are qualitatively explained, many experimental facts are still open to further investigations. On the other hand, appreciable progress has been made in both experimental and theoretical studies on warm or hot electron problems at higher temperatures. One of the characteristics of investigation of hot-electron phenomena lies in the fact that it gives a more detailed information about the energy-loss of conduction electrons than the usual ohmic current does.[2] Therefore, it is quite natural to expect that the low-temperature electrical breakdown effect may give a valuable information about a mechanism of the energy-loss of conduction electrons at very low temperature. The purpose of the present paper is to give a result of a preliminary analysis performed by such expectation as mentioned previously. As a result of the analysis we have found that the mechanism of the low-temperature breakdown is rather complicated, because many elementary processes are participated, each in its degree which depends upon a state of each specimen. At present, our knowledge of these elementary precesses is rather poor, so that we are inevitably compeled to introduce somewhat ambiguous assumptions. However, since the low-temperature breakdown effect is a very good source of information of the elementary processes at very low temperature, we hope that the further progress of study on the former will make a good contribution to understanding of the latter.

§ 2. Models and Assumptions

First, we shall give a brief account of models and assumptions with which we shall start the analysis. They are quite conventional ones, but not always free from objections. (1) The shape of energy surfaces is spherical. (2) The conduction electrons are scattered by the acoustic mode of vibrations, ionized-impurity centers and neutral impurity centers. (3) The scattering due to ionized impurities and neutral impurities is elastic. Thus, the energy loss of the conduction electrons comes only from the acoustic lattice scattering. (We shall see later that this assumption is not right, when the density of impurities is above a certain limit.) (4) The rate of the lattice scattering is given by the usual formula, and the acoustic mobility at low temperature is estimated from observed values in the temperature range from 100 to 300°K.[3] Then, it is

$$\mu_L = 2.4\times10^7/T^{3/2} . \tag{1}$$

In germanium mc^2, where m is the average effective mass and c is the sound velocity in the lattice, is much smaller than KT even at liquid helium temperature, so that the so-called high temperature approximation is expected to be valid. (5) The rate of ionized-impurity scattering is given by[4]

$$\mu_i = \frac{8\sqrt{2}\,\kappa^2(kT)^{3/2}}{N_i e^3\sqrt{m'}\,\pi^{3/2}\ln\{1+(\kappa kT/e^2N_i^{1/3})^2\}} , \tag{2}$$

where N_i is the density of charged scatterers. Here $\boldsymbol{m'}$ is regarded as an adjustable parameter to fit the observed datas. However, the accurate value of it is unknown, because the density of the charged centers is not accurately determined. Here we assume tentatively $\boldsymbol{m'}=0.12\boldsymbol{m}_0$ (the averaged effective mass). As is well known, there is another formula of the ionized-impurity scattering, that is, the Brooks-Herring formula. Here we prefer to use the Conwell-Weisskopf formula rather than the *B–H*. The reason will be mentioned in section 7. (6) The rate of the neutral-impurity scattering is given by Erginsoy's formula.[5] The mobility is

$$\mu_n = 8\pi^3 m'' e^4/20\kappa h^3(N_D-N_A) , \tag{3}$$

where N_D is the density of donors and N_A is that of acceptors. Here it is better to interpret $\boldsymbol{m''}$ as an adjustable parameter which has been determined as $0.21\boldsymbol{m}_0$ by Sclar and Burstein.[6] (7) When the energy of the conduction electrons is larger than the ionization energy of the impurity center, they ionize an electron from the impurity center. The rate of energy loss due to the ionization, however, is quite small as compared with that due to the lattice scattering. Thus, the ionization process has little influence on the energy distribution of the conduction electrons.

As to mechanism of the low-temperature breakdown we follow the idea proposed by Koenig.[7] When the intensity of the applied field becomes large, the mean kinetic energy of the conduction electrons becomes large and some of them obtain enough energy to ionize an electron bound to the impurity center. The process which works to reduce the electron density is a capture process of the conduction electrons by empty donors. Since the rate of the ionization increases rapidly with increasing field and the capture cross section decreases with increasing electron energy, there should be a field intensity in which the rate of the ionization becomes as fast as that of the capture process. If the field intensity is above this critical value, no equilibrium state is expected to the conduction electrons. Therefore, this critical field is regarded as the breakdown field. The mathematical formula for this condition is

$$A_t(N_D-N_A-n)+n\{A_i(N_D-N_A-n)-B_t(N_A+n)\}-n^2B_i(N_A+n)=0 . \tag{4}$$

The quantities A_t and A_i represent the rates of carrier production by thermal generation and impact ionization, respectively, and B_t and B_i the respective inverse process, that is, single-electron capture and Auger recombination. The coefficients A_i, B_t and B_i depend both upon the lattice temperature and the electron distribution. In practice we have $n \ll N_A$, N_D-N_A. If in addition the Auger recombination is neglected, the result simplifies to

$$n = A_t(N_D-N_A)/\{B_tN_A-A_i(N_D-N_A)\} . \tag{5}$$

Then, the condition of the breakdown is given by

$$B_tN_A = A_i(N_D-N_A) . \tag{6}$$

§ 3. Distribution Function and Electron Temperature

We start from the Boltzmann equation. Let us denote the distribution function by

$$f(\vec{K}) = f_0(E) + K_x g(E) , \tag{7}$$

where $\vec{K}$ and E are the wave number vector and energy of conduction electrons, respectively, and x is the direction of the applied field. Then, the B.E. is

$$\left[\frac{\partial f}{\partial t}\right]\equiv\left[\frac{\partial f}{\partial t}\right]_F+\left[\frac{\partial f}{\partial t}\right]_{ac}+\left[\frac{\partial f}{\partial t}\right]_i+\left[\frac{\partial f}{\partial t}\right]_n=0\,. \tag{8}$$

The meaning of the sufixes is: F=electric field, ac=acoustic scattering, i=ionized impurity scattering and n=neutral impurity scattering. The explicit expressions of these terms are:

$$\left[\frac{\partial f}{\partial t}\right]_F=\frac{eF}{\hbar}\left[g+\frac{2}{3}E\frac{dg}{dE}+\frac{\hbar^2}{m}K_x\frac{df_0}{dE}\right], \tag{9}$$

$$\left[\frac{\partial f}{\partial t}\right]_{ac}=-\frac{8ec^2}{3\sqrt{\pi}kT}\frac{1}{\mu_a}\frac{1}{\sqrt{E}}\left[E^2\frac{d^2f_0}{dE^2}+\left(\frac{E^2}{kT}+2E\right)\frac{df_0}{dE}+\frac{2E}{kT}f_0-\frac{E}{2mc^2}K_xg\right], \tag{10}$$

$$\left[\frac{\partial f}{\partial t}\right]_i=\frac{4e}{3m\sqrt{\pi kT}}\frac{6(kT)^2}{\mu_iE\sqrt{E}}K_xg \tag{11}$$

and

$$\left[\frac{\partial f}{\partial t}\right]_n=\frac{e}{m\mu_n}K_xg\,. \tag{12}$$

At very low temperature we can neglect the effect of the optical mode of vibrations. Then, it is not hard to find an analytical solution of B.E. In appendix we give the explicit expression of the solutions. If the distribution function is once obtained, the mobility or the rate of ionization of impurity centers will be determined by usual procedures. The distribution functions which were obtained, however, are rather complicated, so that numerical calculations are always required for further applications. An approximate procedure to obtain a more convenient, though less accurate, distribution function was developed by Stratton.[8] (A relation between this approach and the Boltzmann approach was discussed by us.[2]) In that approximation the distribution function $f_0(E)$ is assumed to be

$$f_0(E)=\frac{2}{\sqrt{\pi}(kT_e)^{3/2}}\exp(-E/kT_e)\,. \tag{13}$$

The electron temperature T_e is determined as a function of the applied field by the condition of the energy conservation:

$$e\sigma F^2=\int E\left[\frac{\partial f}{\partial t}\right]_{ac}\sqrt{E}\,dE\,, \tag{14}$$

where σ is the conductivity. Let us examine the condition for following three cases.

(a) Acoustic and neutral impurity scattering. After a simple computation the following condition is derived:

$$p(\mu(F)/\mu_a)=2(T_e/T)^{1/2}(T_e/T-1)\,, \tag{15}$$

where p and $\mu(F)$ are defined by

$$\mu(F)=\mu_a\left(\frac{T_e}{T}\right)^{1/2}\int_0^\infty\frac{x\sqrt{x}\,e^{-x}dx}{\sqrt{x}+\rho(T/T_e)^{1/2}}\,, \tag{16}$$

$$\rho=3\sqrt{\pi}\,\mu_a/4\mu_n \tag{17}$$

and

$$p=3\pi\mu_a{}^2F^2/16c^2\,. \tag{18}$$

When the condition $\mu_n\ll\mu_a$ is fulfilled, $\mu(F)$ is simply expressed as

$$\mu(F)=\mu_n\left\{1-\frac{32}{9\pi}\frac{\mu_n}{\mu_a}\left(\sqrt{\frac{T_e}{T}}-1\right)\right\}. \tag{19}$$

(b) Acoustic and ionized impurity scattering. The electron temperature is determined by

(15) with the definition of $\mu(F)$:

$$\mu(F)=\mu_x\left(\frac{T}{T_e}\right)^{1/2}\left\{1-q^2\int_0^\infty \frac{ue^{-u}du}{u^2+q^2}\right\}. \tag{20}$$

Here q is determined by

$$q=q_0(T/T_e)\{G(T_e)/G(T)\}^{1/2} \tag{21}$$

with the defimition of $G(x)$ and q_0:

$$q_0{}^2=6\mu_a/\mu_i \quad \text{and} \quad G(x)=\ln\{1+(3\kappa kx/e^2N_i{}^{1/3})^2\}. \tag{22}$$

By inserting the electron temperature T_e in $G(x)$ we take into account the energy dependence of q through $G(x)$. Performing a well known integral in (20) we have a final expression of the condition:

$$p\left\{1-q^2\left[\left(\frac{\pi}{2}-S_i(q)\right)\sin q-C_i(q)\cos q\right]\right\}=2\left(\frac{T_e}{T}\right)\left(\frac{T_e}{T}-1\right). \tag{23}$$

(c) When three mechanisms of the scattering are effective, the relation between the field and the electron temperature is again given by (15), but with the definition of $\mu(F)$:

$$\mu(F)=\mu_a\left(\frac{T}{T_e}\right)^{1/2}\int_0^\infty \frac{x^3e^{-x}dx}{x^2+q^2+\rho(T/T_e)^{1/2}x\sqrt{x}}. \tag{24}$$

§4. Rate of Impact Ionization and Rate of Thermal Recombination

Here we consider the impact ionization process in a p-n junction. A conduction electron which has a larger energy than the threshold of the impact ionization can transfer an electron from the valence band to the conduction band. Since this process occurs with a large probability, the distribution function above the threshold is mainly determined by this process and the applied field. In the low-temperature breakdown the situation is completely different. Since the number of impurity ions is much smaller than that of the lattice atoms, the perturbing effect of the impact ionization of the donors on the distribution function is not appreciable. At low temperature the condition $\mu_a \gg \mu_n$, or $\mu_a \gg \mu_i$, is always satisfied, so that the mean free path of the electron is mainly determined by scattering due to the ionized-, or neutral impurities. Then, since the cross section of the elastic scattering for very slow electrons is enormously larger than that of the ionization, the latter process has little influence on the mobility of the conduction electron. As for the energy loss of the conduction electron a more careful consideration is necessary. Let nS be the average number of electrons which enter into the conduction band per unit time by the impact ionization and E_0 be the average energy which is necessary for the ionization, then the energy loss due to the impact ionization is given by

$$n\int E\left[\frac{\partial f}{\partial t}\right]_{ion}\sqrt{E}\,dE=nSE_0. \tag{25}$$

Then, the previous expression of the energy conservation is now extended to:

$$e\mu(F)F^2=\frac{16ec^2}{3\pi\mu_a}\left(\frac{T_e}{T}\right)^{1/2}2\left(\frac{T_e}{T}-1\right)+SE_0, \tag{26}$$

or

$$p\left(\frac{\mu(F)}{\mu_a}\right)=2\left(\frac{T_e}{T}\right)^{1/2}\left(\frac{T_e}{T}-1\right)+\frac{3\pi\mu_a}{16ec^2}SE_0. \tag{27}$$

In the next section we shall make a numerical estimate of each term. The result is that even at the breakdown field the second term in (27) is still smaller than the first and can be safely disregarded, unless the density of impurities is above $10^{16}/\mathrm{cm}^3$. In the following we shall assume that the distribution functions which are derived in the previous section are still approximately valid, even when the applied field is as large as the breakdown field. Then, the time rate of the impact ionization is given by:

$$S=(N_D-N_A)\int_{\Delta E}^{\infty} vQ(E)f_0(E)\sqrt{E}\,dE\,, \tag{28}$$

where $Q(E)$ is the cross section of the impact ionization, v is the velocity of the colliding electron and ΔE is the depth of the donor-level from the bottom of the conduction band. It is a difficult problem to evaluate $Q(E)$ from the first principle. The experiment shows, however, that the cross section of the ionization of a hydrogen atom by a slow electron is nearly equal to its geometrical cross section πa_0^2. Therefore, for the purpose of a rough estimate of $S(T_e)$ it may be allowed to put*

$$Q(E)=\pi(\kappa a_0)^2\,. \tag{29}$$

Then, $S(T_e)$ is evaluated as

$$S(T_e)=2\sqrt{\frac{2\pi kT_e}{m}}(\kappa a_0)^2\left(\frac{\Delta E}{kT_e}+1\right)\exp\left(-\frac{\Delta E}{kT_e}\right)(N_D-N_A)\,. \tag{30}$$

Next, we shall discuss the rate of the thermal recombination. The magnitude of the coefficient for thermal electrons in the temperature range 4–10°K has been determined experimentally by Koenig.[9] However, we have no experimental knowledge about the thermal recombination time of the hot electron, so that we must rely upon theory. In order to estimate temperature dependence of the recombination time we followed the method of Lax.[10] The result is:

$$\tau_c(T_e)\equiv 1/B_tN_A=aT_e/N_A=2\times10^{-8}T_e(5\times10^{12}/N_A)\,. \tag{31}$$

The constant a is determined so as to fit Koenig's data when both lattice and electron temperature are about 4°K.

§ 5. Low Temperature Breakdown and Comparison with Experiments

From Koenig's experiment of the low-temperature breakdown we pick up four specimens in which detailed information of physical properties is available (Table I). At first, by using Eqs. (15) and (24) we evaluate the electron temperature T_e as a function of the apllied field. The results are shown in Fig. 1 and Fig. 2. In Fig. 1 we show also a T_e–F curve of an ideal case in which no impurities exist. We find a tendency that the T_e–F curves come together at the high temperature region, $T_e>10T$, and approach to the ideal curve at high temperature, if the density of donors and acceptors is sufficiently small; $(N_D-N_A)\sim10^{13}$ and $N_A<10^{13}$. Therefore, we except that the electron temperature of these specimens is roughly determined by the applied field irrespective of a

Table I.

No.	T°K	(N_D-N_A)	N_A	$(N_D-N_A)/N_A$	F_b (volt/cm)
1	4.55	1.0×10^{12}	4.0×10^{12}	0.25	14
2	4.55	1.5×10^{13}	5.0×10^{12}	3.0	4.8
3	5.056	2.2×10^{14}	2.8×10^{13}	7.6	9.1
4	4.79	1.9×10^{15}	2.3×10^{13}	83	14.3

---

* This cross section is quite small as compared with that of the elastic scattering, where $Q(E)=20(\kappa a_0)/K$. The ratio $20(\kappa a_0)/K$: $\pi(\kappa a_0)^2$ is equal to 40: 1 when $\Delta E=\hbar^2K^2/2m=0.01$ eV.

impurity content, and the breakdown field depends only upon the ratio $(N_D-N_A)/N_A$. In other specimens, No. 3 and No. 4, the situation is different. The T_e–F curve runs fairly apart from the ideal curve and it does not show a tendency of the convergence to the latter, unless the electron temperature is extremely high. In the following we shall designate the electron temperature which corresponds to the observed breakdown field as

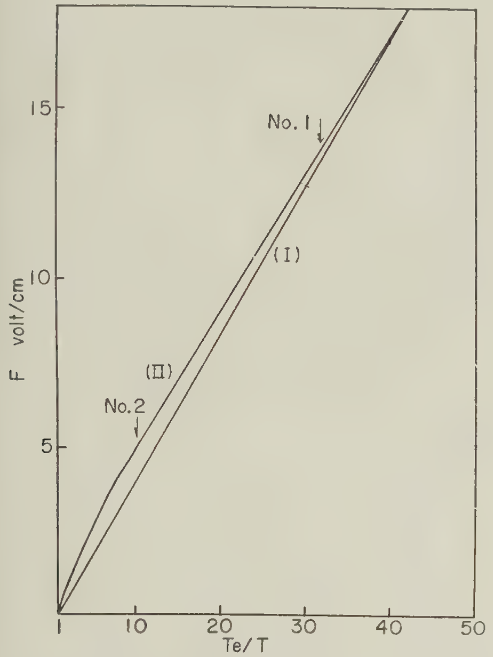

Fig. 1. Electron temperature vs. applied field (I) of ideal case, and (II) of specimens No. 1 and No. 2.

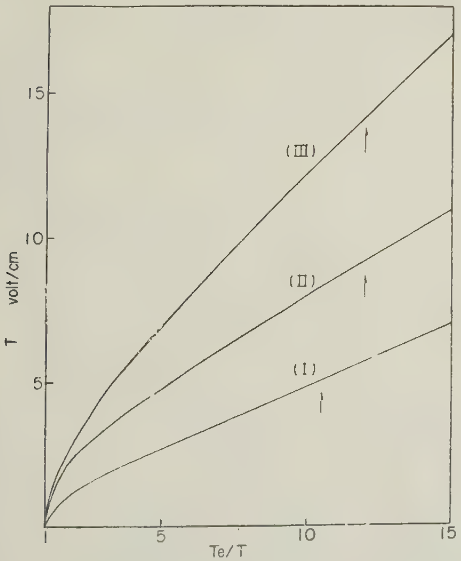

Fig. 2. Electron temperature vs. applied field (I) of specimen No. 2, (II) of specimens No. 3 and (III) of specimen No. 4.

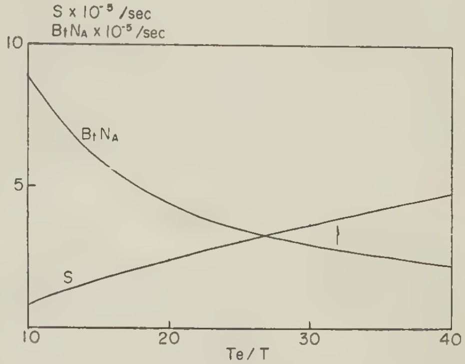

Fig. 3 (a). The rate of the impact ionization S and the rate of the thermal recombination coefficient B_tN_A in specimen No. 1.

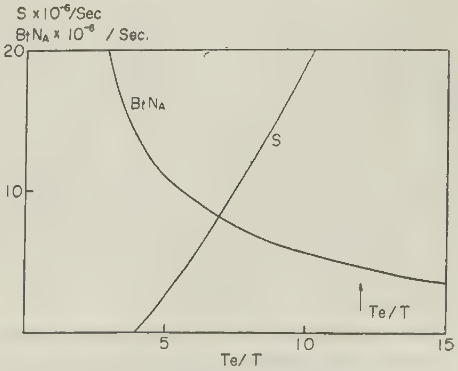

Fig. 3 (c). in specimen No. 3.

the breakdown temperature T_b. We show T_b by an arrow in Fig. 1 and Fig. 2. Next, let us estimate $S(T_e)$ from Eq. (30). The result is shown in Fig. 3. By using Eq. (31) we also estimate the value of $B_t(T_e)N_A$ for these specimens. The result is shown also in Fig. 3. As seen from the figure the condition (5) is roughly satisfied at specimens No. 1 and No. 2. Although the result of the present analysis must be judged very carefully, it seems to be consistent with the model of the low-temperature breakdown proposed first by Koenig.

At specimen No. 3 the agreement between the theory and experiment is not so good as at specimens No. 1 and No. 2, but the accuracy of the present analysis is so poor that we can say nothing definite about this specimen. However, the theoretical result is clearly inconsistent with the experiment at specimen No. 4. (Table II). According to the theory mentioned previously the breakdown temperature must decrease with increasing $(N_D-N_A)/N_A$, but in fact the breakdown temperature has a minimum as a function of $(N_D-N_A)/N_A$.

Sclar and Burstein[1)] investigated behaviors of the low-temperature breakdown for specimens which contain the donors $10^{14}-2\times10^{16}/\mathrm{cm}^3$. They find that the breakdown field is roughly proportional to (N_D-N_A) when the density of the donors is above $10^{15}/\mathrm{cm}^3$. Although experimental evidence of the proportional relation is not very convincing owing to the limited number of their specimens, it may be regarded as a very important experimental fact.

§ 6. On Specimens Containing High Concentration of Donors

The relation between (N_D-N_A) and F_b observed by Sclar and Burstein seems to be inconsistent with the theory mentioned previouly. In fact, the breakdown field depends upon both the electron temperature and the ratio $N_A/(N_D-N_A)$, but they did not mention about the latter. If we assume, however, that the ratio is nearly the same through their uncompensated specimens and it is of the order of several percent, then it is concluded from the theory that, when the neutral impurity scattering is a main cause of the resistance, the breakdown field is roughly proportional to $(N_D-N_A)^{1/2}$, but not to (N_D-N_A) itself. On the other hand, the observed result maintains that the energy loss of the conduction electrons is proportional to (N_D-N_A), so that there must be other mechanisms of the energy loss which are proportional to (N_D-N_A) and their contribution to the energy loss will surpass that from the acoustic scattering when the density of impurities is above $10^{15}/\mathrm{cm}^3$.

At present, it is not clear what mechanism is really effective to cause such energy loss. In the following we shall examine some of possible mechanisms.

(1) First, we examine the energy loss due to the impact ionization from Eq. (27). This effect, however, does not seems to be hopeful. If we put $T_e/T=10$ and $E_0=0.01\,\mathrm{eV}$, then the ratio of the first and the second term of (27) is:

$$\frac{3\pi\mu_a}{16ec^2}E_0S \Big/ 2\left(\frac{T_e}{T}\right)^{1/2}\left(\frac{T_e}{T}-1\right)\sim10^{-9}S\,.$$

Since the value of S becomes nearly equal to 10^9 when the density of donors reaches $10^{16}/\mathrm{cm}^3$, the energy loss due to the impact ionization alone does not seem to explain the observed facts. The energy loss due to the excitation of the bound electron from the ground state to the lowest excited state of the donor is expected to make nearly the same amount of contribution to the energy loss.

(2) As is well known, the energy levels of an electron bound to a donor split to two sets of singlets and triplets. If the energy of the conduction electron is larger than energy difference of two levels, the conduction electron is able to excite the bound electron from singlets to triplets. If we assume tentatively that the energy difference is 0.001 eV and the cross section of this process is $20\pi(\kappa a_0)^2$, then the energy loss due to

this process at the density of donors of 10^{15}/cm^3 is nearly equal to that due to the acoustic scattering at $T_e=10T$. Therefore, if these assumptions are reasonable, then the energy loss of the conduction electrons is almost proportional to (N_D-N_A) at specimens of high impurity density. (We suppose that this inelastic scattering is caused by an exchange process: a conduction electron falls into an empty triplet level and a bound electron at a singlet level of the same donor jumps into the conduction band with conserving energy.) Since the cross section of the elastic scattering due to a neutral donor is estimated from Erginsoy's formula as about $130\pi(\kappa a_0)^2$ at $E=0.001$ eV, the above assumed value $20\pi(\kappa a_0)^2$ does not seem to be very unreasonable. However, this idea is not quite hopeful because of the following reason. We see easily that this effect is inherent in *n*-type Ge, but not in *p*-type Ge, while Sclar and Burstein observed the proportional relation mentioned previously at both *n*- and *p*-type Ge.

(3) Another possible mechanism of the energy loss is the impurity scattering accompanyed by emission or absorption of a phonon. We, however, have no reliable knowledge of this process. We must wait a new experimental result which suggests an inelastic scattering due to impurities.

Even if we find a mechanism which can reasonably explain the observed relation between (N_D-N_A) and F_b, there remains a question whether or not the thermal recombination coefficient B_t is independent of (N_D-N_A). If B_t is independent of it, we can determine F_b and T_b from the following relations:

$$S(T_b)\equiv A_i(T_b)(N_D-N_A)=B_t(T_b)N_A\ , \qquad (32)$$

$$[p]_{F=F_b}=\frac{\mu_l}{\mu(F_b)}\left[2\left(\frac{T_b}{T}\right)^{1/2}\left(\frac{T_b}{T}-1\right)\right.$$
$$\left.+\alpha(T_b)(N_D-N_A)\right]. \qquad (33)$$

By choosing $\alpha(T_b)$ and F_b so as to fit the observed date at specimen No. 4 we find that $T_b/T\sim5$ and $\alpha(T_b)/2(T_b/T)^{1/2}(T_b/T-1)\sim5$. This value of α is so large that the second term in (33) has an appreciable contribution even at specimen No. 3. If we take into account it, the value of (T_b/T) is newly determined as 7 instead of 12. Then, we see from Fig. 3 that this value of T_b satisfys the condition (32) approximately. In fact, the breakdown field depends upon both the electron temperature and the ratio $(N_D-N_A)/N_A$ through (32). The latter is, however, not important, because $S(T_e)$ increases very rapidly with increasing T_e in the temperature range $T_e<5$, and consequently the breakdown field becomes roughly proportional to the density of the impurities irrespective of the ratio $(N_D-N_A)/N_A$.*

§ 6. Negative Resistance

By studying impact ionization in highly compensated germanium containing both III and V impurities from 5×10^{14} to 10^{16}/cm^3 McWhorter and Rediker[11)] have found a very interesting behavior of the low-temperature breakdown which is not observed in uncompensated specimens. The characteristic feature of the low-temperature breakdown in highly compensated germanium is that a region of negative resistance appears in a voltage-current relation. According to their observation the sustaining field, typically one-third to two-thirds the breakdown field, is approximately proportional to N_D+N_A and agrees with the breakdown field in uncompensated germanium for the same total impurity concentration.

Since this phenomenon is observed only in highly compensated specimens, it compels us to introduce a special mechanism of the energy loss which is inherent in compensated specimens. Although this phenomenon has been observed only in *p*-type germanium, the essential point in the mechanism of the negative resistance may be indifferent to the type of the specimen. In the beginning let us investigate characteristics in these specimens. First, we notice that the prebreakdown conduction is predominantly impurity conduction. The concentration of impurities, however, is still smaller than the critical concentration for possible formation of an impurity band, so that the current is presumably carried by a hopping motion of a bound electron from an impurity center to its adjacent empty center. Secondly, we notice that the specimen contains so many impurities that the potential field in the lattice is by no means regular and consequently the energy levels of donors are not exactly the same, but may be distributed in a certain energy interval. When there is no external field, the bound electrons occupy these energy levels according to the statistical law. When ths external field is applied, the current is expressed as:

---

* However, if B_t increases with increasing density of the impurities, the situation is not so simple as mentioned above. Then, we expect that the breakdown temperature is higher, and $\alpha(T_b)$ is smaller than the respective value estimated before.

$$j=e(n_c\mu_c+n_i\mu_i)F\ , \tag{34}$$

where $en_c\mu_cF$ represents the current carried by conduction electrons and $en_i\mu_iF$ represents the impurity conduction. In the prebreakdown conduction the latter is much larger than the former. Here we consider the energy balance of the conduction electrons which would be given by:

$$en_c\mu_cF^2=(32ec^2/3\pi\mu_a)(T_e/T)^{1/2}(T_e/T-1)n_c+(N_D-N_A)L(T_e)n_c+W(c,\ i)n_cn_i\ . \tag{35}$$

Here the first term in the right side gives the energy loss due to the acoustic scattering, the second term gives that due to other mechanisms which were considered in the previous section and the last term represents the contribution from mutural interaction between the conduction- and impurity electrons. On the other hand, the number of conduction electrons is assumed to be determined by the formula

$$n_c=A_t(N_D-N_A)/\{B_t(T_e)N_A-S(T_e)\}\ , \tag{36}$$

as a function of the electron temperature. From Eq. (35) we see easily that, if $W(c,\ i)$ does not depend upon n_c and n_i, the last term in (35) works only to displace the breakdown field to a higher value. Therefore, we see that a special assumption is necessary for $W(c,\ i)$ in order to have a negative resistance in (34).

Let us introduce an assumption that the mutual interaction between two electron systems is sufficiently strong to keep a thermal equilibrium between them. Then, the impurity electrons distribute among the energy levels according to the Maxwell law with the electron temperature T_e. In this case some amount of energy is transfered from the impurity electron system to the lattice by emission of phonons, because the temperature of the impurity electron eystem is higher than the lattice temperature. Under these circumstances the rate of the energy loss of the conduction electrons due to the mutual interaction of the electron systems is determined by the rate of the energy loss of the impurity electrons due to the interaction between these electrons and the lattice.* This rate is clearly proportional to n_i, but is independent of n_c, if the both electron systems are in equilibrium. Therefore we can write the energy balance condition in the following way:

$$e\mu_cF^2=(32ec^2/3\pi\mu_a)(T_e/T)^{1/2}(T_e/T-1)+L(T_e)(N_D-N_A)+(n_i/n_c)W(i,\ L;\ T_e)\ . \tag{37}$$

Here we note that $W(i,\ L)=0$ at $\Gamma_e=T$. From this condition we can easily derived the negative resistance. Since n_c is much smaller than n_i, the energy loss of the conduction electrons is predominantly determined by the last term of (37). Thus, the electron temperature does not rise to the breakdown temperature, even when the applied field is larger than the field which can lead the breakdown at uncompensated specimens. On the other hand, if the breakdown is supposed to occur, the number of conduction electrons increases much, and then the last term in (37) would be disregarded as compared with other terms. Therefore, the sustaining field should be determined by:

$$e\mu_cF^2=(32ec^2/3\pi\mu_a)(T_s/T)^{1/2}(T_s/T-1)+L(T_s)(N_D-N_A)\ , \tag{38}$$

---

* The distribution of the impurity electrons with T_e may be established through the thermal-and the impact ionization of donor electrons and the thermal recombination of conduction electrons. The equilibrium may be attained within a time interval of 10^{-8} sec. On the other hand, in order to emit a phonon an impurity electron must transfer from a donor site to its adjacent empty site. The life time of this process is expected to be sufficiently long.

and

$$B_t(T_s)N_A=(N_D-N_A)A_i(T_s)\ , \tag{39}$$

where T_s is the electron temperature which corresponds to the sustaining field. According to McWhorter and Reiker's experiment the sustaining field agrees with that in uncompensated specimens containing the same total impurity concentration. They observe also that the sustaining field is roughly proportional to (N_D+N_A). If we assume that the rate of the energy loss due to the inelastic scattering of impurities is nearly the same both for the ionized impurity centers and the neutral impurity centers, their experimental results are easily understood by the discussion mentioned in the previous section. In order to show a theoretical prediction about the negative resistance it is convenient to use the electron temperature as an auxiliary variable. Here we suppose that n_i and μ_i take given values irrespective of the electron temperature, and the functional form of $L(T_e)$ and $W(T_e)$ is also known. We disregard field-dependence of $\mu_c(F)$ for simplicity. By eliminating n_c from (34) and (36) we have a relation between j and T_e, and from (34) and (37) a relation between F and T_e:

$$j=J(T_e) \tag{40}$$

and

$$F=F(T_e)\ . \tag{41}$$

These equations represent a relation between j and F. When T_e is nearly equal to T, the number of the conduction electrons is practically the same as the number of them at thermal equilibrium, and the current is almost carried by the impurity electrons. With increasing T_e, F increases according to (37) and the number of conduction electrons increases according to (36), but the increase is not appreciable, unless the electron temperature is close to the critical temperature. Therefore, the current is still approximately given by $j=en_i\mu_iF$, which is expected to be ohmic. When T_e is close to the critical temperature, the number of conduction electrons increases and its contribution to the current is no more disregarded. Then, the current will be non-ohmic because of increase of n_c with increasing field. Finally when T_e approaches very closely to the critical temperature, n_c increases very rapidly with increasing T_e, and the contribution from the last term in (37) drops off suddenly. Therefore, the field begins to decrease with increasing electron temperature when T_e arrives at a certain limiting value. This value of T_e corresponds to turning point in the j–F curve and it is interpreted as the breakdown field of the compensated specimen. If T_e is equal to the critical temperature given by (39), then the number of conduction electrons becomes sufficiently large to make the last term in (37) negligibly small, and the sustaining field is now determined by (38). In this way we can interpret qualitatively the appearance of the negative resistance in the low-temperature breakdown. According to McWhorter and Rediker the negative resistance disappears rather abruptly in a narrow lattice temperature range, which depends upon the concentration of the impurity. This nature may be interpreted as follows. With increasing lattice temperature the ratio $n_i/n_c(T)$ decreases exponentially, so that the contribution from the last term in (37) becomes unimportant when the lattice temperature rises above a certain limit. Since this limiting temperature is connected with the ratio $n_i/n(T)$, the limiting temperature is expected to be higher, higher the concentration of the impurity. It is observed that the breakdown voltage is considerably reduced by illumination. This effect is also easily interpreted by the model proposed here. The illumination produces conduction electrons, so that it works to reduce the value of n_i/n_c.

§ 7. Number of Conduction Electrons and Mobility

The Hall constant of specimens No. 3 and No. 4 has been measured by Koenig and Gunther-Mohr.[12] A full curve Fig. 4 represents the inverse of the Hall constant of No. 3. The curve is normalized so as to be one

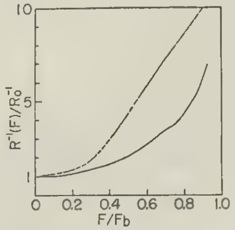

Fig. 4. $R(F)^{-1}/R(0)^{-1}$ vs. applied field in specimen No. 3.

at weak electric field. In fact, when the ionized impurity scattering and the neutral impurity scattering exist, a correction is necessary to derive a number of conduction electrons from the Hall constant.[13] We denote the correction factor as δ, and then we have a relation: $ne=\delta R^{-1}$. In specimen No. 3 the correction factor may amount to 0.7∼0.8 when the field is weak, and it becomes smaller when the electron temperature rises higher. From Eqs. (30) and (31) we see that $S(T_e)$ is quite small as compared with $B(T_e)\cdot N_A$, unless the electron temperature is close to the breakdown temperature. Therefore, in the region of the field $F<0.7F_b$, we expect that increase of the conduction electrons will come from decrease of the thermal recombination coefficient, which was estimated to be inversely proportional to T_e. Then, if we put tentatively δ as one, we can estimate the electron temperature from the observed $R^{-1}-F$ curve. (The correction of δ may increase the electron temperature by a factor 1.2 or 1.3.) In the region of the filled $F>0.8F_b$ the contribution from $S(T_e)$ to the denominator of Eq. (5) is no more negligibly small, so that the $R^{-1}-F$ curve gives only the upper limit of the electron temperature. If we estimate the breakdown temperature from this curve, it may be $7T$ or $8T$, which is in good agreement with the temperature estimated in the previous section. On the other hand, we have calculated the relation between T_e and F by using the assumption that the energy loss comes from only the acoustic scattering.

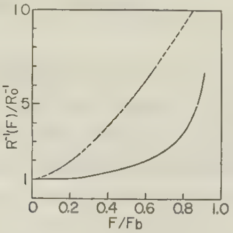

Fig. 5. $R(F)^{-1}/R(0)^{-1}$ vs. applied field in specimen No. 4.

The result is shown in a dotted curve. We find here another evidence for a certain mechanism of energy loss besides the accoustic scattering. The same idea is applicable specimen No. 4. Here the correction factor δ is expected to be close to one, because the contribution from the neutral impurity scattering is dominant in this specimen. In Fig. 5 we show the experimental $R^{-1}-F$ relation by a full curve and the theoretical T_e-F relation by a dotted curve. From the curve the breakdown temperature is estimated as about $5T-6T$, which is again in resonable agreement with the estimation given in the previous section.

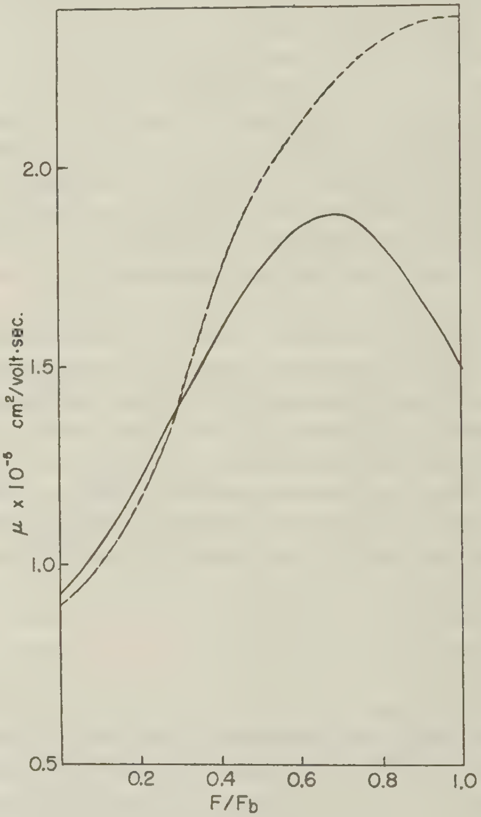

Fig. 6. Observed Hall mobility in a full curve and calculated drift mobility in a dotted curve (specimen No. 3).

The Hall mobility of specimen No. 3 and No. 4 has been observed by Koenig and Gunther-Mohr. In Fig. 6 we show the Hall mobility of No. 3 by a full curve. It may be larger than the drift mobility by a factor 1.2 or 1.3. The drift mobility of No. 3 was calculated in section 4. Accuracy of the theoretical value is not high owing to simplifying assumptions introduced there, but we show it in Fig. 6 by a dotted curve. In Fig. 7 we show the two curves which represent the observed Hall mobility and the calculated drift mobility. An apparent agreement between the theory and the experiment is fairly good.

In the computation of the mobility we have used the Conwell-Weisskopf formula. If we use the Brooks-Herring formula, the ohmic mobility becomes much smaller. For example, the ohmic mobility of No. 3 is 0.1×10^5 cm²/volt sec, and that of No. 4 is 9×10^3 cm²/volt sec, respectively. These values seem to be too small to fit the experimental datas, even when we underestimate the accuracy of the experiment. As is well known, the two formulas give closely the same results, when the conduction electron density is nearly equal to the ionized impurity density. They give quite different result, however, when the conduction electron density is appreciably less than the ionized impurity density. The difference comes from different treatments of the screening for the Coulomb scattering. At very low temperature, the number of conduction electrons is extremely small as compared with the number of changed scattering centers, so that the screening due to the conduction electrons is negligibly small. However, the Coulomb field due to a charged center is still screened by the field of other charged centers of the opposite sign. If the charged centers of both signs are distributed more or less uniformly, the range of the Coulomb field may be nearly equal to the half of the average distance between the nearest neighbour impurity ions. This assumption leads to the Conwell-Weisskopf formula.

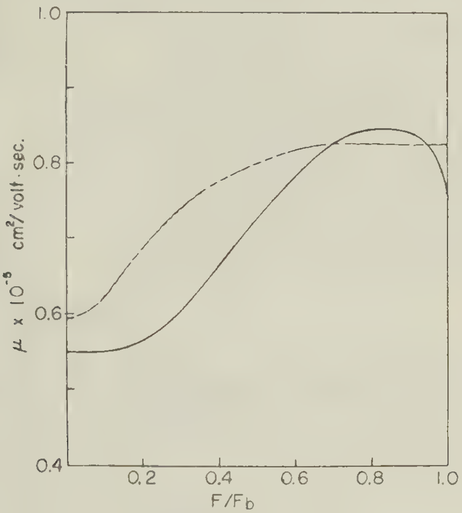

Fig. 7. Observed Hall mobility in a full curve and calculated drift mobility in a dotted curve. (specimen No. 4).

Appendix. Solutions of the Boltzmann equation

(a) There exist the acoustic scattering and the neutral impurity scattering. Since the neutral impurity scattering is nothing to do with energy loss, we derived easily a set of coupled equations:

$$\frac{8ec^2}{3\sqrt{\pi}\,\mu_a}[x^2f_0''+(x^2+2x)f_0'+2xf_0]=\frac{eF}{\hbar}\left(g+\frac{2}{3}x\frac{dg}{dx}\right) \tag{A-1}$$

and

$$g=-[F\hbar/(a\sqrt{x}+b)]\frac{df_0}{dx}\ , \tag{A-2}$$

where $x=E/kT$, $a=4/3\sqrt{\pi}\,\mu_a$ and $b=1/\mu_n$. Then, f_0 is determined as:

$$f_0(x)=Ne^{-x}(x+\rho\sqrt{x}+p)^p\exp\left\{-\frac{p\rho}{\sqrt{p-1/4\cdot\rho^2}}\tan^{-1}\left[\frac{\sqrt{x}+\rho/2}{\sqrt{p-1/4\cdot\rho^2}}\right]\right\}, \tag{A-3}$$

when $p\geqq\rho^2/4$, and

$$f_0(x)=Ne^{-x}(x+\rho\sqrt{x}+p)^p$$
$$\times\left[\sqrt{x}+\frac{\rho}{2}+\sqrt{\frac{1}{4}\rho^2-p}\Big/\sqrt{x}+\frac{\rho}{2}-\sqrt{\frac{1}{4}\rho^2-p}\right]^r, \tag{A-4}$$

when $p\geqq\rho^2/4$. Here p, r and ρ are defined by:

$$p=3\pi\mu_a{}^2F^2/16c^2\ , \tag{A-5}$$

$$r=p\rho/2\sqrt{\frac{1}{4}\rho^2-p} \tag{A-6}$$

and

$$\rho=b/a\,.$$

(b) There exist the acoustic scattering and the ionized impurity scattering. Then the fundamental equations are Eq. (A–1) and

$$g=-[F\hbar x\sqrt{x}/(ax^2+b')]\frac{df_0}{dx}\,, \tag{A-8}$$

where $a=4/3\sqrt{\pi}\,\mu_l$ and $b'=24/3\sqrt{\pi}\,\mu_i$. Then, the equation for $f_0(x)$ is:

$$\left(x^2+\frac{px^3}{x^2+q_0{}^2}\right)f_0{}''+\left\{x^2+2x+\frac{d}{dx}\left(\frac{px^3}{x^2+q_0{}^2}\right)\right\}f_0{}'+2xf_0=0\,, \tag{A-9}$$

where

$$q_0{}^2=6\mu_l/\mu_i \tag{A-10}$$

Then, the solution of (A–9) is

$$f_0(x)=Ne^{-x}(x^2+px+q_0{}^2)^{p/2}\exp\left\{-\frac{p^2}{2}\frac{1}{(q_0{}^2-p^2/4)}\tan^{-1}\left[\frac{x+p/2}{\sqrt{q_0{}^2-p^2/4}}\right]\right\}, \tag{A-11}$$

when $q_0{}^2\geqq p^2/4$, and

$$f_0(x)=Ne^{-x}(x^2+px+q_0{}^2)^{p/2}$$
$$\times\left[x+\frac{p}{2}+\sqrt{\frac{p^2}{4}-q_0{}^2}\Big/x+\frac{p}{2}-\sqrt{\frac{p^2}{4}-q_0{}^2}\right]^{p^2/4\sqrt{p^2/4-q^2_0}} \tag{A-12}$$

when $q_0{}^2\leqq p^2/4$.

(c) In the general case, where three mechanisms of the scattering must be taken into account, the fundamental equations are again (A–1) and

$$g=-[F\hbar x\sqrt{x}/(ax^2+bx\sqrt{x}+b')]\frac{df_0}{dx}\,. \tag{A-13}$$

In this case $f_0(x)$ can not be expressed by a simple analytic function, but it is given by

$$f_0(x)=Ne^{-x}\exp\left\{p\int^x\frac{xdx}{x^2+\rho x\sqrt{x}+px+q_0{}^2}\right\}. \tag{A-14}$$

Studies on the Boundary between Etched and Ground Regions of Ge and Si Single Crystal Surfaces by X-Ray Diffraction Topography

By Zensho ISHII*

Electrotechnical Laboratory, Nagatacho, Tokyo

(Received December 3, 1960)

The anomalous boundary effect similar to these found by Fukushima in guartz were studied by x-ray diffraction topography methods in Ge and Si single crystals. Both Laue and Bragg cases are examined using CuKα and AgKα radiations for various net planes. Results are reasonably explained by assuming a strain gradient perpendicular to the boundary as the previous workers. It was shown that the Borrmann effect as well as the ordinary extinction effect are useful in point-by-point examination of lattice distortions in nearly perfect single crystals.

§1. Introduction

It is well known that the integrated intensity of x-rays reflected from a single crystal is generally enhanced by surface treatments such as grinding[1]. Fukushima[2] found that a region produced by the following treatment had higher intensity than a ground region for a quartz crystal: after grinding a Z-cut surface, a part was etched to produce the boundary line parallel to a Y-plane, and then it was found that at the boundary the integrated intensity of x-rays reflected from the Y-plane in transmission was about twice that from the ground region which remained unetched. Afterwards, this effect, which will be called the boundary effect in this paper, was studied in more detail by Kato[3] with the use of a double crystal spectrometer in quartz, $NaClO_3$ and calcite crystals.

Recently, x-ray diffraction topographic methods have been developed to study lattice defects[4]. In the present experiment, the boundary effect for Ge and Si single crystals was studied by x-ray diffraction topography with a parallel beam arrangement[5)-10)]. By this technique, a topographic information from an extended region was easily obtained with higher resolution (about 20 μ) in comparison with the point-by-point measurement with the counter method which had been used by previous workers. For Ge crystals, photographs of transmission as well as reflection by CuKα were taken for several net planes. For Si crystal, a transmission photograph by AgKα was obtained for net plane parallel to the boundary line on the surface.

§2. Experimental Procedures

2.1. *Preparation of specimens*

Specimens of Ge, about 1 mm thick, were cut parallel to the (110) plane from a single crystal grown from the melt by pulling. The surface was polished and etched with CP4 solution. Before the following surface treatment, the dislocation density of the specimens was estimated to be of the order of $10^3/\text{cm}^2$ by counting individual images of dislocation lines in x-ray transmission photographs. Then one side of the specimen was ground with 1,000 mesh carborundum on a glass plate. After grinding, a part of the surface was covered with commercial cellophane tape**, and etched with CP4 solution for about a half minute. The tape was then stripped off from the specimen. Thus a boundary between the etched and the ground region was produced.

Silicon samples were prepared in a similar way by cutting a wafer, about 1 mm thick, parallel to the (111) plane, from a single crystal. In this case, mixture of HF and HNO_3 (volume ratio=1:3) was used for etching instead of CP4.

2.2. *X-ray technique*

For specimens of Ge and Si, CuKα and AgKα were used, respectively. The apparatus was in principle the same one as those in the previous works[7),8)]. The effective size of the source was about $0.01\times5\,\text{mm}^2$. Fuji autoradiographic plates were used; exposures in transmission took about 1 hour both for CuKα (35 kV, 0.3 mA) and AgKα (45 kV, 0.3 mA), and in reflection about 5 minutes. With this, x-ray transmission or reflection photographs from the extended area of the specimen (about 2×5 mm^2 for transmission and 2.5×7 mm^2 for reflection) was obtained.

* Present address: Sony Corporation Research Laboratory, 351, Kitashinagawa-6, Tokyo.

** This was neither dissolved nor stripped off during etching processes.

§ 3. Experimental Results and Discussions

For Ge crystals, transmission (Laue case) as well as reflection photographs (Bragg case) were taken for two reflecting planes for each case, to study the direction of strain gradient at the boundary.

3.1. *Transmission photographs*

In one case, the boundary line was produced in a direction of [001] (Fig. 1a), while in another case, in a direction of $[\bar{1}10]$ (Fig. 1b). In both cases, the thickness of the specimens, D, was almost the same, about 1 mm. Since $\mu=379$ cm^{-1}, μD was about 37.9 and very large compared with unity. As transmission photographs, both diffracted beams (denoted by R) and transmitted beams (denoted by R_0) were taken, both of which gave the same results. Therefore, it is concluded that the intensity contrast is caused by the Borrmann effect[11]. X-ray transmission photographs of the $(\bar{2}20)R_0$ with CuKα in the former and latter cases are shown in Fig. 2 and 3.

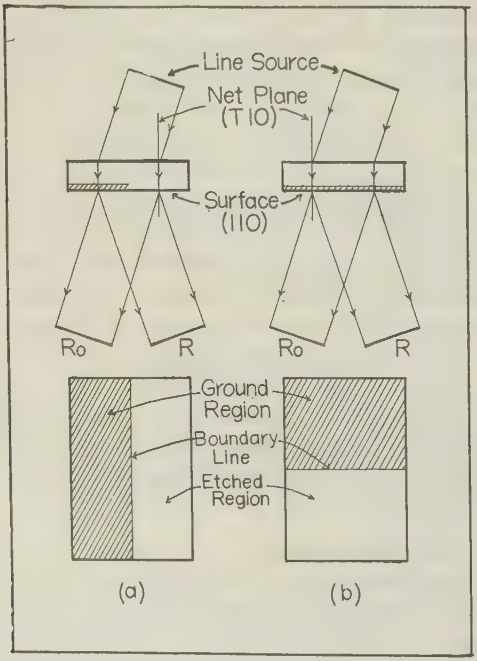

Fig. 1. Schematic diagrams of experimental arrangements.
(a) Boundary Line // [001]
(b) Boundary Line // $[\bar{1}10]$

3.2. *Reflection Photographs*

Photographs of the specimen used in 3.1. was taken by reflection method, that is, the Berg-Barrett method, with the use of CuKα. As reflecting planes the (110) and (100) planes were used. The former is parallel to the surface, whereas the latter intersects the surface at 45 degrees, as shown in Fig. 4, and had not been tried by previous workers. X-ray photographs of the (220) and (400) reflections are given in Fig. 5 and 6, respectively. In the (220) reflection no change of intensity was observed at the boundary, but in the (400) reflection a noticeable change was observed.

3.3. *Discussions on the experiments with Ge*

(a) It has been established that the anomalously transmitted intensity is weakened at distorted regions, such as dislocation lines[5,6,12] and strains[7,8,13], in comparison with the one at perfect regions. It is expected as in the case of extinction effect that the decrease of the anomalous transmission is largest if the direction of the strain gradient is normal to the net plane concerned. For both cases corresponding to Fig. 2 and 3, the mean intensity of the etched region was stronger than that of the ground region, but the intensity change at the boundary was different; for the former case, the intensity decrease compared with that of the ground region was observed, while not for the latter case. From these transmission photographs it is concluded that the distortion is stronger at the boundary than in the ground region, and the strain gradient has a component perpendicular to the boundary. This conclusion is in agreement with that of previous workers.

(b) In the reflection photographs, the boundary effect was not observed for the (220) reflection, whereas it was observed for the (400) reflection. As a cause for the above difference, two possibilities might be considered. Firstly, it might be considered that the strain gradient has no component normal to the surface. As its result, the boundary effect will not be observed for the (220) reflection. However, even if the component of the strain gradient normal to the surface exists, it would be plausible that the boundary effect will not come into observation for the (220) reflection, if the penetrating thickness of x-rays is negligible in comparison with that of the region responsible for the boundary effect.

(c) In transmission as well as in reflection photographs, local fluctuations of the intensity are observed not only on the ground but also on the etched regions. These phenomena

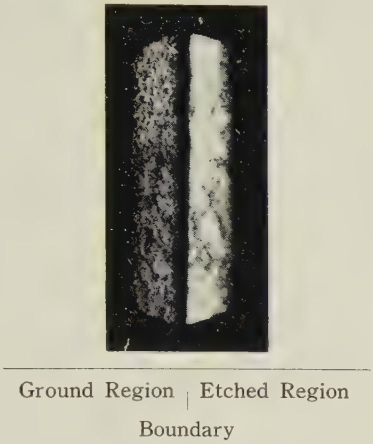

Fig. 2. Transmission photograph of $(\bar{2}20)R_0$ on Ge, the net plane being parallel to the boundary.

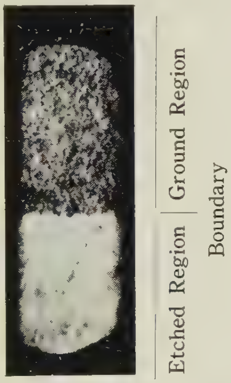

Fig. 3. Transmission photograph of $(\bar{2}20)R_0$ on Ge, the net plane being perpendicular to the boundary.

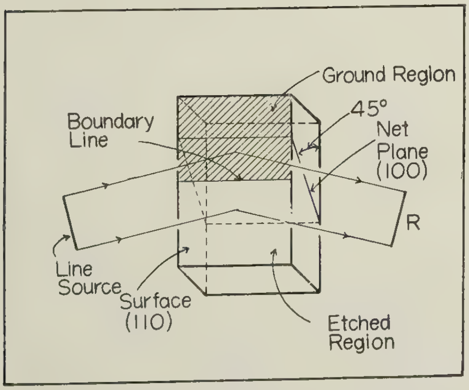

Fig. 4. Schematic diagram of experimental arrangement for reflection photographs.

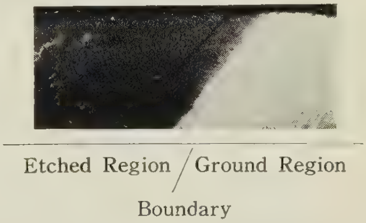

Fig. 6. The (400) reflection photograph of Ge.

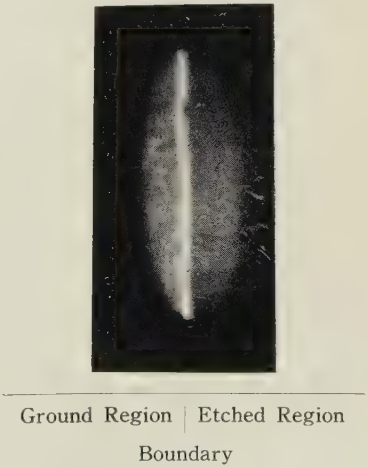

Fig. 7. Transmission photograph of $(\bar{2}20)R$ on Si, the net plane being parallel to the boundary.

mean that some parts remain in a rather perfect state still after grinding, and on the other hand, some parts are still distorted after half-minute etching. It is considered that distortions caused by grinding are localized, and some distortions cannot be removed by the etching.

In Fig. 6, a subsidary intensity decrease on the side of the ground region was also observed near the boundary. This might be probably attributed to the fact that a less distorted region exists close to the boundary.

3.4. *Transmission experiment in Si*

For a specimen of Si, a boundary line perpendicular to $[\bar{1}10]$ on the surface (111) was produced. Diffraction photograph of $(\bar{2}20)$R in transmission with AgKα is shown in Fig. 7. Contrary to the case of Ge, the intensity contrast was caused by the ordinary extinction effect because μD was very small, about 0.8*. The intensity in the ground region was stronger in comparison with the one in the etched region, and at the boundary it was stronger than in the ground region. This result is essentially the same as that of previous workers and also consistent with that of 3.1.

Present informations are insufficient for discussing the fine structures above-mentioned in more detail. But the diffraction topography method proves to be useful for studying the fine structures of the boundary, because the topographic information is easily obtained with high resolution in comparison with the point-by-point intensity measurement.

The Switching Circuit Logically or Functionally Equivalent to a System of Biochemical Reactions

By Motoyosi SUGITA

Hitotsubashi University, Kunitachi, Tokyo, Japan

(Received October 26, 1960)

The analogy or the correspondence between the controlled or catalytic reaction and the switching circuit is given, showing that an arbitrary logical circuit can be translated into a system of controlled chemical reactions, which are catalyzed by some of the reaction products of this system. The realizability of such a chemical system is not considered but the logical possibility is discussed using several examples. Nevertheless, we can imagine a way to combine the knowledge of biochemical reactions to various physiological functions and can give useful suggestions to the experimental analysis of the biochemical reactions from the view-point of logical or functional analysis.

§ 1. Introduction

There is an idea of reconstructing a system, which has at least some functions resembling the organism, using the parts of the same organism. For this purpose *logical analysis of the function* of the composed system is necessary. The author has suggested[1] the analogy between switching circuits and enzymatic reactions, where enzyme actions are considered as on-off controls. In this note it is proposed to translate the mutual interaction within a complex chemical system, the reaction rates of which are controlled by the reaction products, to the equivalent logical circuit having the same logical functions.

§ 2. Logical Circuit and Chemical Reaction

Let us consider at first the correspondence of the controlled or catalyzed reaction like $A \xrightarrow{X} B$ to the switching circuit. For simplicity, we consider only the state of the existence or of the non-existence of the catalyzer X. We assign 1 to the former and 0 to the latter. Then $X=1$ corresponds to the *on* state, and $X=0$ to the *off* state of the switching circuit. Only the *on-off control* is considered here.

In the same way only the existence or non-existence of A or B will be considered. The accumulation of the substance B, for instance, will be neglected, considering that the leakage of B due to the consecutive reactions like $A \xrightarrow{X} B \longrightarrow \cdots\cdot$ makes $B=0$ after a short time when the reaction $A \xrightarrow{X} B$ has been repressed. The transient state during the short interval between the cut off of the flux $A \longrightarrow B$ and the terminal state of B, to which 0 is assigned, will be neglected.

If the repression is due to $X=1$, X is called the *repressor*, while, if it is due to $X=0$, X is called the *inducer*. The repression is written as

$$A \xrightarrow{\bar{X}} B \quad \text{or} \quad A \xrightarrow{\overset{X}{\not\downarrow}} B \qquad (1)$$

where $\bar{X}$ is the *negation* of X and $X \not\longrightarrow$ is equivalent to $\bar{X}$. If X is an inducer and $X=1$, the steady level of B will attain a certain value which is not equal to 0. We will consider only the *steady state* of B and assign 1 to the state of B which is not zero. Therefore, we can get the logical relation:

$$\left.\begin{array}{lll} B=X & \text{for inducer} & \text{and} \\ B=\bar{X} & \text{for repressor.} & \end{array}\right\} \qquad (2)$$

Therefore, in the case of a repressor, the existence of $X\,(X=1)$ corresponds to the non-existence of B and the non-existence of X $(X=0)$ to $\bar{X}=1$ and then to the existence of B.

The device for the conversion of X to $\bar{X}$ is called the *Not* element and represented by $\not\longrightarrow$ of (1). The following system of chemical reactions will have function of *Not*.

$$A \xrightarrow{X} B,\ P \xrightarrow{\bar{B}} Q \quad \text{or} \quad \begin{tikzcd} & X \arrow[d, "+"] & & \\ A \arrow[r, no head] & {} \arrow[r] & B \arrow[d, "/" marking] & \\ & P \arrow[r, no head] & {} \arrow[r] & Q, \end{tikzcd} \tag{3}$$

then we have

$$Q=\bar{X} \qquad \text{or} \qquad X \nrightarrow Q=\bar{X}, \tag{4}$$

where the notation $\xrightarrow{+}$ denotes the induction. $+$ is used here to differentiate the transfer of information or of the controlling action from the flux of chemical reaction. It is also true for $\nrightarrow$. The difference between the flux of *information* and that of chemical reaction is very important and should not be confused[2].

Meanwhile, in the following case:

$$\left.\begin{array}{l} \qquad A\xrightarrow{\bar{X}}B,\quad P\xrightarrow{\bar{B}}Q, \\ \text{we can see that} \\ \qquad\qquad Q=X \end{array}\right\} \tag{5}$$

because $Q=\bar{B}$, $B=\bar{X}$,

therefore,

$$Q=\bar{\bar{X}}=X, \tag{6}$$

i.e. the negation of negation of X is X itself. The enzyme induction of the type (5) is indirect. However, we will abstract the difference of the *direct* and the *indirect* types of enzyme induction from the *logical* point of view. According to this view-point the following system of reactions

$$\left.\begin{array}{l} A\xrightarrow{X}B,\ P\xrightarrow{B}Q,\ S\xrightarrow{Q}T,\ U\xrightarrow{T}V, \\ \text{can be expressed simply by} \\ V=X \quad \text{or} \quad U\xrightarrow{X}V. \end{array}\right\} \tag{7}$$

Besides *Not* there are two further logical elements, which are at least necessary for the construction of logical circuit, i.e. *Gate* and *Buffer*.

Gate is rather easy to construct. Let us take the following consecutive reactions

$$A\xrightarrow{X}B\xrightarrow{Y}C. \tag{8}$$

Assuming two valued logic and on-off control of X or Y, we can see that the equation of the *logical product*

$$C=XY, \tag{9}$$

shows the logical structure of that controlled reaction (8). (9) may correspond to the product effect of some medicals.

It is rather painstaking to imagine a chemical system having the character of a *Buffer*, having a series or consecutive structure instead of a parallel one (the parallel one corresponds to the conversion of the bi-path of the metabolic pathway to the main route, for instance). The author has considered the following scheme

$$A\xrightarrow{\bar{X}}B\xrightarrow{\bar{Y}}C,\quad S\xrightarrow{\bar{C}}P. \tag{10}$$

Then we have

$$C=\bar{X}\bar{Y},$$

and

$$P=\bar{C}.$$

From the formula of symbolic logic we have

$$P=\bar{C}=\overline{\bar{X}\bar{Y}}=X+Y. \tag{11}$$

(11) is the equation of the *logical sum*. The correlation of reactions can be written schematically in

$$\begin{tikzcd} & X \arrow[d, "/" marking] & & Y \arrow[d, "/" marking] & & \\ A \arrow[r, no head] & {} \arrow[r] & B \arrow[r, no head] & {} \arrow[r] & C \arrow[d, "/" marking] & \\ & & & S \arrow[r, no head] & {} \arrow[r] & P, \end{tikzcd} \tag{12}$$

§ 3. Chemical Equivalent of Flip-Flop

Concerning the function of *Storage* we can imagine the system of chemical reactions rather easily. For instance, let us translate the logical circuit of flip-flop to a system of controlled chemical reactions. Then we have the scheme given by

$$\left.\begin{array}{l} \quad A_2\xrightarrow{\bar{a}}A_1\xrightarrow{\bar{x}}A, \\ \qquad \sigma_1\xrightarrow{\bar{A}}\sigma,\quad x_2\xrightarrow{\bar{\tau}}x_1\xrightarrow{\sigma}x, \\ \text{and} \\ \quad B_2\xrightarrow{\bar{b}}B_1\xrightarrow{\bar{y}}B, \\ \qquad \tau_1\xrightarrow{\bar{B}}\tau,\quad y_2\xrightarrow{\bar{\sigma}}y_1\xrightarrow{\tau}y. \end{array}\right\} \tag{13}$$

or by Fig. 1

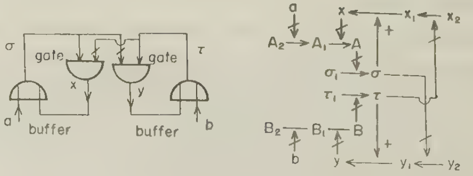

Fig. 1.

The logical equations are common to both systems, electric circuit as well as chemical system, and are given by

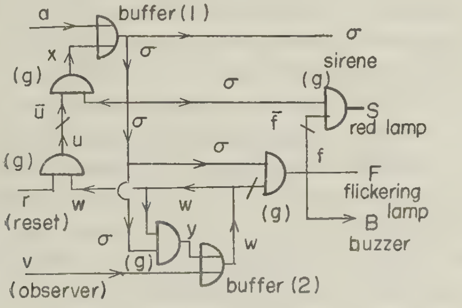
$$\sigma=a+x\,,\quad x=\sigma+\bar{\tau}\,;\quad \tau=b+y\,,\quad y=\tau+\bar{\sigma}\,. \tag{14}$$

The analogy of flip-flop and the reaction in vivo may be rather crude. However, many types of the resembling phenomena can be seen, which are the conversion of the course of the reaction systems, like immunological memory, the change of the course of the reaction systems at the start of cell division, the recovery in the resting state of the daughter cells. In such cases this analogy of flip-flop may be suggestive. Rhythmic reaction of iron in HNO_3 solution may also be interpreted from this point of view. The author is not sure whether the change of ionic permeability of cell membrane of nerves can be explained in this manner.

How to realize the system of reactions (13) is neglected here. Only the existence of such a conversion of the mode of reaction systems is considered from the logical point of view.

§4. Translation of a Logical Circuit of Industry into Chemical Systems

Let us try to translate a logical circuit of modern factory responding to the alarm from the control system as is given by Fig. 2,



(g): Gate, a: signal from the control system

Fig. 2.

where a is the signal corresponding to an extraordinary state of affairs. σ is the corresponding signal, which will actuate the siren. v is the signal from the button of the watcher. If it is pushed, then $v=1$ and $w=1$, because v and w are connected by the Buffer (2). If $w=1$ and $\sigma=1$ the logical product y is 1, which is put in the Buffer and the signal w is reproduced and is held, though v is cut off. If w and r are not zero, the logical product $u=rw$ is 1, where r is the signal of reset action. Therefore, $\bar{u}=\bar{r}+\bar{w}$ shows that the siren is not stopped during the interval in which $r=0$ or $w=0$, accusing the carelessness of the service men, because the internal instead of external (a) input to the Buffer (1), $x=\sigma+\bar{u}$, reproduces the signal constantly during this interval.

The flickering lamp F will go out, if $w=1$, because there is a *Not* element, i.e. $f=\sigma\bar{w}$. If $f=0$, then $s=\sigma\bar{f}=1$ and the red lamp will go on.

To translate the logical function of this circuit, we have taken the following reaction systems into account

$$\left.\begin{array}{llll}
1) & A\xrightarrow{\bar{a}}B\xrightarrow{\bar{x}}C & 5) & w_1\xrightarrow{\bar{Z}}w \\
2) & \sigma_1\xrightarrow{\bar{C}}\sigma & 6) & Z_2\xrightarrow{\bar{y}}Z_1\xrightarrow{\bar{v}}Z \\
3) & x_2\xrightarrow{\bar{u}}\bar{x}_1\xrightarrow{\sigma}x & 7) & y_2\xrightarrow{\sigma}y_1\xrightarrow{w}y \\
4) & u_2\xrightarrow{w}u_2\xrightarrow{r}u & &
\end{array}\right\} \tag{15}$$

The branched reactions are

$$S_2\xrightarrow{\sigma}S_1\xrightarrow{\bar{f}}S,$$
$$F_2\xrightarrow{\sigma}F_1\xrightarrow{\bar{w}}F.$$

The intuitive representation of (15) is given by Fig. 3. If we assume here that $a=0$, then the reactions (1) and (6) are realized and other reactions are stopped. If a is introduced which corresponds to a substance introduced into our body, 1) is repressed and 2) and 3) will start. Then, if the signal v is put in, the reaction 6) is repressed and 5) and then

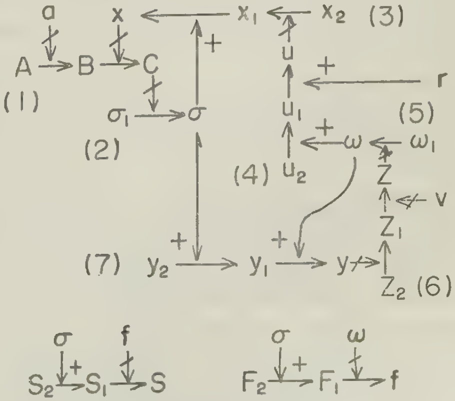


Fig. 3.

7) will start. If the reset key is pushed, the reaction 4) is excited and 3) is stopped. Then x becomes zero and 1) is again set in action. 2) and 7) are then stopped and 6) starts again. Thus 5) and 4) are also stopped and the total system recovers the initial state.

The corresponding logical relations, which are common to Fig. 2 and Fig. 3 are

$$\left.\begin{array}{l} \sigma=a+x\ ,\ x=\sigma\bar{u}\ ,\ u=rw \\ w=v+y\ ,\ y=\sigma w \\ \text{for the main circuit and} \\ f=\sigma\bar{w}\ ,\quad s=\sigma\bar{f} \end{array}\right\} \qquad (16)$$

for the branched reactions.

There may be many other possible block diagrams like Fig. 2 or chemical systems like (15) logically equivalent to (16), while only the logical possibility is considered here. Therefore, the correspondence above considered is not the only one possible but merely tentative. Our aim, however, is to take such logical correspondence into consideration in the analysis of the *physiological* functions of the chemical system in vivo.

§ 5. Concluding Remark

We are not yet well acquainted with the analogy considered above, because our knowledge concerning the biochemical facts is not enough to clarify the correspondence between the chemical reaction systems and the logical circuit in details. So that just an attempt to show the possibility is given in this paper. Some examples of logical circuits are translated into a scheme of chemical system. However, the translation of chemical systems, which are well known, to an equivalent logical circuit is more important and moreover our final aim. While the details of such chemical systems in vivo are not well known to us yet, the above consideration will suggest a way to proceed to the experimental analysis of such systems and to connect biochemistry to physiology.

We have considered here a simplified model of on-off control based on the two-valued logic. There may be many more complex forms of interactions such as, the regulation of the reaction systems, conversion of the mode of the chemical reactions as a whole, adaptive formation of enzymes, the change of the enzyme patterns, immunological memory, and maintenance of the dynamical equilibrium of open systems. In these and other cases, analogue simulation as well as many-valued logic may prove to be more useful, although the analysis may be very difficult.

The interaction or correlation between chemical systems considered above resulted from the catalytic action of some reaction products. In this type of interaction to be called the indirect interaction, one reaction controls the neck factor of the other reaction. The flux J of the latter reaction is determined by

$$J=\text{neck factor}\cdot\text{intensive factor}\ . \qquad (17)$$

Here the intensive factor is a quantity of thermodynamical nature and depends on the chemical potentials, for instance, of the reacting components[3]. The neck factor depends on the rate constants which may be controlled by the catalyzer. There is another type of interaction, to be called the direct interaction, in which the effect of one reaction enters in the intensive factor of the other reaction. In general, we must take both types of interactions, but, for simplicity, we have considered only the indirect one.

In the ordinary theory of irreversible processes, the neck factor has been assumed constant in the phenomenological equations like (17) but the system with indirect correlation cannot be treated by such a formulation. The author has called the theory containing variable neck factors the *flexible neck theory* and the indirect correlation controlled by the flexibility of neck factors the *informational correlation*. Application of this theory to biophysics is given in another paper[2] (in Japanese) and its revised version in English will be published in the near future[4].

Mass Spectrometric Study on the Evaporation of Volatile Components in Polyethylene

By Kisaku NAKAGAWA

Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation, Musashino-shi, Tokyo, Japan

(Received December 20, 1960)

Many ions were observed in the spectra of polyethylene heated in the ion source of a mass spectrometer for the temperature range of 150–330°C. With elevation of temperature, the rate of ionic yield displayed a stage of slower increase, Process I, followed by a steeper uprise, Process II. For two commercially available polyethylene, Marlex and Hostalen, it was found that the values of activation energy for the latter stage appeared to be 34 kcal/mol for Marlex and 24.7 kacl/mol for Hostalen. On the contrary, the values for Process I were found to be 6.5 ± 1.2 kal/mol for both samples. According to the mass spectra obtained and the values of activation energy, it was concluded that Process II is corresponding to the stage of thermal degradation, while Process I would be explained by the presence of a stage of evaporation of lighter components included originally in polyethylene.

§ 1. Introduction

A mass spectrometer has been utilized by many investigators to analyze the gaseous components of decomposed polymers[1),2)]. In spite of the various advantages proper to the instrument, the technical difficulties of making the sample into gaseous state and the limited mass range or the finite resolving power have prevented the direct application of this sensitive instrument to the analysis of high polymers. The work carried out by Bradt, et. al.[3)] has been quite unique, but further reports have not been appeared thereafter.

However, the recent advances in the field of high molecular weight mass spectrometry have enabled us to deal with the heavy hydrocarbons with carbon atoms as many as 40 or more[4),5),6)]. Fortunately, moreover, the straight chain hydrocarbons with more than about 15 carbons were shown to exhibit relatively simple spectra[4)]. That is, as the number of carbon atoms increases the mass spectra tend to approach to a particular pattern in which the principal peaks appear within the range of C_3–C_8, followed by the heavier ions diminishing monotonously. This means that the difficulties due to the distribution of molecular weight could be eliminated so long as their structures were concerned. Furthermore, when the short branches or double bonds were present in almost linear chains, the deviation in the spectra from the normal pattern would be expected to appear.

On the other hand, the high polymers may be supposed to have a considerable amounts of low molecular weight components in their wide-spread distribution. Among these lighter components the molecules so small as to be volatile under certain conditions may be expected to exist. Aside from the question whether these smaller molecules are still similar to the longer or not, it may be interesting to make a trial to assure the presence and the possibility of direct analysis of these volatile components. The complete analysis of innumerable members constituting the polymer would be impossible, but a statistical informations about the structure, especially for the branches or terminals, if obtainable, might be much helpful in the future development for the study of the molecular structures of high polymers.

This is a report of a experiment carried out preliminarily for commercially available polyethylene, Marlex 50–15 and Hostalen GD. Emphasis was placed on the confirmation of possibility if the ions could really be detected at the temperature where the thermal degradation has not been taking place.

§ 2. Experimental

A conventional ion source was slightly modified by stringing tungsten heater around the gas inlet glass pipe to serve as a simple furnace. Sample polymer placed in a small glass vessel were pushed into the furnace as seen in Fig. 1. Temperature was estimated by an Alumel-Chromel thermocouple enclosed in a glass tubing.

The mass spectrometer used was the Hitachi RMU-5 type. The ion acceleration was reduced to 1,000 volts to extend the mass range to about C_{18} group. The resolving power at the condition was 170 or slightly less. In this work, sample polymer were sliced to small pieces of about 0.5 mm thick from the raw pellets which had not been undergone any previous treatments.

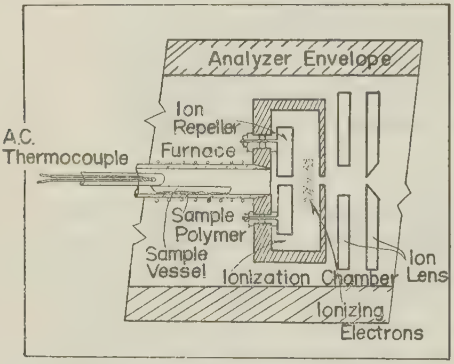

Fig. 1. The ion source with the furnace.

Experiments were carried out at the several points between 150–330°C. The heating to higher temperature could not be performed because the rapid increase of the products from the polymer provoked the electric breakdown between the high voltage electrode and the grounded analyzer envelope. Thus, in our case, the upper limit of temperature was determined by the amounts of sample loaded.

Throughout the experiments the ion source temperature was kept constant at 200°C. The value was determined by a preparatory experiment in which the standard n-$C_{16}H_{34}$ molecules were found to exhibit the smallest fluctuation in the pattern against the ion source temperature variation.

It took about 15 minutes to scan from C_1 to C_{18}, the repeated runs represented no remarkable decrease in ion intensity. The memory effect was examined by ceasing the heating of the furnace before elevating temperature to the next stage. About half an hour was sufficient to reduce the peaks to the amount corresponding to the sample temperature, which was in equilibrium to the ion source temperature. In conclusion, the memories were not essential in this case because the rate of increase of ionic yield was high

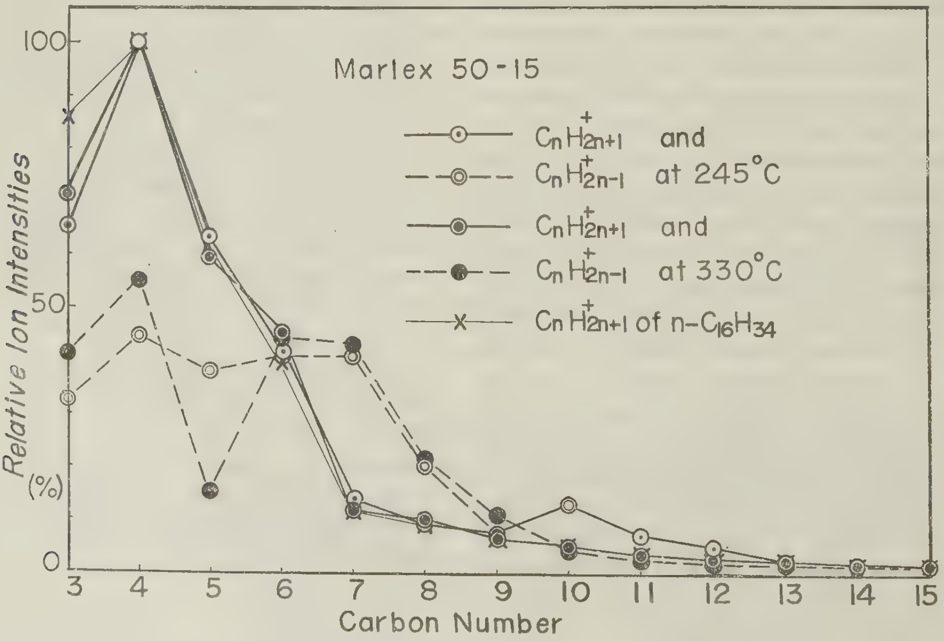

Fig. 2a. The relative intensities of $C_nH^+_{2n+1}$, and $C_nH^+_{2n-1}$ for each C_n-group obtained from Hostalen GD (nominal molecular weight; 70,000). The corresponding values from n-$C_{16}H_{34}$ were shown, too.

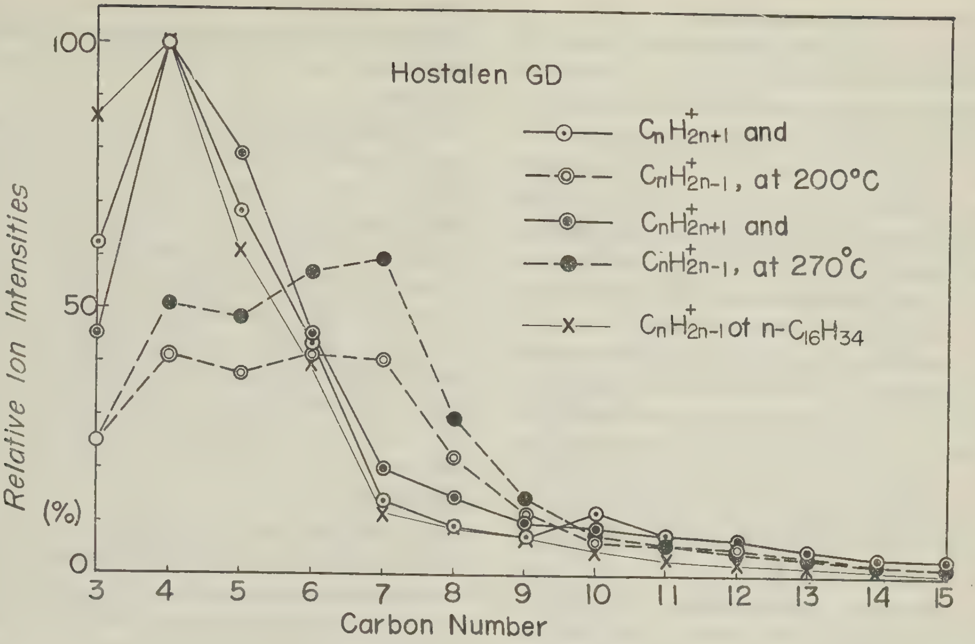

Fig. 2 b. The relative intensities of $C_nH_{2n+1}^+$, and $C_nH_{2n-1}^+$ for each C_n-group obtained from Marlex 50-15. (nominal molecular weight; 70,000) The corresponding values from n-$C_{16}H_{34}$ were shown, too.

enough to neglect the memories of the previous stage.

§ 3. Results and Discussion

F or both polyethylene, lots of peaks were observed in group for every carbon number to the extent of our upper limit of mass range. The succeeding groups, except for the anomalies seen in C_{10}'s and C_{11}'s, displayed a monotonous decrease from group to group with the increase of carbon number. Each group consisted of $C_nH_{2n+1}^+$, $C_nH_{2n-1}^+$, $C_nH_{2n}^+$, $C_nH_{2n-2}^+$, and lower intensity ions. Of all ions and at all temperature stages, $C_4H_9^+$ was the largest (base) peak. The percentage intensities of $C_nH_{2n+1}^+$'s and $C_nH_{2n-1}^+$'s relative to the base peak were illustrated in Fig. 2 a) and b) for two stages of temperature. The corresponding peaks of standard n-$C_{16}H_{34}$ were superimposed thereon. Although the mere resemblance appears to be difficult to bring detailed informations, it is verified that the ions of hydrocarbon molecules having considerable long chains, at least 18 carbon atoms, were obtained from polyethylene under these conditions.

A tentative classification for each sample and for each sequence of $C_nH_{2n+1}^+$ and $C_nH_{2n-1}^+$ was made with respect to their behavior of the relative intensities against the sample temperature. Accoring to the result of this classification, $C_3H_7^+$, $C_{10}H_{21}^+$, $C_{11}H_{23}^+$, and $C_3H_5^+$ were shown to exhibit abnormal behavior to all other ions in their respective

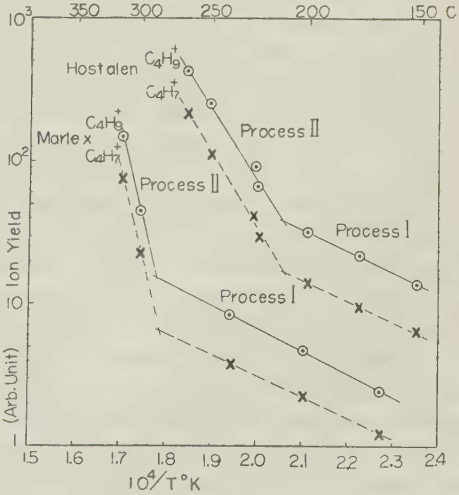

Fig. 3. Ionic yield versus the reciprocal of the temperature heated. Above the top abscissa the temperature in °C was given.

sequence. The disappearance of $C_{10}H_{21}^+$ and $C_{11}H_{23}^+$ at the higher temperature might be correlated to the fact that these ions were quite sensitive to the ion source temperature.

In Fig. 3, the temperature dependence of typical peaks was shown by semi-log plot. As seen clearly from the figure, the processes of ionic production, namely, the production of vapor from the polymer, composed of two stages: gradual increase of the yield in the lower temperature range, Process I, and following steeper uprise at the higher temperature, Process II. Since in our case, the peak-heights could be regarded as to be directly proportional to the rate of yield of vapor products which are to make impacts with electrons in the ionization chamber to form the positive ions, the activation energy could be calculated from the figure directly.

For Process II, the activation energy was calculated to give the values of 24.7 kcal/mol and 34 kcal/mol for Hostalen and Marlex, respectively. Two ionic species for a sample were regarded to behave similarly to each other. These values are much lower than those of thermal degradation presented by Jellinek[7] who offered the values of 46–66 kcal/mol for different molecular weights of polyethylene examined, and Madorsky's value[8] of 71 kcal/mol. Interesting is the fact that one of our values are happened to be very close to the value, 24.5 kcal/mol, which was proposed by Jellinek[7] in his work where polystyrene was degradated in vacuum at the temperature range, 248–340°C. Jellinek assumed that the weak link decomposition and the inhibition take place simultanesusly. In view of the molecular weight of Marlex used (estimated by viscosits measurements to give 47,000), the value, 34, kcal/mol, is too low to correspond to the random C–C scissions. Although it is not obvious at this stage whether the agreement for Hostalen with polystyrene is accidental or it indicates that the proceess of weak link rupture is essentially independent of the kinds of polymer, Hostalen and Marlex might possibly be concluded to begin to degradate at about 200°C and near 300°C, respectively. To determine the reaction mechanism dominating this stage, much more works are required.

The situation was illustrated in Fig. 2 a) and b). The patterns obtained at Process I give almost similar featurs for both polyethylene, whereas the values at Process II exhibited departure from each other as well from the standard.

For the Process I, the calculated values of the activation energy turned to be 6.7 and 5.8 kcal/mol for $C_4H_9^+$ and $C_4H_7^+$ from Hostalen, and 7.6 and 6.5 kcal/mol for the corresponding ions from Marlex. Taking the mean values of all other ions belonging to each sequence, the value for Process I appeared to be 6.5±1.2 kcal/mol. Taking into account the limited accuracy of the measurements, the whole ions which appeared at the temperature range lower than the knick shown in Fig. 3, could be regarded to have been generated through a stage, Process I.

In view of the low values of activation energy obtained for this pre-degradation stage, a process of evaporation were assumed to exist. Employing the spin-echo technique, McCall et. al.[9] estimated the activation energy of the low pressure polyethylene to be 5.3 kcal/mol. The leveling off of this value at about C_{20}–C_{30} was reported by the same authors in correlating to the segmental motion in the molecular flow in polymer. On the other hand, Jensen[10] estimated the vapor pressure of polyethylene (details were not given) by evacuating a oven containing the polymer through an orifice. Jensen reported that the vapor pressure, P, for the temperature range from 30°C up to 180°C, were expressible as $\log P = 7.4 - 4{,}500/T$, which is equivalent to the energy of activation of 8.9 kcal/mol.

Considering the difference in the ratio of the sample area to pump-out speed of outs and Jensen's, our values at Process I would indicate that the evaporation of lighter components aae taking place, and the rate of the process are determined by the diffusion of the components through polymer molecules.

§ 4. Conclusion

The behavior of the production of vapor of polyethylene was examined in a mass spectrometer. The rate of increase of ionic yield was found to be composed of two stages, Process I and II. The values of activation energy were calculated to be 6.5±1.2 kcal/mol for Process I, and 24.7 kcal/mol (for Hostalen) and 34 kcal/mol (for Marlex) for Process II. The latter stage would be correlated (for

Marlex) for Process II. The latter stage would be correlated to the thermal degradation, the mechanism of which was dominated by a reaction having a lower energy of activation, such as, for instances, the weak link rupture or so.

From the view points of the low lying value of activation energy and the mass spectra in which the hydrocarbon ions with a considerable long chains appeared, a stage of evaporation of the ligher components was concluded to exist. In this stage, Process I, the rate of production may perhaps be determined by the stage of diffusion of the lighter components through polymer molecules.

The author wishes to express his grateful thanks to Dr. A. Nishioka in his much instructive suggestions and constant encouragements during this work. He would like also to thank to Mr. Takei for the assistance in the measurements.

Interaction between Polyions and Low Molecular Ions

By Nobuhisa IMAI

Faculty of Science, Nagoya University, Chikusa, Nagoya

(Received January 6, 1961)

The characteristic nature of ion-binding of much charged polyions has been investigated mainly on the basis of the Poisson-Boltzmann (P.B.) equation and partly through the conductance experiment. In general, the ion-binding can be classified into two types, the ψ-binding and the P-binding. The former is due to the electrostatic field around polyions, while the latter is due to the short-range interaction between ionized groups of polyions and salt-ions. Through the theoretical analysis of non-linear property of the P.B. equation, we have found, for every shape of polyions, the strong ψ-binding of counterions which greatly depresses the polyion-charge within a thin ion-condensation phase around the polyion. By exactly solving the two-dimensional P.B. equation, we have also obtained the ion-distribution around many rod-like polyions and found the two-step ion-condensation phenomenon; at the first step, counterions are condensed in the neighbourhood of the assembly of polyions, and at the second step, a similar condensation phenomenon occurs around each of the polyions. The alteraction of spatial arrangement of polyions causes a larges change of activity coefficient of small ions.

Through the conductance measurement, we have found the strong P-binding of divalent cations to polyions. Generally, the P-binding is very much strengthened by the effect of ψ-binding.

§ 1. Introduction

Recently, it has been reported that there are many interesting salt-effects upon the aggregation phenomena of polyelectrolytes[1)-4)] or proteins in solutions[5),6)]. For the systematical interpretation of such specific ion-effects, it is one of the important works to study the counterion-binding to a polyion.

In polyelectrolyte solutions, counterions each of which has a charge opposite to polyions are strongly adsorbed to the polyions. Such adsorption of counterions can be classified into two types with respect to the mechanism of interaction. The binding simply due to the strong electrostatic interaction is called ψ-binding and has been investigated theoretically by many authors[7)-13)]. In most cases, there exists the other kind of ion-binding due to the short-range interaction between small ions and ionized groups on polyions. This kind of binding formed by covalent bonds or quasi-covalent bonds is called P-binding. The P-binding is generally strengthened by the ψ-binding, and sometimes bridges of counterions are formed between two groups on polymer chains.

In the study on polyelectrolyte solutions, it is very desirable to simplify or generalize the complicated P-binding phenomenon. Experimentally, the ion-binding problem has been investigated through the measurements of thermodynamical or current carrying properties[14)-16)] of polyelectrolyte solutions, and has been also studied by the transference experiment using isotope ions[17)]. It is, however, not so easy to separate experimentally the effect of P-binding from that of ψ-binding. This separation can be made to a certain degree in the system of polyacids by employing quaternary ammonium ions as counterions, because this cation can be postulated not to be bound to polyanion in the P-binding state on account of its large size and stable electronic structure[14)]. By using this large cation as a standard, the amount of the specific binding of other various cations can be estimated without much difficulty.

Now, in the theoretical studies on the ψ-binding, the ion-distribution around a polyion has usually been calculated mainly on the basis of the Poisson-Boltzmann equation (P.B. equation) to obtain the activity coefficients of counterion and byion. It should be emphasized that in solving the P.B. equation, the linearizing procedure adopted in the Debye-Hückel theory or in the early works on polyelectrolyte[8] is unsuitable for the present system of much charged macro-ions. In fact, no characteristic nature of polyelectrolytes could be deduced from the rough solution by linearization.

Fortunately, the P.B. equation has recently been solved exactly for the system of a single rod-like polyelectrolyte in its neutral free-volume[9] and also has been approximately solved for the system of a much charged coiled polyion in its free-volume[10)-12]. Through these results, one can find the strong adsorption of counterions in the vicinity of polyion and the powerful salt-effect which depress the apparent polymer charges. On the basis of these studies, the abnormal behaviors of activity coefficient of counterion observed in dilute polyion solutions can be explained at least qualitatively. In this paper, we will describe the theoretical analysis of the ion-binding in the cases of rigid and coiled spherical macro-ions, because we have not yet met exact calculations in these cases, and we will discuss the general feature of ψ-binding in the dilute and homogeneous systems of polyions.

Through the theoretical investigation of ψ-binding described in this paper, we found the characteristic phase of condensed counterions around a polyion. That is to say, if the charge ne_0 of a polyion situated in a finite free-volume exceeds a certain constant value n^*e_0, there appears the ion-condensation phase around the polyion in which $(n-n^*)$ counterions are strongly bound, and however larger n may become, the excess of n over n^* is retained in this phase and the total charge inside the condensation phase (n^*) is unaltered. In general, this condensation phase is very narrow and is clearly demarcated from the outer region, but it becomes diffuse with increasing polymer or salt concentration.

Nowadays, however, it is rather important to investigate the interaction of polyions in their concentrated system, such as gel-state or crystal-state. This investigation is of significance also for the physical interpretation of protein interactions. In order to understand such complicated macro-ion systems, we must rather investigate in the first place the general and common characters of counter-ion-distribution on the basis of the P.B. equation than solve the equation concretely for the individual cases. It is also necessary to deal with this problem in the aggregation system of polyions as well as in the homogeneous system. Recently, the P.B. equation for the system of more than two rod-like polyions has been partially solved by us[18], and the characteristic ion-distribution essentially different from that obtained by superposing single polyion systems has been found. We will report in this paper the complete solution for the problem of many rod-like polyions, discussing as generally as possible the ψ-binding in the aggregation state of polyions.

If some polyions (named $1, 2, \cdots, j, \cdots$, and having charges $n_1, n_2, \cdots, n_j, \cdots$) are aggregated in their common free-volume, there appear the following two kinds of ion-condensation. In the first place, if the total charge of these polyions $(\sum n_j)$ exceeds a constant value $n_0{}^*e_0$, condensation phase appears around the whole of these polyions and $(n-n_0{}^*)$ counterions are gathered in this phase. In the second place, when the charge of any polyion n_je_0 becomes larger than n^*e_0 which is the same value with that given in the above single polyion-system, the second condensation phase appears around this j-th polyion. Thus it is the essential fact implied in the P.B. equation that counterions from the condensation phase of the first or the second kind around a polyion or polyions.

In this paper, is also treated the P-binding problem, particularly the problem or divalent cation-binding on the basis of our conductance experiments, in which poly-(acrylic acid) solutions are employed to determine the amount of monovalent and divalent cations bound to carboxyl groups on polyions. A method of analysis to obtain the equivalent conductance of a polyion was adopted. By the use of this equivalent conductance, it was found that every species of salt-cations except quaternary ammonium ions is strongly bound to polyions in the P-binding state. Particularly, in the case of divalent cations, added cations are almost fully bound to polyions so far as dissociated carboxyl groups on the polyions remain unmasked by the cations. It is noteworthy that the counterions in the ψ-binding state, such as quaternary ammonium ions contribute to the ionic conductivity of polyion solutions almost completely. In our experiments, was also confirmed the surprising fact reported by Wall et al.[19] that simple monovalent cations such as sodium ions are pronouncedly bound to polyanions, though these cations are completely dissociated in low molecular acetate solutions. This fact is no doubt due to the ψ-binding effect which strengthens the P-binding. Moreover, our results show that these bound monovalent cations are replaced by newly added divalent cations, and generally P-binding is accompanied by much dehydration.

§ 2. Solution of the Poisson-Boltzmann Equation for the System of Spherical Polyions having Many Charges

It has been proved that the Poisson-Boltzmann equation is available for the determination of electric potential or counterion distribution around fixed polyions in their free-volume neutralized by counterions, but the equation cannot be applied for the calculation of the statistical distribution of polyions around a fixed polyion[10]. Therefore, hereafter we will always adopt the free-volume model for the study of the counterion distribution.

Now, when a rigid spherical polyion with charge ne_0 and radius a is settled in the centre of its neutral free-volume with radius R (Fig. 1), the electric potential ψ around this polyion can be obtained by the following P.B. equation and the boundary conditions;

$$\frac{D}{e_0}\Delta\psi=\frac{(n+j)e^{Y}}{\int_a^R e^{Y}r^2dr}-\frac{j\,e^{-Y}}{\int_a^R e^{-Y}r^2\,dr}\equiv\frac{4\pi\rho}{-e_0}\,, \tag{1}$$

$$(d\psi/dr)_{r=a}=-ne_0/Da^2\,,\qquad (d\psi/dr)_{r=R}=0\,, \tag{2}$$

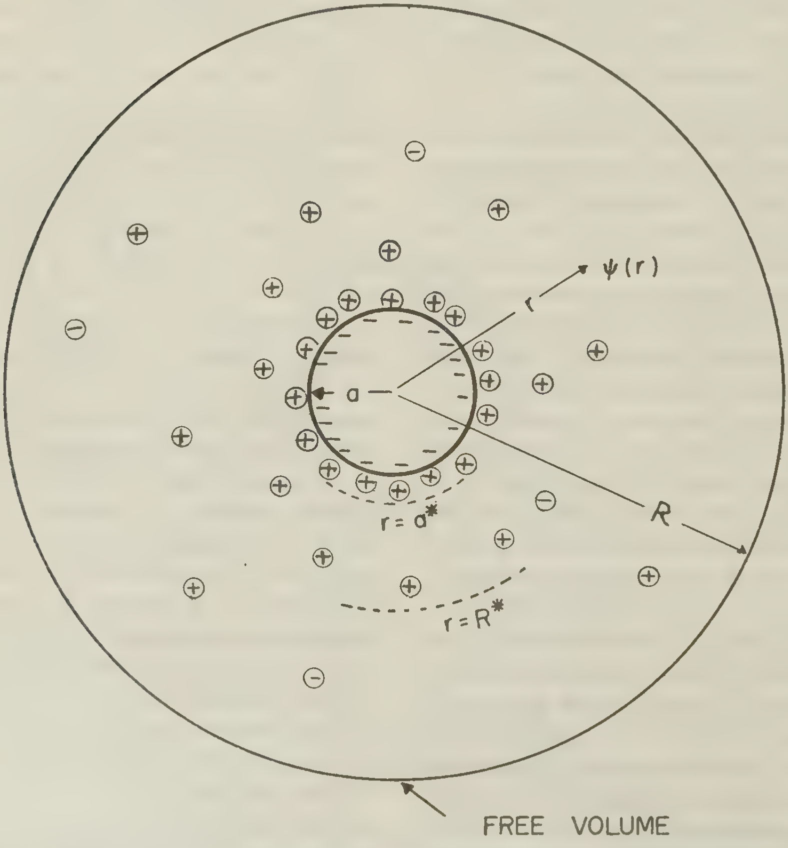

Fig. 1. A rigid spherical polyion having many charges and surrounded by low molecular ions in the neutral free volume.

where

$$Y \equiv e_0\psi/kT\,, \qquad (3)$$

$$\Delta = d^2/dr^2 + (2/r)\,d/dr\,,$$

r is the cubic coordinate whose origin is the centre of the free-volume, the integrals are the normalization factors, kT is the Boltzmann factor, D is the dielectric constant of solvent, and j is the number of byions in this free-volume. The polymer concentration is given by $(a/R)^3$ in our free-volume model.

Putting

$$\kappa^2 \equiv (n+j)\,e_0^2 \Big/ \left[DkT \int_a^R e^Y r^2\,dr\right], \qquad (4)$$

$$\theta^2 \equiv j\int_a^R e^Y r^2 dr \Big/ \left[(n+j)\int_a^R e^{-Y} r^2\,dr\right], \qquad (5)$$

and

$$p \equiv r(dY/dr)\,, \qquad (6)$$

we can rewrite the equation as follows;

$$d(rp)/dr = \kappa^2 r^2 (e^Y - e^{-Y})\,. \qquad (7)$$

Even though the exact solution of this equation cannot be obtained, the physical characters involved in it can be easily deduced through the mathematical analysis of the equation for the following typical cases;

1) The case when $3\log(R/a) \gg 1$ and $(R/a)^2 \gtrsim je_0^2/DkTa \geqq 0$; that is, the case when polyion concentration is extremely dilute but the salt-concentration is practically unrestricted, (d-system)
2) The case when $(je_0^2/DkTa) \gg (R^3-a^3)/a^3$; that is, the case when salt-concentration is high and the polyion is not so dilute. (c-system)

It is then an important character of our method of analysis that no restriction is put for the value of Y, but the polyion or salt concentration is limited as noted above. In this paper, only the results for the above two cases will be described.

[1] *The dilute system of rigid spherical polyions*

Let us define R^*, n^* by the following relations;

$$\frac{n^*e_0^2}{DkTa} = 3\log\frac{R}{a} - \log\left(\frac{je_0^2}{DkTa} + \frac{n^*e_0^2}{DkTa}\right) \qquad (\gg 1)\,, \qquad (9)$$

$$R^*/a = (R/a)^{1/2} \qquad (\gg 1)\,. \qquad (8)$$

Then, in the system satisfying $n \geqq n^*$, the sphere $R = a^*$ which satisfies the following relation can exist in the outside of the polyion;

$$(dY/dr)_{r=a^*} = p(a^*)/a^* = n^*e_0^2/DkTa^*\,, \qquad (10)$$

and the given free-volume can be divided into the following three regions;

(1) the region in which r satisfies $R^* \leqq r \leqq R$ (This region is named D. H. Region.),
(2) the region in which r satisfies $R^* \geqq r \geqq a^*$ (This region is named Intermediate Region.), and
(3) the region in which r satisfies $a^* \geqq r \geqq a$ (This region is named Ion-Condensation Region.).

For the system $n < n^*$, there is no Ion-Condensation Region.

According to our analysis, the following facts can be found without much difficulty.

1) In the D. H. Region, Y is much smaller than unity and accordingly, Y can readily be obtained by linearizing the equation. (The concrete form of Y is not written here.)
2) In the Intermediate region (I-Region), the function $g(r)$ defined by the following relation

is much larger than unity;

$$g(r)=\frac{p}{\kappa^2 r^2(e^Y-\theta^2 e^{-Y})}\,, \tag{11}$$

and by the use of the condition $g\gg 1$, p in this region can be expressed in the form;

$$\left.\begin{array}{ll} p=(a^*/r)\cdot p(a^*) & \text{for}\quad n\geqq n^*\,, \\ p=(a/r)\cdot p(a) & \text{for}\quad n\leqq n^*\,. \end{array}\right\} \tag{12}$$

3) In the present system, g is zero at $r=R$, and increases at the first step with decreasing r, but it becomes small again inside the Condensation-Region (C-Region). The maximum point of g exists in the I-Region.

4) In the Ion-Condensation Region (C-Region), both Y and p are very large compared with unity, and the following important relation can be introduced;

$$1<\frac{a^*}{a}<1+\frac{3\log p(a^*)}{p(a^*)}+O\left(\frac{1}{p(a^*)}\right)\,. \tag{13}$$

5) Near the point $r=a^*$, the conditions $g(a^*)\gg 1$ and $p(a^*)\ll 1$ are both satisfied, and therefore, the approximate solution of Y in the I-Region and that in the C-Region can be analytically connected with each other.

6) Similarly, near the point $r=R^*$, both the conditions $Y(R^*)\ll 1$ and $g(R^*)\gg 1$ are simultaneously satisfied, and then the D. H. Region and the I-Region can be analytically connected with each other. In the domain where r is much smaller than R, the expression of p obtained from the D. H. approximation takes the form of $(1/r)$, which is same with that valid in the I-Region.

7) With increasing value of R/a, the above analytical continuations become incorrect, because two kinds of the approximations can not be simultaneously satisfied at $r=a^*$ or $r=R^*$ unless R/a is sufficiently large.

8) The concrete form of Y in the C-Region can be introduced from the following soluble equation which can be obtained by neglecting the term $\exp(-Y)$ in (7) and using the approximation $p\gg 1$.

$$d(\kappa^2 r^2 e^Y)/dp=(p+2)/(p+\kappa^2 r^2 e^Y)\,.$$

Especially, $Y(a)$ is given in the form;

$$Y(a)=p(a^*)+\log\{p(a)^2-p(a^*)^2+1\}\,. \tag{14}$$

9) The normalization factors κ and θ can be obtained through the above analytical continuation and are given in the form;

$$\kappa^2 a^2=\frac{3(n+j)e_0^2}{DkTa}\frac{a^3}{R^2}\,,\qquad \theta^2=\frac{j}{n+j}:\qquad \text{for}\quad n\leqq n^*\,,$$

$$\kappa^2 a^2=\frac{3(n^*+j)e_0^2}{DkTa}\frac{a^3}{R^2}\,,\qquad \theta^2=\frac{j}{n^*+j}:\qquad \text{for}\quad n\geqq n^*\,.$$

From the above results for the d-system, we can conclude the following facts; when n becomes very large beyond the value of n^*, $(n-n^*)$ counterions are concentrated in the narrow region around a polyion, and the potential-distribution in the outside of this narrow region and the normalization factors are both kept constant for values of n larger than n^*. This means that for the large value of n, the apparent charge of the polyion can be always given by n^*. With decreasing polymer or salt concentration, n^* generally increases, and if n^* becomes larger than n, the ion-condensation region disappears. Inversely, if polymer concentration becomes high, the ion-condensation phase appears even for small

n, but in this case, the boundary of this phase becomes unclear.

[2] *The concentrated system (c-system) of rigid spherical polyions*

In the c-system in which the relation $je_0^2/DkTa \gg (R^3-a^3)/a^3$ is satisfied, the following results can be introduced from the same fundamental P.B. equation.

1) If a' and n' are defined by the relations;

$$p(a')=1\ , \qquad n'e_0^2/DkTa'=1\ ,$$

the free-volume can be divided into the following two regions, the region $a' \leqq r \leqq R$ (named D. H. Region) and the region $a' \geqq r \geqq a$ (named C-Region). In the D. H. Region, Y and p can be obtained by linearizing the equation.

2) The function $g(r)$ defined by (11) is very much smaller than unity everywhere.

3) Under the conditions $g(r) \ll 1$ and $p(r) \geqq 1$, the equation can be approximately solved, and Y in the C-Region is given in the form;

$$e^Y = \left(\frac{q+1}{q-1}\right)^2 ,$$

$$q \equiv 4\sqrt{2}\,\kappa a \cdot \exp\{\sqrt{2}\,(\kappa a - \kappa r)\}\ .$$

4) The solutions of Y thus obtained in the above two regions can be smoothly connected with each other in the neighbourhood $r=a'$, and the normalization factors in this system are determined as follows;

$$\kappa^2 a^2 = \frac{3je_0^2}{DkTa}\,\frac{a^3}{R^3-a^3} \qquad (\gg 1)\ ,$$

$$\theta = 1 - 4\exp\{\sqrt{2}\,(\kappa a - \kappa R)\}\cdot(\sqrt{2}\,\kappa R)^{-1}\ .$$

5) In the C-Region, a' satisfies the following relation;

$$1 < (a'/a) < 1 + O\{(\log \kappa a)/\kappa a\}\ .$$

This shows that the C-Region is very narrow.

Through these results for the c-system, we can find the following ion-condensation phenomena; however larger the polyion charge ne_0 may become, the normalization factor κ is unaltered and $(n-n')$ counterions are condensed in the vicinity of the polyion, and the apparent polyion charge $n'e_0$ is very small, being nearly independent of the polyion charge n.

[3] *Coiled spherical polyion system*

When a coiled polyion which has n ionized groups uniformly distributed in the average volume $v(=(4/3)\pi a^3)$ is situated at the centre of the free-volume (in place of the rigid spherical polyion in the above system) (Fig. 2), the following equation and the boundary conditions are established in the region $r \leqq a$;

$$\frac{D}{4\pi}\Delta\psi = -\rho + \frac{ne_0}{v}\ , \qquad (15)$$

$$\frac{d\psi}{dr}\ ,\ \ \psi \text{ are continuous at } r=a\ , \qquad (16)$$

$$(d\psi/dr)_{r=0} = 0\ , \qquad (17)$$

where n is the total chain-charge of the polyion and ρ denotes the charge density of small ions given in (1). In the region $r>a$, the equation (1) and the boundary condition $(d\psi/dr)_{r=R}=0$ are both valid without any alteration. Although a similar equation to (15) has often been treated by many authors for the same purpose, the general character of the ion-distribution in the internal region of a coiled polyion have not been deeply discussed under the consideration of the strong influence of the outer region of the polyion.

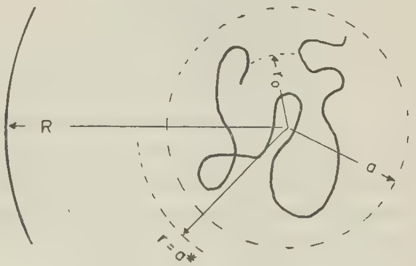

Fig. 2. A much charged coiled polyion with mean radius a in the free-volume.

In this section, we will discuss mainly the important correlation between the ion-condensation phase around a polyion and the characteristic ion-distribution inside the coiled polyion in the dilute system. The main results obtained in this system can be summarized as follows;

(a) In general, there appears the same kind of ion-condensation phase on the surface of the polyion as found in the rigid polyion system, provided that the polyion charge ne_0 exceeds a certain value n_1. This n_1 is expressed for the dilute system by the following relation:

$$\left[\frac{6n_1e_0^2}{DkTa}\cdot\log\left(\frac{3n_1e_0^2}{DkTa}\right)\right]^{1/2} = \frac{n^*e_0^2}{DkTa}\ ,$$

where n^* given in (8) is the critical value for the appearance of the condensation phase in the rigid polyion-system. As seen in this relation, somewhat larger n is necessary for the existence of the C-Region than in the case of rigid polyion-system. In the usual case of the dilute system of much charged polyions, however, the condition $n>n_1$ as well as that $n>n^*$ is satisfied. If n becomes smaller than n_1, the ion-condensation phase disappears and the Intermediate Region (I-Region) is directly continated with the region inside of the coiled polyion (on the surface).

(b) The value of p on the surface of the polyion $p(a)$ increases with increasing n, and is expressed for the case of very large n ($\gg n^*$) as follows;

$$p(a)=\left[2e^{-1}\frac{ne_0^2}{DkTa}\right]^{1/2} .$$

(c) If r_0 is chosen in the internal region of a polyion such that

$$p(r_0)=1 \qquad (r_0<a) ,$$

r_0 satisfies the relation;

$$(a-r_0)/a\approx\left(\frac{12ne_0^2}{DkTa}\right)^{-1/2}\cdot\log\left(\frac{3ne_0^2}{DkTa}\right) .$$

This relation means that p varies sharply near the surface of the coiled polyion.

(d) When we define $\lambda(r)$ as degree of neutralization of chain-charges at r by the following formula;

$$\lambda(r)=\rho v/ne_0 ,$$

it is proved that $\lambda(r)$ is small enough compared with unity except near the edge of the polyion, for instance, at $r=r_0$,

$$\lambda(r_0)=(3ne_0^2/DkTa)^{-1/2} .$$

Therefore, $\lambda(r)$ varies sharply in the surface region $r_0<r<a$, and particularly, at $r=a$, the relation;

$$1-e^{-1}<\lambda(a)<1 .$$

is established. In this relation, the upper limit 1 of $\lambda(a)$ is satisfied in the case $n\leqq n_1$, while the lower limit $1-e^{-1}$ of $\lambda(a)$ is satisfied in the case $n\gg n_1$.

From the above results, the character of the ion-distribution in the system of coiled polyions can be summarized as follows. The polymer charges are nearly completely depressed inside the sphere of the coiled polyion by the counterions. In the outside of the polyion, there appears the same ion-condensation phase as found in the rigid spherical polyion. Thus, the coiled polyion is equivalent, as regards the charge-distribution, to the rigid spherical polyion with a certain surface charge. The whole region inside the sphere $r=a^*$, that is to say, the C-Region plus the inside region of a coiled polyion is the ion-condensation phase in this system.

[4] *The ion-condensation phenomenon in the single polyion system*

A similar **ion-condensation** phenomenon can be easily found also in the single rod-like polyion system, for which the analytical solution of the P.B. equation has been exactly obtained by Lifson, Katchalsky[9]. In this system, potential ψ $(=YkT/e_0)$ around a sufficiently long rod-like polyion with radius a and a linear charge density ne_0 can be expressed in the following form;

$$e^{-Y}=[(1+\delta)(r/R)^{-\delta}-(1-\delta)(r/R)^{\delta}]^2(r/2\delta R)^2 , \tag{18}$$

where r is a cylinder coodinates whose origin is chosen at the axis of the polyion, R is the radius of the cylindrical free-volume, and δ is a constant. Provided that a/R is very small, it is proved that δ takes a real value almost equal to $1-A$ $(A\equiv ne_0^2/DkT)$ when A is smaller than about unity, but with increasing ne_0, δ becomes small, and when A exceeds about unity, it changes to pure imaginary after taking the value of zero. Further, it can be proved that the increase of A beyond unity does not alter the ion-distribution around the polyion except on its surface. Thus, the real—imaginary transformation of the integral constant just corresponds to the ion-condensation phenomenon in the thin rod-like polyion system.

Through the investigations in the above sections, it is found that the ion-condensation phenomenon is a remarkable common character in every system of much charged polyions. This abnormal ion-distribution may be briefly described in another expression; the Donnan equilibrium is approximately established between the ion-condensation phase and its outer region in the free-volume of polyion. In fact, the abnormal behavior of the activity coefficient of low molecular ions can be attributed to the existence of the ion-condensation phase or the Donnan equilibrium state near the polyion. In general, activity coefficient of counterions becomes abnormally small in any case when the counterions are distributed around many fixed charges which are locally and densely gathered with each other, but it takes a normal value when the fixed charges are uniformly dispersed in the system. Thus, even though the analysis of the P.B. equation is not so simple, the final conclusion is essentially concentrated in the concept of the counterion condensation. By using this concept we can find the character of the ion-distribution in more complicated systems without directly solving the P.B. equation. The significancy of Ion-Condensation phenomenon can be more clarified in the system of aggregated polyions as discussed in the next section.

§ 3. Counterion-distribution around Many Rod-like Polyions

It is interesting to study the characteristic nature of ion-distribution around more than two polyions, which results from the co-operative effect of these polyions. The analysis of the P.B. equation upon this problem is further more difficult as compared with that for the single polyion system. This problem, however, can be successfully dealt with for the system of rod-like polyions in salt-free solutions on the basis of the exact solution of the two-dimensional P.B. equation.

For the two-dimensional many-centre problem the following equation can be established;

$$\frac{\partial^2 Y}{\partial r^2}+\frac{1}{r}\frac{\partial Y}{\partial r}+\frac{1}{r^2}\frac{\partial^2 Y}{\partial \theta^2}=\kappa^2 e^Y\,, \qquad (19)$$

$$\kappa^2=4\pi n e_0{}^2\Big/\left(DkT\iint e^Y r\,dr\,d\theta\right), \qquad (20)$$

where r, θ are polar coordinates, n is the total number of counterions out of all polyions and the integral term is the normalization factor. The general solution of this equation has been found and applied by us for the system of two infinitely thin polyions. In this paper we will extend our previous result to the more general system, and describe in detail the procedure of solving this problem.

Now, the general solution of (19) can be expressed by employing two arbitral functions g_1, f_1 as follows;

$$e^{-Y}=\frac{1}{8}\kappa^2[g_1(z)f_1(z^*)-g_2(z)f_2(z^*)]^2\,, \qquad (21)$$

where

$$g_2\equiv g_1\int^z g_1{}^{-2}\,dz\,, \qquad f_2\equiv f_1\int^{z^*} f_1{}^{-2}\,dz^*\,,$$

and z, z^* are defined by $z=re^{i\theta}$, $z^*=re^{-i\theta}$. For the system satisfying $Y(r,\theta)=Y(r,-\theta)$, the solution is written simply in the form[18];

$$e^{-Y}=\frac{1}{8}\kappa^2[g_1g_1{}^*-g_2g_2{}^*]^2\,, \qquad (22)$$

where $g_i{}^*$ is defined by $g_i{}^*=g_i(z^*)$ $(i=1,2)$.

Let $g_1(z)$ be a solution of the following equation including a suitable function $u(z)$;

$$\frac{d^2g_1}{dz^2}+u(z)g_1=0\,, \qquad (23)$$

then, for every kind of $u(z)$, g_2 is the other solution of (23). Thus, ψ can be obtained if the arbitral function $u(z)$ for the given system is determined.

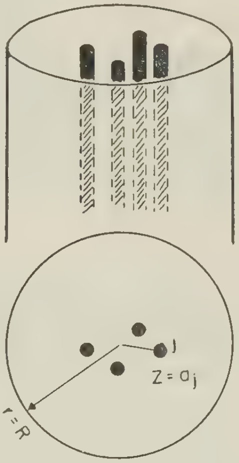

Fig. 3. Rod-like polyions in their common cylindrical free-volume.

The general theory for the dilute system of very thin rod-like polyions

Consider a system in which m rod-like polyions with negative charges $-n_1, -n_2, \cdots, -n_m$ are situated at the points $(r_1,\theta_1), (r_2,\theta_2), \cdots, (r_m,\theta_m)$ in the common cylindrical free-volume (neutrality zone) with radius R (see Fig. 3). In this system, the electric potential resulting from only the fixed polyions (denoted by ψ_p) is written as follows;

$$\frac{e_0\psi_p}{kT}=\sum_{j=1}^{m}A_j\log(z-a_j)(z^*-a_j{}^*)+C\,; \qquad A_j\equiv\frac{n_je_0{}^2}{DkT}\,, \qquad (24)$$

where C is a constant, $a_j=r_je^{i\theta}$, and $a_j^*=r_je^{-i\theta}$. Hereafter, we will deal with only the dilute system in which each of r_k satisfies the condition $r_k \ll R$.

Putting

$$g_{1,2}=q_{1,2}\prod_{j}^{m}(z-a_j)^{-A_j/2}\,, \tag{25}$$

we have the following relation;

$$\exp(-Y+Y_p)=\exp(-Y_g)=\log[g_1g_1^*-g_2g_2^*]^2+C'\,, \tag{26}$$

where Y_g means the electric potential resulting from only the counterions distributed in the free-volume, and C' is a constant. Now, referring to (25), q_1 and q_2 both satisfy the following equation;

$$\frac{d^2q}{dz^2}+\sum_{j=1}^{m}\frac{A_j}{z-a_j}\frac{dq}{dz}+V(z)q=0\,, \tag{27}$$

where $V(z)$ is an arbitral function employed instead of $u(z)$. Our purpose is to determine the form of function $v(z)$ from the following physical conditions established in the present system.

(A) Y should be analytic except at the polyion.

(B) On the surface of the free-volume,

$$(\partial Y/\partial r)_{r=R}\doteqdot 0\,, \qquad \oint(\partial Y/\partial r)_{r=R}\,d\theta=0\,.$$

(C) $dY/d\theta$ becomes very small for large r.

From (27) and the condition (A) neither q_1 nor q_2 becomes infinity except at $z=\infty$ and they must not similtaneously be zero anywhere except at the polyions. On the other hand, from the condition (C), it is evident that q_i $(i=1,2)$ takes a form of z^b at large z. Then, in order to satisfy these conditions, $V(z)$ should be given on the basis of the Liouville's and Frobenius, theorem as follows;

$$V(z)=\sum_{j=1}^{m-2}C_jz^j\Big/\prod_{k=1}^{m}(z-a_k)\,, \tag{28}$$

where C_j $(j=1,2,\cdots,m)$ are constants independent of z. The solution of this equation is composed of many solutions each of which is valid only in its own convergence region. The constants C_j's are determined from the analytical continuation by which these solutions are smoothly connected with each other.

The solution of (27) with $V(z)$ given by (28) can be easily found for large $|z|$, and by applying this solution, Y at large r is deduced as follows;

$$e^{-Y}=\left[D_0\left(\frac{r}{R}\right)^{\delta}-\frac{1}{D_0}\left(\frac{r}{R}\right)^{-\delta}\right]^2\frac{\kappa^2r^2}{8\delta^2}\,, \tag{29}$$

where the constant D_0 is determined by the condition (B) and given in the form $[(1-\delta)/(1+\delta)]^{1/2}$; the constant δ is expressed by C_{m-2} given in (28) and determined by the analytical continuation with the solutions valid in the other region of r. If R/r_j is sufficiently large for every j, δ tends to $1-\sum_j A_j$ and the solution (29) coincides with one centre problem. The expression of Y in (29) is similar to that in (18) established in the single polyion system. Therefore, it is obvious that with increasing $\sum_j A_j$, the constant δ in (29) decreases taking a real value at the first step, and then it changes to pure imaginary. This fact means that the ion-condensation phenomenon appears around the whole assembly of fixed polyions when the total polyion-charge exceeds a critical value $(=1)$. Through the same analysis as done in the single polyion system, it is easily confirmed that however larger the total polyion-charge may become, no appreciable increase of Y takes place at the region apart from the neighborhood of polyions, so far as the constant δ takes an imaginary value. This type of the ion-condensation is called "the first kind of ion-condensation."

On the other hand, the solution of Y available in the neighborhood of j-th polyion (at $z \approx a_j$) may be expressed in the form:

$$e^{-Y} = \left[B_j S_j^{1-A_j} - \frac{1}{B_j} S^{-1+A_j} \right]^2 \frac{\kappa^2 S_j^2}{8(1-A_j)_2}, \tag{30}$$

where S_j is $|z-a_j|$ and B_j is a constant. This expression of Y is the same with (18) valid for the system of an infinitely thin polyion, and therefore, it is obvious that the ion-condensation in the vicinity of a polyion appears similarly to the single polyion system, provided that A_j of each polyion exceeds the value of unity. This type of ion-condensation is called the second kind of ion-condensation.

It is noteworthy that the counterions are condensed in the vicinity of the whole of aggregated polyions before the second kind of condensation appears around each of the polyions, and that with increasing number of polyions coexisting in the system, the first kind of ion-condensation occurs easily.

Now, if m rod-rike polyions having equal charge ne_0 ($\equiv ADkT/e_0$) are arranged axial-symmetrically on a circle with radius a, Y can be concretely expressed by the well-known hyper-geometric functions, and then the analysis in this case is very simple. By putting

$$\left.\begin{aligned} &t = (r/a)^m e^{im\theta}, \qquad t^* = (r/a)^m e^{-im\theta}, \\ &g_j = (1-t)^{(1-\varepsilon)/2} q_j, \qquad (j=1,2), \qquad \varepsilon = 1-A, \end{aligned}\right\} \tag{31}$$

Y_p is written in in the form; $Y_p = A \log(1-t)(1-t^*)$, and the equation (27) is transformed into the following form;

$$\left.\begin{aligned} &t(1-t)\frac{d^2q}{dt^2} + [\gamma - (\alpha+\beta+1)t]\frac{dq}{dt} - \alpha\beta q = 0, \\ &\alpha = \gamma - \varepsilon - \beta, \qquad \gamma \equiv 1 - n^{-1}, \end{aligned}\right\} \tag{32}$$

where β is a constant which should be determined by the analytical continuation. The solution of (32) is composed of several hypergeometric functions each of which has its own convergence region, and then Y is also expressed in various forms corresponding to these convergence regions. For example, in the region $|t-1| \leqq 1$ and $|t-1| \geqq 1$, Y_g is written in the forms;

$$8\exp(-Y_g) = [E_0 H_1 H_1^* - E_0^{-1}\{(1-t)(1-t^*)\}^{\varepsilon} H_2 H_2^*]^2 \kappa^2 \varepsilon^{-2} \qquad \text{for} \quad |t-1| \leqq 1, \tag{33}$$

$$8\exp(-Y_g) = [D_0 (tt^*)^{-\beta} K_2 K_2^* - D_0^{-1}(tt^*)^{-\alpha} K_1 K_1^*]^2 \kappa^2 \delta^{-2} \qquad \text{for} \quad |t-1| \geqq 1, \tag{34}$$

where

$$H_1 = F(\alpha, \beta, \alpha+\beta-\gamma+1; 1-t), \qquad H_2 = F(\gamma-\alpha, \gamma-\beta, \gamma-\alpha-\beta+1; 1-t),$$

$$K_1 = F(\alpha, \gamma-\beta, \alpha-\beta+1; (1-t)^{-1}), \qquad K_2 = F(\beta, \gamma-\alpha, \beta-\alpha+1; (1-t)^{-1}).$$

According to the mathematical relations deduced from the analytical continuation, each of K_1 and K_2 is expressed by the linear combination of H_1 and H_2. Substituting this relation into (34) and comparing this result with (33), we obtain the relation between the constants D_0 and E_0, and at the same time obtain the following transcendental equation to determine the value of β;

$$\frac{1-\delta}{1+\delta}\left(\frac{a}{R}\right)^{2\delta} = \frac{\Gamma^2(\delta)\Gamma(\gamma-\beta)\Gamma(1-\beta)\Gamma(1+\alpha-\gamma)\Gamma(\alpha)}{\Gamma^2(-\delta)\Gamma(\gamma-\alpha)\Gamma(1-\alpha)\Gamma(1+\beta-\gamma)\Gamma(\beta)},$$

where δ is defined by $\delta = n(\beta-\alpha)$. Here, it is proved that this relation is the necessary and sufficient condition for every continuation of various Y's, each having a different available region. From this relation, we can find the following facts;

1) When A is small, β takes a small value of $O(A^2)$.
2) When a/R tends to zero, β becomes zero, and the functions K_1, K_2 become unity, and then, the result coincides with one-centre problem.
3) For the system of infinity thin polyions, ε is given by $1-A$ as noted in (31), but for the system of very thin but finite polyions, ε may generally take other values.
4) When A is smaller than about $(1/m)$, $\varepsilon=1-A$ and $\delta=1-mA$.
5) When A is increased beyond $(1/m)$, δ changes to pure imaginary at the first step. In this case, α and β, C_0 and $(1/C_0)$, $K_1K_1^*$ and $K_2K_2^*$ are conjugated complexes, respectively, but $H_1H_1^*$ and $H_2H_2^*$ are real.
6) At the second step, when A is increased beyond 1, δ and ε both become pure imaginary. In this case, α and $\gamma-\alpha$, β and $\gamma-\beta$, $H_1H_1^*$ and $H_2H_2^*$, $K_1K_1^*$ and $K_2K_2^*$ are conjugated complexes, respectively.

Thus, we can concretely see the two-step ion-condensation phenomenon through the real—imaginary transformation appearing in the transcendental equation. This phenomenon can be found also through the calculation of the force between two rod-like polyions[20]. The argument upon the problem of interaction will be done in the other paper.

§4. The P-binding of Divalent Cations in Poly(-Acrylic Acid) Solutions

The above theoretical treatment was concerned with only the ϕ-binding state of counterions. However, the P-binding also plays a great role in the interaction of counter ions with polyions. Actually, our experiment clearly showed that in general a considerable amount of counterions are tightly bound to

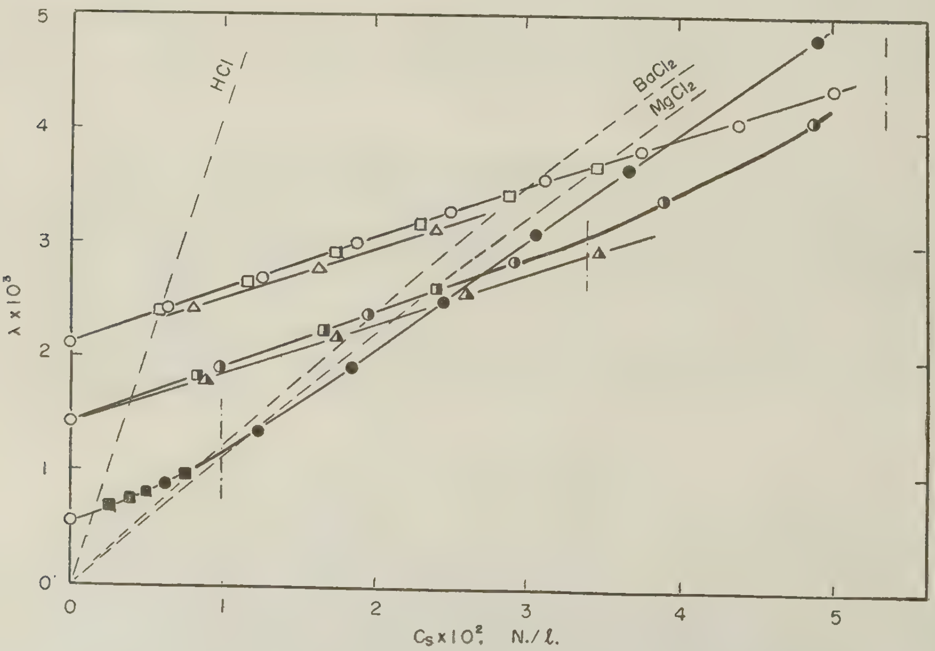

Fig. 4. The relation between specific conductances $\lambda(C_s)$ of polyacid-salt neutralized by tetra-n-butyl ammonium hydroxide and added salt concentration $C_s(N/l)$ at 25°C. The broken lines indicate the corresponding simple salt solutions and the vertical lines indicate the precipitation points with $BaCl_2$. Polymer concentration is always kept constant at 0.06 N/l.

polyions in the P-binding state. Therefore, we add a brief description on the result of this experiment and point out the importance of the P-binding. We adopted a new method of analysis for the conductance experiments, and determined the amount of bound cations to polyanions having many (5000—20000) carboxyl groups. The solutions employed here are poly-acrylic acid (PAA) solutions neutralized by NaOH or $N(Bu)_4OH$, tetrabutyl ammonium hydroxie, at various degrees of neutralization α, which mean fraction of carboxyl groups not taking a form of COOH but taking a form of COO^- or COO–Me (Me denotes a metal ion).

In Fig. 4, conductances λ of the PAA solutions neutralized by $(NBu)_4OH$ and containing added salt-ions are plotted against the concentration of involved salt-ions C_s (expressed in normal conc.) at a fixed polymer concentration C_p (=0.06 N/l). In this figure, three solid lines correspond to the different α's, and the other two solid lines show similar results in the case of HCl which is added to the polymer solutions at $\alpha=0.7$ and 1.0, respectively. (In the case of HCl, λ's are plotted against the concentration of involved Cl^-.) The conductances of the corresponding simple salt solutions are indicated by the dashed curves. It is seen in this figure, that λ increases linearly with C_s within the value of C_s smaller than αC_p and slope $d\lambda/dC_s$ is much smaller than that of simple salt solution. These facts suggest that added cations are strongly absorbed to polyions so far as COO^- groups remain not to be bound[23].

Now, let λ_c, λ_a, and λ_t denote equivalent conductances of added cation, added anion and tetrabutyl ammonium ion, respectively, then, conductance of polymer solutions can be expressed, on the basis of independent migration of all ions, in the following relation;

$$\lambda=(\alpha C_p-C_m-C_t)\lambda_p+(C_s-C_m)\lambda_c+C_s\lambda_a+(\alpha C_p-C_t)\lambda_t\ , \quad (35)$$

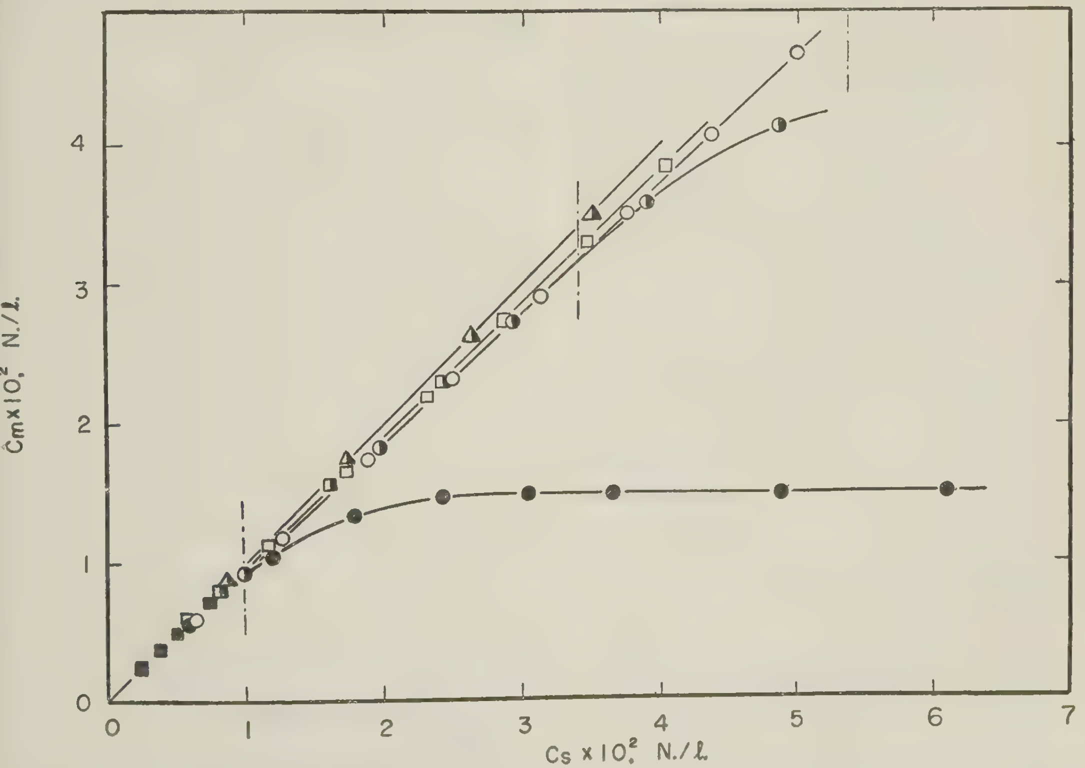

Fig. 5. The relation between the amount of bond cations $C_m(N/l)$ and the concentration of added salts $C_s(N/l)$ at various α's. Polymer concentration is 0.06 N/l.

□: $BaCl_2$, $\alpha=1$; ◨: $BaCl_2$, α=0,7; ■: $BaCl_2$, $\alpha=0.25$;
◭: HCl, $\alpha=0.7$.

where C_m and C_t denote the amount of bound salt-cations, and the amount of bound tetrabutyl ammonium ion, respectively.

Differentiating both sides of (35) with respect to C_s, we at once obtain the relation;

$$\frac{\Delta\lambda}{\Delta C_s}=\lambda_a+\lambda_c-\frac{\Delta C_t}{\Delta C_s}(\lambda_p+\lambda_t)$$
$$-\frac{\Delta C_m}{\Delta C_s}(\lambda_c+\lambda_p)\,. \tag{36}$$

Now, according to Fig. 4, it is obvious that for the cases of added Mg^{++}, Ba^{++} and H^+, the value of $\Delta\lambda/\Delta C_s$ at comparatively low C_s is independent of C_s. Therefore, in this case, by putting

$$\Delta C_m/\Delta C_s=h\,, \qquad C_t=b(1-fC_s)\,,$$

the relation (36) can be simply written in the form;

$$\Delta\lambda/\Delta C_s=bf(\lambda_p+\lambda_t)-h(\lambda_c+\lambda_p)+\lambda_x+\lambda_c\,, \tag{37}$$

where h, b, and f are constants independent of C_s, and b and f can be called ion-exchanging parameters which depend on α. Fig. 4 shows that conductances, each of which belongs to different α and the same salt-species, are increased in almost parallel with each other. Therefore, in order to obtain from (37) the expression of λ independent of α, it is necessary to assume that h is nearly independent of α and bf is very small in com-

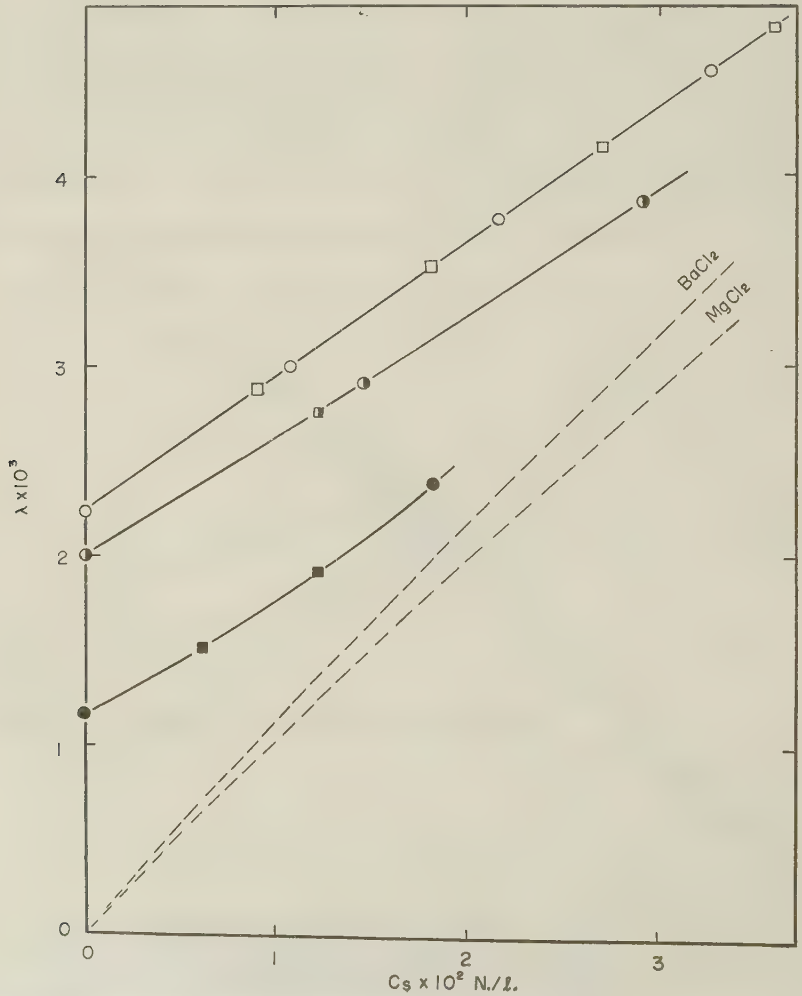

Fig. 6. The relation between specific conductances $\lambda(C_s)$ of polyacid-salt neutralized by NaOH and added salt concentration $C_s(N/l)$ at 20°C. The broken lines indicate the corresponding simple salt solutions. Polymer concentration is always kept constant at 0.089 N/l.

□: $BaCl_2$, $\alpha=1$; ◨: $BaCl_2$, $\alpha=0.7$; ■: $MgCl_2$, $\alpha=0.3$.

parison with h. Thus, for the case of these cations, we have the relations;

$$\Delta\lambda/\Delta C_s=\lambda_a+\lambda_c-h(\lambda_c+\lambda_p)\ . \qquad (38)$$

On the other hand, from the pH measurements, it was found that when HCl was added into the polyion solution neutralized by $(NBu)_4OH$ at $\alpha=0.7$ or 1.0, the value of pH changed from 7.2 to 5.2 or from 9.9 to 7.8, provided that the final concentration of added Cl^- is less than αC_p. This pH change corresponds to the increase of H^+-concentration at most about 10^{-5} mol/liter and is negligibly small. Hence, it is reasonable to put $h=1$ in (38) for the case of added H^+.

Thus, we can obtain the value of λ_p without difficulty. By substituting this value of λ_p and the experimental results into (38) or more generally (36) with no ΔC_t term, we obtain the value of C_m in the case of $(NBu)_4OH$—neutralized solutions (Fig. 5). A similar result for the case of added NaCl has been obtained by us, and from the result, it has been concluded that the amount of bound Na^+ is about 60∼70% when Na^+-concentration is nearly αC_p.

Next, by putting $C_s=0$ in (35) and substituting the value of λ_p and the experimental result in the case of no salt into (35), we can calculate the value of C_t/C_p and study the contribution of $(NBu)_4^+$ to the conductance. Although this value cannot be accurately determined because the ionic concentration in our system is too high to assume the independent migration of ions, it can be roughly concluded that about 70–80% of $(NBu)_4^+$ ions can contribute to the ionic conductance of salt-free poly(-acrylic acid) solution.

Turning to the relation (35), it is expected that in the case of the polymer solutions neutralized by NaOH, the value of $\Delta C_m/\Delta C_s$ will depend on α, since bf in this case is is supposed to be a function of α. This fact can be proved by the experimental results shown in Fig. 6. As seen in this figure, the slope of λ increases with increasing α. It is, however, an unsolved problem to determine the concrete values of ion-exchanging parameters.

Thus, through the conductance measurements, we can see very complicated binding phenomena related to both the P-binding and the ψ-binding.

§ 5. Discussion and Conclusions

As discussed in the above sections, there is neither the ideal ψ-binding nor the ideal P-binding in the ion-binding state of polyions. The specific binding of salt-ions to polyions are much strengthened by the *ion-condensation* phase around polyions theoretically expected to appear in the system of much charged macroions. The clear evidence of this effect has been observed in the adsorption phenomenon of various salt-cations to PAA molecules (§ 4).

It must be emphasized here that the ψ-binding effect becomes more conspicuous in the system of locally aggregated polyions than in the system of dispersed polyions. On the basis of the *two-step ion-condensation* which has been deduced in this paper, it is expected that the great change of the activity coefficient of small ions appears when the rearrangement of polyions or the phase change in polymer solutions does occur. This fact may be examined through the experiments of membrane potential.

In general, in order to obtain the information about such complicated ion-binding, it is convenient to adopt the conductance[14)–16)] or dielectric constant measurements[21),22)]. The former method is useful to estimate the amount of salt-ions in specific binding state as described in § 4, while the latter is sometimes convenient to study the ψ-binding effect on the basis of the Maxwell-Wagner effect. The remarkable increase of dielectric constant and its abnormal dispersion in salt-free solutions recently observed by Fuoss and Allgén prove the existence of ionic double phase around a polyion. However, they cannot give the direct support to the ion-condensation phenomenon due to our theory. Nevertheless, it is an interesting problem how the influence of the two-step ion-condensation does appear in the dielectric constant when the aggregation—dispersion transformation is observed in the solution.

It can be briefly concluded through the above investigations that by the concept of the ion-condensation of the first and the second kind deduced from the non-linear character of the P.B. equation, we can make theoretical discussions on the further more complicated polyion system without solving directly the corresponding P.B. equation, and that the strong effect of the ψ-binding appears in reinforcement of the adsorption of cations to polyanions, as observed in the experiment.

There are, however, many unsolved experimental problems upon the ion-binding, such as the influence of added salts, dehydration of bound ions, the relation between the ion-binding and the aggregation phenomena of polyions, etc. These problems are being made clear through the recent work upon the salting-out experiment, the measurements of diffractive index and ultrasonic velocity. Our studies upon this problem will be reported in other papers.

Acknowledgement

It is author's pleasure to acknowledge the useful advice and discussion of Prof. Oosawa. The author is also deeply indebted to the members of author's laboratory for giving him valuable discussions.

Study of the Hydration-Dehydration in Polyelectrolyte Solutions by the Ultrasonic Technique

By Hiroshi ASAI

Department of Physics, Faculty of Science, Nagoya University, Nagoya Japan

(Received January 9, 1961)

In this study, the ultrasonic velocity and the density of the polycarboxylic acid solutions which are neutralized at various degrees by sodium hydroxide or tetra-n-butyl ammonium hydroxide have been measured. From these results, the amount of hydrated water molecules has been estimated. An abnormal behavior of hydration has been found in polyacid solutions neutralized by NaOH, which is interpreted as being due to the partial dehydration resulting from Na ion-polyion binding at high degree of neutralization. The effects of adding various mono- or di-valent salts upon the hydration state of polyanion were also examined. From these experiments, it has been found that Ba ion-polyion binding gives rise to 40 percent dehydration of the water molecules which were hydrated in no binding state, and Mg ion-polyion binding gives rise to 20 percent dehydration. The whole results in polyacids were always compared with the results in monoacids, and it was concluded that the above dehydration phenomenon was one of the important characteristics of polyacids.

§ 1. Introduction

In the recent studies of polyelectrolyte solutions, it is one of the important subjects to investigate the specific ion-binding and precipitation phenomena in polyelectrolyte solutions. These phenomena are closely related to the hydration of polyions which is much influenced by the various ionic conditions. Although there have been many studies upon the ion-binding[1)-4)] or the salting out of polyions[5-9)], few direct investigations have been made on the hydration problem. It is expected that the information of the hydration in polyelectrolyte solutions can be obtained through the ultrasonic velocity experiment which was employed to estimate the amount of hydration in simple electrolyte solutions[10)-12)]. We have, therefore, undertaken to apply this method for the study of the hydration-dehydration in polyelectrolyte solutions. We measured the ultrasonic velocity and the density of solutions of polyacids (polymethacrylic acid and polyacrylic acid) neutralized by sodium hydroxide and tetra-n-butyl ammonium hydroxide. The comparison of two kinds of counterions gave some new knowledge on the counterion-binding of polyion and the resulting dehydration. We also examined the effects of various mono- and di-valent salts on the neutralized polyacids. As a result, we found the cation binding accompanied by dehydration, the amount of which depends on the species of cations. The same experiments were carried out in monocarboxyl acids and the results were compared with those in polyacids.

§ 2. Experiments

Apparatus

The ultrasonic velocity of the solutions was measured at the frequency of one megacycle by an ultrasonic interferometer which was similar to that used by McMillan and Lagemann[13)] or Gucker and Haag[14)]. The reproducibility of the measured velocities was within 0.3 m/sec. The density of solutions was measured by picnometers. All measurements were made in the water bath at constant temperature 25.0±0.03°C.

Material and preparation

PMA. Crystalline methacrylic acid monomer supplied by the courtesy of Dr. Nagasawa was dissolved in distilled water to a nearly saturated concentration and the degree of neutralization was adjusted to 0.05 with sodium hydroxide. A small amount of the initiator (ammonium persulphate) was added. After incubation for 27 hours at 64°C, monomer solution was polymerized into a jelly-like solution of polymethacrylic acid (PMA). No appreciable amount of unreacted monomer was detected by chemical analysis of the double bond of monomer. The solution was diluted by distilled water. The average degrees of polymerization were found to be 2800 from the intrinsic viscosity[15] in 0.2 M HCl solution.

PAA. The polyacrylic acid (PAA) solution obtained through Towa Gosei Co. as a laboratory sample was dialyzed againt many changes of distilled water for two weeks. The average degrees of polymerization estimated from the intrinsic viscosity[16] in 2 N NaOH solution were found to be 1900.

MMA. The methacrylic acid (MMA) solution obtained by dissolution of the crystalline monomer contained a small amount of the polymerization inhibitor (0.033 percent hydroquinone and 0.05 percent methylene blue), which prevented monomers from photo-polymerization. The presence of small amount of the inhibitor gave no disturbance in our experiments.

Other chemicals were reagent grade. The solute concentration in all original solutions was determined by the titration of carboxylic groups in the presence of sufficient NaCl. The completely neutralized solution in the absence of salt was obtained by addition of the calculated amount of pure hydroxide solution (sodium hydroxide or tetra-n-butyl ammonium hydroxide) into acid solution. Solutions at various degrees of neutralization were prepared by mixing the acid solution and the completely neutralized solution at various ratios.

§ 3. Results

A. *Increase of hydration in acid solution by ionization*

Fig. 1 shows ultrasonic velocity V and density ρ of MMA and PMA solutions at various degrees of neutralization by NaOH. The velocity and the density of MMA solutions increase linearly with the degree of neutralization α. The density of PMA solutions also increases linearly with α. The increment of velocity of PMA solutions by ionization, however, decreases with increasing α. The adiabatic compressibility β of solution is related to the velocity and density by the equation $\beta=1/V^2\rho$; and the apparent partial molar compressibity $\bar{\beta}$ of solute can be calculated by the equation

$$\bar{\beta}=\frac{10^3\beta-v_0\beta_0}{C}\,, \tag{1}$$

where C is the molar concentration of solute in monomer unit, v_0 is the volume of solvent per liter of solution, and β_0 is the compres-

sibility of solvent. A non-linear relation between $\bar{\beta}$ of PMA and α can be seen in Fig. 2.

To examine whether or not non-linearity of $\bar{\beta}$ disappears at sufficiently low concentration of polyacid, we made similar experiments at various concentrations of PMA as well as MMA. As shown in Fig. 3, no essential difference was observed in concentration dependence of $\bar{\beta}$ between PMA and MMA. Consequently, $\bar{\beta}$ of PMA at sufficiently low concentration does not vary linearly with α but shows a similar behavior to that at finite concentration.

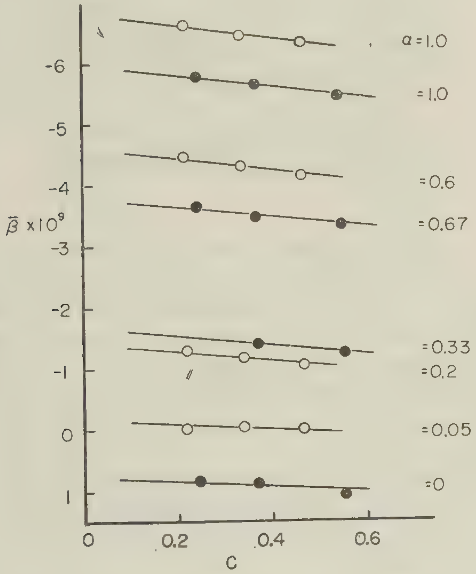

Fig. 3. Relation between $\bar{\beta}$ and acid concentration *C*. -●-; MMA, -○-; PMA.

To evaluate the amount of hydration from the measured value of $\bar{\beta}$ we put the following two assumptions. In the first place, it is assumed that the compressibilities of hydrated water and small ions are negligibly small as compared with that of free water. In simple strong electrolyte solutions, this assumption has been justified[11] by the fact that the amount of hydration estimated under this assumption is in good agreement with that estimated by other experiments. In the second place, it is assumed that the compressibility of the hydrophobic group in acid molecules is not altered by ionization of carboxyl group. Under these assumptions we can estimate the increase of the amount of hydration H_α (moles per mole of solute) by ionization up to α by the following relation, although we can not know the amount of hydration at $\alpha=0$;

$$H_\alpha = -\frac{\beta_\alpha - \beta_{\alpha=0}}{\bar{v}_0 \beta_0} \qquad (2)$$

where $\bar{v}_0$ is the partial molar volume of water. The right ordinate of Fig. 2 shows the value of H_α. Thus, in the term of hydration the results in the figure are described as follows; in MMA the increment of hydration by ionization of each carboxyl group does not depend on α; and in PMA the increment of hydration by ionization of each carboxyl group on polymer chain decreases gradually with increasing α. Such an abnormal behavior of hydration in PMA was also found in PAA. It is then likely that this is a common characteristics of polycarboxyl acids.

Now, in order to examine whether or not this behavior is due to the binding between polyion and Na ion, it is suitable to employ tetra-n-butyl ammonium (TBA) ion as counterion instead of Na ion because this TBA ion can be postulated not to be bound to polyion on account of its large size. Fig. 4 shows the apparent partial molar compressibilities of PAA and acetic acid (Ac) neutralized by TBA-

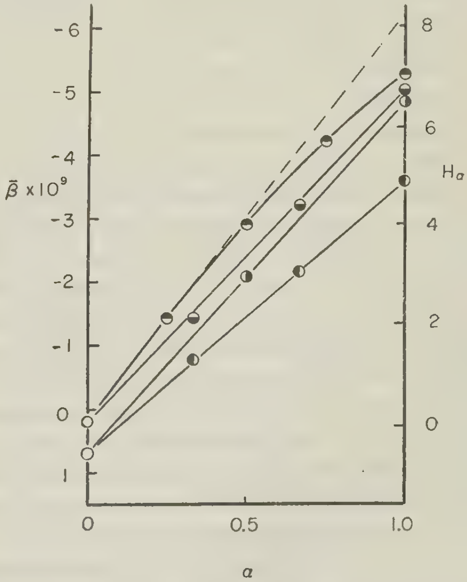

Fig. 4. Plots of $\bar{\beta}$ of acetic acid and PAA neutralized by TBA-OH or by NaOH against α. ◐; TBA-Ac at 0.29 m/L. ◑; Na-Ac at 0.29 m/L, ◒; TBA-PAA at 0.29 m/L, ◓; Na-PAA at 0.30 m/L.

OH and those neutralized by NaOH. The linear relations between $\bar{\beta}$ and α was found in TBA-PAA system as well as in TBA-Ac system, while the non-linear relation was found in Na-RAA system. Therefore, the non-linearity in Na-polyion systems is interpreted as being due to the binding of Na ion to polyion. But for this binding, the difference of $\bar{\beta}$ between Na-PAA and TBA-PAA system should be equal to the difference of $\bar{\beta}$ between Na-Ac and TBA-Ac system. As a matter of fact, the former difference is found to be smaller than the latter. The broken line in the figure gives the value of $\bar{\beta}$ of Na-PAA expected under the supposition of no binding. The actual discrepancy can be attributed to the dehydration accompaning Na ion-PAA ion binding. The estimated amount of dehydration is very small at low α and increases sharply with α. This fact consists at least qualitatively with the experimental results on Na ion binding made by Wall and Eittel[4]. If the fraction of bound Na ion at $\alpha=1$ is about 60 percent as reported by the above authors, the amount of dehydrated water molecules is estimated to be about two molecules per ion binding. This value is fairly small in comparison with the amount of water molecules which were hydrated in no binding state.

B. *Dehydration in polyacid solutions by adding salts*

By using a similar method, we studied the hydration in PMA solutions in the presence of mono- and di-valent salts (NaCl, $MgCl_2$, $BaCl_2$) at various degrees of neutralization by NaOH. The results were compared with those in MMA solutions. The apparent compressibility of the mixed solution of MMA and salts ($10^3\beta-v_0\beta_0$) varies linearly with mixing ratio r. This fact means that hydration of MMA is not affected by the presence of salts. A similar result is obtained in the mixed solution of PMA and mono-valent salt. However, the velocity of the mixed solution of PMA and divalent salts does not vary linearly with r, but has a remarkably low value (except at low α). Typical examples are shown in Fig. 5. The density of the mixed solution of PMA and divalent salt does not appreciably deviate from the straight line. Since the presence of divalent salt gives rise to precipitation of the neutralized polyacid at some critical concentration, the measurements were carried out up to its critical concentration. The experimental results suggest that the added divalent cations are bound to polyions and part or all of the water molecules which were hydrated in no binding state are dehydrated.

The difference $\Delta\Phi$ of the measured value of the apparent compressibility of a mixture from the value expected on the hypothetical

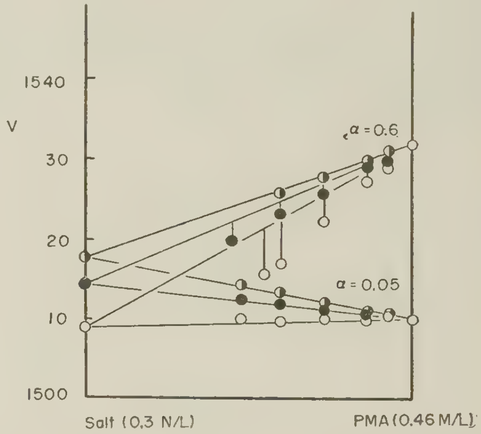

Fig. 5. Plots of V in the mixed solutions of PMA and various salts against mixing ratio r. ◑; NaCl, ●; $MgCl_2$. ○; $BaCl_2$.

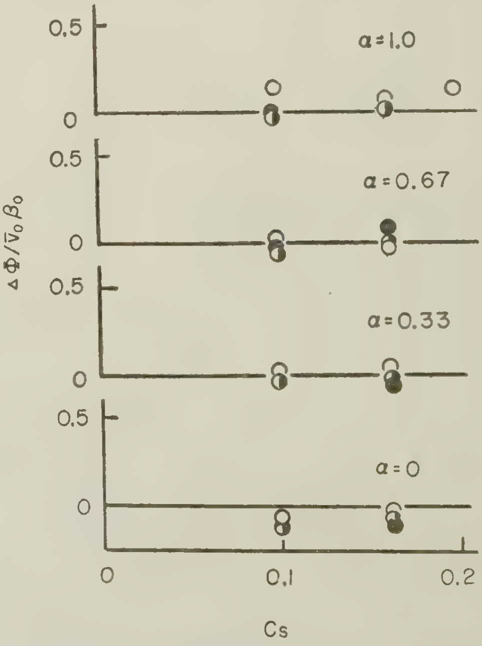

Fig. 6. Plots of $\Delta\Phi/v_0\beta_0$ in the mixed solutions of MMA and various salts against the added salt-concentration C_s (normal/L). ◑; NaCl, ●; $MgCl_2$, ○; $BaCl_2$.

condition of no dehydration can be expressed as follows,

$$\Delta\Phi=(10^2\beta-\beta_0 v_0)-(C_s\bar{\beta}_s+C\bar{\beta})\ , \qquad (3)$$

where C_s is the concentration of salt in a mixed solution and $\bar{\beta}_s$ is the apparent partial molar compressibility of salt. The amount of dehydrated water molecules per liter of solution is given by $\Delta\Phi/\bar{v}_0\beta_0$. Plots of $\Delta\Phi/\bar{v}_0\beta_0$ against salt-concentration are shown in Figs. 6 and 7.

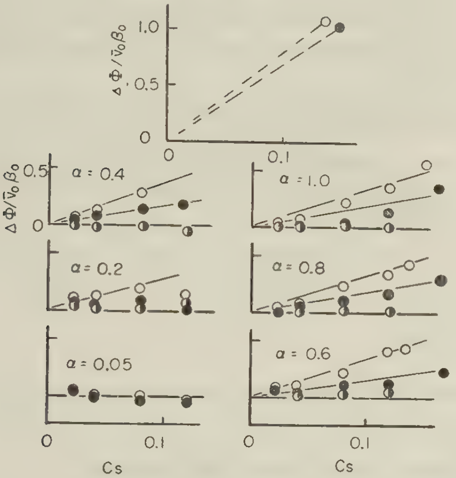

Fig. 7. Plots of $\Delta\Phi/\bar{v}_0\beta_0$ in the mixed solutions of PMA and various salts against C_s. ◑; NaCl, ●; $MgCl_2$, ○; $BaCl_2$. The broken lines show the value of $\Delta\Phi/\bar{v}_0\beta_0$ calculated on the assumption that all of the added divalent cations are bound to polyions and complete dehydration takes places.

It can be seen in Fig. 6 that the addition of various salts does not bring about dehydration of MMA at any α. It can be also seen in Fig. 7 that the addition of monovalent salt to PMA solution does not appreciably bring about dehydration of PMA. On the other hand, the presence of divalent salt brings about a considerable amount of dehydration in PMA solution (except at low α). If it is assumed that the Na ions bound to polyions are not affected by the addition of divalent cations, the amount of dehydrated water molecules estimated from the above equation may be attributed mainly to divalent ion-polyion binding. The fact that the gradient of $\Delta\Phi/\bar{v}_0\beta_0$ against divalent salt-concentration is nearly independent of α suggests that the added cations are almost bound to polyions. This complete divalent cation-polyion binding has been supported by several authors[1),9)]. The broken lines in Fig. 7 show the value $\Delta\Phi/\bar{v}_0\beta_0$ calculated on the assumption that all of the added cations are bound to polyions and the complete dehydration takes place. From the comparison between the broken lines and the measured $\Delta\Phi/\bar{v}_0\beta_0$, it can be said that the Ba ion-polyion binding gaves rise to 40 percent dehydration of the water molecules which were hydrated in no binding state and the Mg ion-polyion binding gives rise to 20 percent dehydration. This difference in the amount of the dehydrated water is originated in the difference in ionic radii between Ba and Mg.

§ 4. Discussion

As seen in Fig. 2 and 4, $\bar{\beta}$ of polyacid is smaller than $\bar{\beta}$ of monoacid at the same α. This fact is due to the low compressibility of polymer skelton formed by the polymerization of monoacids.

In the analysis of dehydration in PMA solutions neutralized by NaOH and containing divalent cations, we assumed that the amount of bound Na-ions is not altered by the absorption of divalent cations to polyanions. It is, however, very possible that when divalent cations are absorbed to polyions, the ion-bridges are formed across the ionized carboxyl groups on polyions. Such bridge-formations might partly release the bound Na ions. This effect will be examined through the studies upon the polyacid solutions neutralized by hydroxides of special cations, such as TBA, having no ability to be bound to polyions.

As described in the above section (Fig. 7), the larger amount of dehydyation is observed in the case of Ba-binding to polyions than in the case of Mg ion-binding. Such difference of the amount of dehydration causes the significant difference of the solubility of polymers between in Ba-ion containing solution and in Mg-ion containing solution.

Through the above experimental results, it is clearly found that the hydration-dehydration change is the very basic and important phenomenon in charged macro-ion system and the ultrasonic measurement is one of the useful method for the study of such hydration phenomenon.

On the Theory of Cross Relaxation in Maser Materials

By Motokazu HIRONO

Radio Research Laboratories, Kokubunji, Tokyo

(Received December 15, 1960)

A theoretical study of cross relaxation in Maser materials has been carried out based on the moment method. The energy level splittings due to the crystalline electric field and the applied magnetic field are utilized for the computation of the moments of the cross relaxation. If the lattice points are populated at random by paramagnetic ions in highly diluted salts, the second moment is much greater than the overlap integral of the individual ordinary resonance line shapes and to some extent influenced by the orientation of the applied magnetic field. The shape function of the cross relaxation is roughly Gaussian but takes slightly less values in the wings. The cross relaxation in ruby Maser successfully operated at liquid nitrogen temperatures has been briefly discussed.

§ I. Introduction

In a recent paper the theory of cross relaxation in spin systems was developed by Bloembergen, Shapiro, Pershan and Artman[1] (hereafter referred to as BSPA). This paper shows the mechanism of spin-spin relaxation, i.e. the process by which a common spin temperature is achieved. A number of experiments[2]-[4] have verified this theory at least qualitatively

The most fundamental process of cross relaxation is when two spins make simultaneous opposite flips, the balance in Zeeman energy being taken up by the dipole-dipole interaction. The process was treated in several theoretical papers.[1],[5],[6] The practical computations in BSPA and in reference 2 were based on replacement of the second moment for cross relaxation with the overlap of individual ordinary line shape functions.

Pershan[5] calculated the second moment for the case of nuclear spins of LiF and showed that the above approximation is useful for concentrated salts to which, however, his consideration is confined. The cross relaxation in highly diluted paramagnetic salts was treated by Kiel[6] in terms of moment method and it was shown that the overlap integral method does not suffice for the diluted salts. In his calculations the effect of the crystalline electric field is neglected. This effect is, however, of fundamental importance for the operation of solid state Masers. In the present paper the rate of cross relaxation is calculated in terms of moment method taking into account the effect of the crystalline electric field in the Maser materials and hence the mechanism of relaxation is essentially different from that of Kiel[6].*

In recent years, the ruby Masers were successfuly operated at liquid nitrogen temperatures by Maiman[7] and Ditchfield.[8] Maiman[7] suggested that the cross relaxation is important for the operation. We briefly examined the process in terms of above mentioned results.

§ 2. General Consideration on Cross Relaxation

Consider the spin Hamiltonian,

$$\mathscr{H}=\mathscr{H}_m+\mathscr{H}_{cr}+\mathscr{H}_{\text{int}} \tag{1}$$

$\mathscr{H}_{cr}$ is the sum of the crystalline field couplings of the individual ions. The Zeeman energy in the applied field is given by

$$\mathscr{H}_m=\sum_i \beta \boldsymbol{H}\cdot \boldsymbol{g}_i\cdot \boldsymbol{S}_i\ .$$

The interaction between the spins are assumed to consist of dipolar and exchange terms:

$$\mathscr{H}_{\text{int}}=\sum \tilde{A}_{ij}(\boldsymbol{S}_i\cdot \boldsymbol{S}_j)+\sum_{j>i}\frac{g^2\beta^2}{r_{ij}^3}\left[(\boldsymbol{S}_i\cdot \boldsymbol{S}_j)-\frac{3}{r_{ij}^3}(\boldsymbol{S}_i\cdot \boldsymbol{r}_{ij})(\boldsymbol{S}_j\cdot \boldsymbol{r}_{ij})\right]$$

where one sort of paramagnetic ions is considered and the usual notations are employed. According to BSPA the interaction energy $\mathscr{H}_{\text{int}}$ can be written in the following forms

$$\mathscr{H}_{\text{int}}=A+B+C+D+E+F \tag{2}$$

$$A=\sum_{j>i}[\tilde{A}_{ij}+g^2\beta^2 r_{ij}^{-3}(1-3\cos^2\theta_{ij})]S_{zi}S_{zj}$$

$$B=\sum_{j>i}[(1/2)\tilde{A}_{ij}-(1/4)g^2\beta^2 r_{ij}^{-3}(1-3\cos^2\theta_{ij})](S_{+i}S_{-j}+S_{-i}S_{+j})$$

$$C=\sum_{j>i}(-3/2)g^2\beta^2 r_{ij}^{-3}\sin\theta_{ij}\cos\theta_{ij}\, e^{-i\phi_{ij}}(S_{+i}S_{zj}+S_{zi}S_{+j})$$

$$D=\sum_{j>i}(-3/2)g^2\beta^2 r_{ij}^{-3}\sin\theta_{ij}\cos\theta_{ij}\, e^{+i\phi_{ij}}(S_{-i}S_{zj}+S_{zi}S_{-j})$$

$$E=\sum_{j>i}(3/4)g^2\beta^2 r_{ij}^{-3}\sin^2\theta_{ij}\, e^{-2i\phi_{ij}}\, S_{+i}S_{+j}$$

$$F=\sum_{j>i}(3/4)g^2\beta^2 r_{ij}^{-3}\sin^2\theta_{ij}\, e^{2i\phi_{ij}}\, S_{-i}S_{-j}$$

where θ_{ij} and ϕ_{ij} are the polar angles of the radius vector connecting ions i and j with respect to the z-axis.

Several types of cross relaxations are considered by BSPA and others. In the following we shall examine the most fundamental processes which proceed through the sets of the neighboring two paramagnetic ions. The probability per unit time for the process that ion

---

* Some terms are, however, dropped in the equation (9) of Kiel. An exact calculation shows that the concentration independent term of (9) vanishes for $S=I=1/2$, since the term arises from the fact that $\mathscr{H}_{12}$ does not commute with $\sum' C_{p\xi}S_{zp}I_{z\xi}$ and this condition holds except for $S=I=1/2$.

i increases its energy by an amount $h\nu_\alpha$ and ion j decreases its energy by $h\nu_\beta$, the balance of energy $h(\nu_\beta-\nu_\alpha)$ being taken up by the spin-spin interaction of the whole array of dipoles, is given by

$$w_{ij}=\hbar^{-2}|\langle E_i,\ E_j|\,\mathscr{H}_{ij}|E_i+h\nu_\alpha,\ E_j-h\nu_\beta\rangle|^2 g_{\alpha\beta}(\nu=0)\ . \tag{3}$$

If m_s is a good quantum number the matrix element is obtained from the term B in (2) and its square is given by

$$|\,\mathscr{H}_{ij}|^2=\eta g^4\beta^4(1-3\cos^2\theta_{ij})^2 r_{ij}^{-6}$$

where (4)

$$\eta=(1/16)(S-m_\alpha)(S+m_\alpha+1)(S+m_\beta)(S-m_\beta+1)\ .$$

When m_s is not a good quantum number, the expression of η is more complicated, nevertheless it is estimated to be of the order of unity for the cases considered in the following. The shape function $g_{\alpha\beta}(\nu)$ should be calculated by the moment method. The total second moment is

$$h^2\langle\nu^2_{\alpha\beta}\rangle=-T_r\{[\mathscr{H}(\sum\mathscr{H}_{ij})-(\sum\mathscr{H}_{ij})\mathscr{H}]^2\}/T_r\{[\sum\mathscr{H}_{ij}]^2\}\ . \tag{5}$$

This method was, however, not use by BSPA for practical computation and instead the overlap integral of the line shape function $F(\alpha,\ \beta)$ was used, where

$$F(\alpha,\ \beta)=\iint g_\alpha(\nu')g_\beta(\nu'')\delta(\nu'-\nu'')d\nu' d\nu''\ . \tag{6}$$

If a Gaussian shape is assumed for $g_\alpha(\nu)$ and $g_\beta(\nu)$ with second moments $\langle\varDelta\nu_\alpha{}^2\rangle$ and $\langle\varDelta\nu_\beta{}^2\rangle$ (6) is reduced to

$$F(\alpha,\ \beta)=[2\pi\{\langle\varDelta\nu_\alpha{}^2\rangle+\langle\varDelta\nu_\beta{}^2\rangle\}]^{-1/2}\exp\{-(\nu_\alpha-\nu_\beta)^2/2[\langle\varDelta\nu_\alpha{}^2\rangle+\langle\varDelta\nu_\beta{}^2\rangle]\}\ . \tag{7}$$

By the use of the formulae together with excellent insight into the mechanism of elementary reactions, BSPA obtained several important agreement between the theoretical predictions and the experimental results. However, more rigorous mathematical treatment of the shape functions is very desirable to examine the various phenomena in the solid Masers. In the following section we give the estimation of the shape function using the moment method under consideration of the crystalline electric field.

§ 3. Estimation of the Shape Function by the Moment Method

The estimation of the shape function $g_{\alpha\beta}$ by the moment method was carried out by Pershan[5] and Kiel[6] for nuclear spins of LiF and dilute paramagnetic salts respectively. For their calculations, however, the effect of the crystalline electric field was not taken into account. In the following treatment we used a state of $C_r{}^{+++}$ ion in ruby as a model and hence the influence of the crystalline electric field plays a leading rôle. In the absence of the interaction between paramagnetic ions, the spin Hamiltonian is given by

$$\mathscr{H}_m+\mathscr{H}_{cr}=\beta[g_\parallel H_z S_z+g_\perp(H_x S_x+H_y S_y)]+D[S_z{}^2-S(S+1)]$$

with

$$S=3/2\ .$$

Writing

$$g_\parallel=g_\perp=g \quad \text{and} \quad D=-\delta\ , \tag{8}$$

since $g_\parallel\simeq g_\perp$ and D is negative, we obtain the spin Hamiltonian for the ith ion in the case that the magnetic field is parallel to the crystal c axis, as follows:

$$W_i=-\delta(S^2_{zi}-\xi S_{zi})\ ,\quad \xi=g\beta H/\delta\ . \tag{9}$$

The four energy levels deduced by this expression against magnetic field are shown in Fig. 1.

The total spin Hamiltonian is given by

$$\mathscr{H}=\sum_i W_i+\mathscr{H}_{\text{int}}\,. \tag{10}$$

In order to calculate the moments, we must select the so-called semi-diagonal part of the Hamiltonian, i.e. we take up only that part of the interaction terms that commute with the one-ion energy term $\sum W_i$. This part can be diagonalized simultaneously with the one-ion energy term, so this selection corresponds to the first order perturbation process which was adopted by Ishiguro, Kambe and Usui[9] for the calculation of the moments of the Larmor-lines.

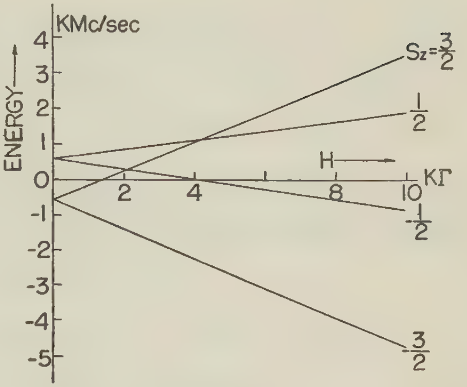

Fig. 1. A model of energy level diagram used for the calculation on the rate of cross relaxation.

The semi-diagonal part of the Hamiltonian may explicitly be written as

$$\overline{\mathscr{H}}=\sum_i W_i+\sum_{j>i}(A_{ij}+B_{ij})S_{zi}S_{zj}+\sum_{j>i}A_{ij}(\overline{S_{xi}S_{xj}}+\overline{S_{yi}S_{yj}}) \tag{11}$$

where

$$\begin{aligned} A_{ij}&=\tilde{A}_{ij}+\frac{g^2\beta^2}{r_{ij}^3}\left(\frac{3}{2}\gamma_{ij}^2-\frac{1}{2}\right), \\ B_{ij}&=-3\frac{g^2\beta^2}{r_{ij}^3}\left(\frac{3}{2}\gamma_{ij}^2-\frac{1}{2}\right) \end{aligned} \tag{12}$$

$$\begin{aligned} \overline{S_{xi}S_{yj}}+\overline{S_{yi}S_{yj}}&=\frac{1}{2}(\overline{S_{+i}S_{-j}}+\overline{S_{-i}S_{+j}}) \\ &=\frac{1}{2}(P_{(3/2)i}P_{(1/2)j}S_{+i}S_{-j}P_{(1/2)i}P_{(3/2)j}+P_{(1/2)i}P_{-(1/2)j}S_{+i}S_{-j}P_{-(1/2)i}P_{(1/2)j} \\ &\quad+P_{-(1/2)i}P_{-(3/2)j}S_{+i}S_{-j}P_{-(3/2)i}P_{-(1/2)j} \\ &\quad+P_{(1/2)i}P_{(3/2)j}S_{-i}S_{+j}P_{(3/2)i}P_{(1/2)j}+P_{-(1/2)i}P_{(1/2)j}S_{-i}S_{+j}P_{(1/2)i}P_{-(1/2)j} \\ &\quad+P_{-(3/2)i}P_{-(1/2)j}S_{-i}S_{+j}P_{-(1/2)i}P_{-(3/2)j}) \end{aligned}$$

where

$$\gamma_{ij}=\cos\theta_{ij} \tag{13}$$

$P_{(3/2)i}$, $P_{(1/2)i}$, $P_{-(1/2)i}$ and $P_{-(3/2)i}$ are the projection operators corresponding to the states $m_i=3/2$, $1/2$, $-1/2$ and $-3/2$ of the i-th ion respectively.

In order to calculate the trace, we select the representation scheme in which each spin is individually space quantized. Thus we have

$$\begin{aligned} P_{(3/2)i}&=(1/6)(S_{zi}+3/2)(S_{zi}^2-1/4)\,, \\ P_{-(3/2)i}&=-(1/6)(S_{zi}-3/2)(S_{zi}^2-1/4)\,, \\ P_{(1/2)i}&=-(1/2)(S_{zi}+1/2)(S_{zi}^2-9/4)\,, \\ P_{-(1/2)i}&=(1/2)(S_{zi}-1/2)(S_{zi}^2-9/4)\,. \end{aligned}$$

Now suppose that one of the two neighboring ions makes $m=1/2\to-1/2$ (α type) transition and the other $m=-3/2\to-1/2$ (β type) transition and the balance of energy $h(\nu_\beta-\nu_\alpha)$ is taken up by the spin-spin interaction.

The operating matrix $\sum\mathscr{H}_{ij}$ in (5) should be replaced by the following expressions

$$\sum_{j>i}\hat{\mathscr{H}}_{ij}=\hat{B}=\sum_{j>i}b_{ij}\Phi_{ij} \tag{14}$$

where

$$b_{ij}=\frac{1}{2}\tilde{A}_{ij}-\frac{1}{4}g^2\beta^2 r_{ij}^{-3}(1-3\gamma_{ij}^2) \tag{15}$$

$$\begin{aligned}\Phi_{ij}=&P_{(1/2)i}P_{-(3/2)j}S_{+i}S_{-j}P_{-(1/2)i}P_{-(1/2)j}+P_{-(1/2)i}P_{-(1/2)j}S_{-i}S_{+j}P_{(1/2)i}P_{-(3/2)j}\\&+P_{-(1/2)i}P_{-(1/2)j}S_{+i}S_{-j}P_{-(3/2)i}P_{(1/2)j}+P_{-(3/2)i}P_{(1/2)j}S_{-i}S_{+j}P_{-(1/2)i}P_{-(1/2)j}\end{aligned} \tag{16}$$

After some elementary calculations we have

$$Tr\{[\sum_{j>i}\hat{\mathscr{H}}_{ij}]^2\}=3(2S+1)^N\sum_{j>i}b_{ij}^2\ , \tag{17}$$

$$\begin{aligned}-Tr\{[\overline{\mathscr{H}}(\sum_{j>i}\hat{\mathscr{H}}_{ij})-(\sum_{j>i}\hat{\mathscr{H}}_{ij})\overline{\mathscr{H}}]^2\}\\=3(2S+1)^N[\sum_{j>i}b_{ij}^2(2\delta+C_{ij})^2\\+\sum_{k\neq(j>i)}\{(5/4)(C_{ik}^2+C_{jk}^2)+(21/8)(A_{ik}^2+A_{jk}^2)\}b_{ij}^2]\end{aligned} \tag{18}$$

where

$$C_{ij}=A_{ij}+B_{ij} \tag{19}$$

and N is the total number of ions in the crystal, and the notation $k\neq(j>i)$ means that k is not equal to j nor i and j is greater than i. In the above expression, terms like

$$\sum_{k\neq(j>i)}C_{ik}C_{jk}b_{ij}^2$$

are neglected compared to the terms like

$$\sum_{j>i}C_{ik}^2 b_{ij}^2\ .$$

Thus we obtain the total second moment using (17), (18) and the equation

$$h^2\langle\nu_{\alpha\beta}^2\rangle=-Tr\{[\overline{\mathscr{H}}(\sum\hat{\mathscr{H}}_{ij})-(\sum\hat{\mathscr{H}}_{ij})\overline{\mathscr{H}}]^2\}/Tr\{[\sum\hat{\mathscr{H}}_{ij}]^2\}\ .$$

For the present case

$$h(\nu_\beta-\nu_\alpha)=2\delta$$

and clearly in the absence of the interaction between ions we have

$$h^2\langle\nu_{\alpha\beta}^2\rangle=(2\delta)^2\ .$$

Thus we get

$$h^2\langle\Delta\nu_{\alpha\beta}^2\rangle=h^2\langle\nu_{\alpha\beta}^2\rangle-(2\delta)^2=M_1+M_2 \tag{20}$$

where

$$\begin{aligned}M_1&=\sum_{j>i}b_{ij}^2C_{ij}^2/\sum_{j>i}b_{ij}^2\\M_2&=\sum_{k\neq(j>i)}\{(5/4)(C_{ik}^2+C_{jk}^2)+(21/8)(A_{ik}^2+A_{jk}^2)\}b_{ij}^2/\sum_{j>i}b_{ij}^2\end{aligned} \tag{21}$$

and the term

$$\sum_{j>i}4\delta C_{ij}b_{ij}^2$$

is neglected compared with the term

$$\sum_{j>i}C_{ij}^2 b_{ij}^2$$

and $C_{ij}=C_{ji}$ and $A_{ij}=A_{ji}$ are assumed.

In the Maser material, usually the paramagnetic ions are highly diluted with diamagnetic ions. Kittel and Abraham[10] suggested that at least two different types of dilution may be contemplated: namely the lattice points are populated at random by the paramagnetic ions or the effect of dilution were to expand the magnetic lattice uniformly. Let us examine the effect of dilution for these cases.

(i) First suppose that the lattice points are populated at random by paramagnetic ions. Let f be the probability that a lattice site is occupied by a magnetic system. For ruby this is the probability that the Al site is replaced by the Cr ion. By a similar method to Kittel and Abraham[10], M_1 and M_2 are reduced to the following expressions:

$$M_1=\sum_j{}' b^2_{ij}C^2_{ij}/\sum_j{}' b^2_{ij}\ , \tag{22}$$

$$M_2=f[\sum_k{}'\{(5/2)C^2_{ik}+(21/4)A^2_{ik}\}-\sum_j{}'\{(5/2)C^2_{ij}+(21/4)A^2_{ij}\}b^2_{ij}/\sum_j{}' b^2_{ij} \tag{23}$$

where $\sum_k{}'$ or $\sum_j{}'$ mean sums over all k or j sites, whether or not occupied. From (12), (19) and (15) we have

$$A_{ij}=\tilde{A}_{ij}-(1/3)B_{ij}\ ,\quad C_{ij}=\tilde{A}_{ij}+(2/3)B_{ij}$$
$$b_{ij}=(1/2)\tilde{A}_{ij}-(1/6)B_{ij}\ . \tag{24}$$

It is seen that M_1 is independent of the dilution and M_2 is proportional to f. When the exchange interaction is absent $\tilde{A}_{ij}=0$ and we get

$$\begin{aligned} M_1&=(4/9)\sum_j{}' B^4_{ij}/\sum_j{}' B^2_{ij}\ ,\\ M_2&=(61/36)f[\sum_j{}' B^2_{ij}-\sum_j{}' B^4_{ij}/\sum_j{}' B^2_{ij}]\ . \end{aligned} \tag{25}$$

According to Van Vleck[11] and Kittel and Abraham[10] the mean square deviation of the frequency from the Larmor value may be written

$$h^2\langle\Delta\nu^2\rangle=[S(S+1)/3]f\sum_j{}' B^2_{ij}=(5/4)f\sum_j{}' B^2_{ij} \qquad \text{for}\quad S=3/2. \tag{26}$$

It is of interest to note that the first term of M_2 resembles this expression.

For the Maser materials, f is of the order of magnitude of 10^{-3} and hence $h^2\langle\Delta\nu^2{}_{\alpha\beta}\rangle$ is expressed by M_1 alone.

(a) If the lattice is simple cubic with the applied magnetic field in the (100) direction, we have

$$\sum_j{}' B^2_{ij}=29.9g^4\beta^4d^{-6} \tag{27}$$

and from (20) and (25) it follows that

$$\langle\Delta\nu^2_{\alpha\beta}\rangle=0.091h^{-2}\sum_j{}' B^2_{ij}=2.7h^{-2}g^4\beta^4d^{-6} \tag{28}$$

where d is the distance between nearest lattice sites. It should be noted that the value is to some extent influenced by the direction of the magnetic field.

(b) If the average of the B^2_{ij} and B^4_{ij} over the sphere, centered at the i-th ion, with the radius r equal to the distance to the (effective) nearest neighbors the number of which is Z, be denoted by $\overline{B^2_{ij}}$ and $\overline{B^4_{ij}}$ respectively, then we have approximately

$$\sum_j{}' B^2_{ij}\simeq Z\overline{B^2_{ij}}\ ,\quad \sum_j{}' B^4_{ij}\simeq Z\overline{B^4_{ij}}\ ,\quad \overline{B^4_{ij}}=2.145(\overline{B^2_{ij}})^2\ ,\quad \overline{B^2_{ij}}=(9/5)g^4\beta^4r^{-6} \tag{29}$$

and hence from (20) and (25) it follows that

$$\langle \Delta\nu_{\alpha\beta}^2\rangle = 1.7h^{-2}g^4\beta^4 r^{-6} \ . \tag{30}$$

If the shape of $g_{\alpha\beta}(\nu)$ is assumed to be Gaussian, we have

$$g_{\alpha\beta}(\nu) = [2\pi\langle \Delta\nu_{\alpha\beta}^2\rangle]^{-1/2} \exp\{-[\nu-(\nu_\beta-\nu_\alpha)]^2/2\langle \Delta\nu_{\alpha\beta}^2\rangle\} \ . \tag{31}$$

In order to compare (31) with (7) we use the following ratio

$$\langle \Delta\nu_{\alpha\beta}^2\rangle/[\langle \Delta\nu_\alpha{}^2\rangle + \langle \Delta\nu_\beta{}^2\rangle] \simeq \langle \Delta\nu_{\alpha\beta}^2\rangle/2\langle \Delta\nu^2\rangle \equiv \lambda^2 \ . \tag{32}$$

For the abovementioned case (a) we have

$$\lambda^2 = (28f)^{-1} \ , \tag{33}$$

and for the case (b)

$$\lambda^2 = 0.38(fZ)^{-1} \ . \tag{34}$$

The former is 36 for $f=10^{-3}$ and the latter 48 for $Z=8$ and $f=10^{-3}$. There is some discrepancy between them. However, in any case the calculated moments are much greater than those deduced by the overlap integral of the individual ordinary resonance line shapes.

(ii) Next suppose that the factor f is unity. From (20) and (25) we have

$$h^2\langle \Delta\nu_{\alpha\beta}^2\rangle = (61/36)\sum_j{}' B_{ij}^2 - (5/4)\sum_j{}' B_{ij}^4 / \sum_j{}' B_{ij}^2 \ .$$

(a) For the cubic lattice with the applied magnetic field in (100) direction we have

$$\langle \Delta\nu_{\alpha\beta}^2\rangle = 1.44h^{-2}\sum_j{}' B_{ij}^2$$

and therefore from (32), (26) and (27),

$$\lambda^2 = 0.58 \ .$$

(b) If the averages over the sphere are taken as in the case (b) of (i), then we have

$$\langle \Delta\nu_{\alpha\beta}^2\rangle = (1.7Z-2.7)\overline{B_{ij}^2}$$

and therefore for $Z=8$, from (32),

$$\lambda^2 = 0.54 \ .$$

Pershan[5] obtained $\lambda^2=(0.8)^2=0.64$, hence our results are nearly equal. If the effect of the dilution changes the location of the magnetic ions as if the magnetic lattice were uniformly expanded, then the ratio λ^2 is constant and $\langle \Delta\nu_{\alpha\beta}^2\rangle$ is proportional to $\langle \Delta\nu^2\rangle$ of Van Vleck.[11] In this case the overlap integral will give a fairly good measure of the cross relaxation.

§ 4. Consideration on the Fourth Moment

In the previous section the shape of $g_{\alpha\beta}(\nu)$ is assumed to be Gaussian. But in principle all higher moments are necessary to determine the exact shape. If we confine our attention to the interval of ν not far from the center, the second and the fourth moment will suffice to outline the shape.

If we write

$$U = \overline{\mathscr{H}}(\Sigma\,\widehat{\mathscr{H}}_{ij}) - (\Sigma\,\widehat{\mathscr{H}}_{ij})\overline{\mathscr{H}} \ ,$$

the total fourth moment is given by

$$h^4\langle \nu_{\alpha\beta}^4\rangle = Tr\{[\overline{\mathscr{H}}U - U\overline{\mathscr{H}}]^2\}/Tr\{[\Sigma\,\widehat{\mathscr{H}}_{ij}]^2\} \ .$$

Here we consider the parts of $\langle\Delta\nu^2_{\alpha\beta}\rangle$ and $\langle\Delta\nu^4_{\alpha\beta}\rangle$ which are independent of the dilution f and much greater than the remaining terms for $f\ll 1$. Then we have after some elementary computations,

$$h^4\langle\Delta\nu^4_{\alpha\beta}\rangle=\sum_j{}' b^2_{ij}C^4_{ij}/\sum_j{}' b^2_{ij}\,. \tag{35}$$

For the diluted magnetic lattice mentioned in (i) (a) of section 3, we have

$$\langle\Delta\nu^4_{\alpha\beta}\rangle=1.35[\langle\Delta\nu^2_{\alpha\beta}\rangle]^2\,,$$

and for the case (i) (b) of section 3

$$\langle\Delta\nu^4_{\alpha\beta}\rangle=1.44[\langle\Delta\nu^2_{\alpha\beta}\rangle]^2\,.$$

If the shape is Gaussian we should have[11)]

$$\langle\Delta\nu^4_{\alpha\beta}\rangle=3[\langle\Delta\nu^2_{\alpha\beta}\rangle]^2\,,$$

hence in the present case the shape will be roughly Gaussian, but will take slightly less value in the wings.

§ 5. Cross Relaxation Time

According to the discussion of the previous section in terms of the moment method the cross relaxation time is obtained as follows:

From (3), (4) and (31) and considering that

$$\sum_j|\mathscr{H}_{ij}|^2=f\sum_i{}'|\mathscr{H}_{ij}|^2$$

we have

$$\sum_j w_{ij}=f\cdot\eta\cdot\hbar^{-2}g^4\beta^4 g_{\alpha\beta}(\nu=0)\sum_j{}'(1-3\gamma^2_{ij})^2 r^{-6}_{ij}\,,$$

and from (12) and (26) this expression is reduced to

$$\sum_j w_{ij}=14\cdot\eta\cdot\langle\Delta\nu^2\rangle\cdot g_{\alpha\beta}(\nu=0)\,,$$

where it should be recalled that $\langle\Delta\nu^2\rangle$ is the second moment of Van Vleck.[11)] To see the relation between the results of the moment method and the overlap integral, we use the notation (32), then it follows that

$$\sum_j w_{ij}=2.8\eta\cdot[2\langle\Delta\nu^2\rangle]^{1/2}\lambda^{-1}\exp\{-(\nu_\alpha-\nu_\beta)^2/4\lambda^2\langle\Delta\nu^2\rangle\}\,. \tag{36}$$

The cross relaxation time T_{21} is obtained by

$$(2T_{21})^{-1}=\sum_j w_{ij}p_j=\frac{1}{4}\sum_j w_{ij}$$

and hence by

$$T_{21}=\left(\frac{1}{2}\sum_j w_{ij}\right)^{-1}. \tag{37}$$

The result of overlap integral is obtained by equating $\lambda=1$ and may agree[2)] with some experimental results of the dilute salts of $K_3(C_0Cr)(CN)_6$. In general, however, the cross relaxation time with $\lambda=1$ gives far longer times than those required by the experimental results, and it is necessary that λ is greater than unity to satisfy the requirement. In this situation BSPA suggested that the relaxation is mainly taking place through the ions with nearest one neighbor in the diluted salts and showed the formulae

$$T_{21}=(Zf)^{-1}\langle\Delta\nu_\alpha^2\rangle_{\mathrm{conc}}^{-1/2}\exp\{Z(\nu_\alpha-\nu_\beta)^2/2[\langle\Delta\nu_\alpha^2\rangle_{\mathrm{conc}}+\langle\Delta\nu_\beta^2\rangle_{\mathrm{conc}}]\}\ . \tag{38}$$

This value is obtained from (36) and (37) with

$$\lambda^2=(fZ)^{-1}\ , \tag{39}$$

namely by equating

$$2(fZ)^{-1}\langle\Delta\nu^2\rangle=2(Z)^{-1}\langle\Delta\nu^2\rangle_{\mathrm{conc}}\simeq Z^{-1}[\langle\Delta\nu_\alpha^2\rangle_{\mathrm{conc}}+\langle\Delta\nu_\beta^2\rangle_{\mathrm{conc}}]$$

and considering that $\eta\sim1$.

Our results (33) and (34) are of the same order of magnitude as the above λ^2, but may be about one third of the latter. The reason that $\lambda\gg1$ seems to be essentially the same as suggested by BSPA. When the value of (34) is adopted we have from (36) and (37)

$$\begin{aligned}T_{21}&=0.21\times(\eta fZ)^{-1}(g^2\beta^2h^{-1}r^{-3})\exp\{(\nu_\beta-\nu_\alpha)^2/3.4(g^4\beta^4h^{-2}r^{-6})\}\\&=(\eta fZ)^{-1}(\rho^3/2.5\times10^{11})\exp\{(\nu_\beta-\nu_\alpha)^2\rho^6/9.25\times10^{21}\}\end{aligned} \tag{40}$$

where ρ denotes the distance of the nearest paramagnetic ions in units of Å. Thus if the lattice points are populated at random by paramagnetic ions the cross relaxation time T_{21} increases very slowly with the decrease of the factor f.

On the other hand if the effect of the dilution changes the location of the magnetic ions as if the magnetic lattice were expanded uniformly, then λ is a constant as shown in the previous section and $\langle\Delta\nu^2\rangle$ is shown to be proportional to the square of the concentration of the paramagnetic ions. Thus we see from (36) and (37) that the cross relaxation time increases very rapidly with the decrease of the concentration of the ions, since $\langle\Delta\nu^2\rangle$ is included in the exponential function.

§ 6. Cross Relaxation in Solid State Masers

We shall evaluate the influence of the cross relaxation on the solid state Masers. First suppose the three level Maser of which the three levels are numbered 1, 2 and 3 from the lowest and n_1, n_2 and n_3 are the spin populations in the three levels as shown in Fig. 2. Let us write $X=2/3\cdot\sum_j w_{ij}$ then the rate equations become, at the steady state,

$$dn_3/dt=W_{13}(n_1-n_3)+S_{32}(n_2-n_3)+w'_{13}(n_1-n_3-\alpha\nu_{31})+w'_{23}(n_2-n_3-\alpha\nu_{32})+X(n_2-n_3)=0\ ,$$

$$dn_2/dt=-W_{31}(n_1-n_3)-w'_{13}(n_1-n_3-\alpha\nu_{31})+w'_{21}(n_2-n_1+\alpha\nu_{12})+X(n_2-n_3)=0\ ,$$

where we introduce such a cross relaxation that $i(1\to2)$ and $j(3\to2)$ transitions simultaneously take place and w'_{ij}, W_{31} and S_{32} denote transition probabilities due to thermal lattice vibrations, strong pumping *rf* power and signal power respectively, and $\alpha=(1/3)Nh/kT_L$, and it is assumed that $h(\nu_{12}-\nu_{23})/kT_{ad}\simeq0$, with T_L the lattice temperature and T_{ad} the final temperature after the spin system has come into internal equilibrium adiabatically. Using the notations

$$w'_{21}\sim w'_{23}\equiv w'=(2T_1)^{-1}\ ,\quad X=(2T_{21})^{-1}$$

we have from the above equations

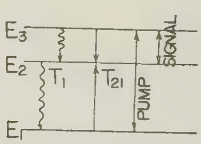

Fig. 2. A three level Maser system used to illustrate the relaxation processes.

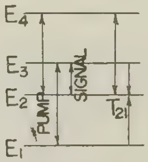

Fig. 3. A push-pull Maser pumping scheme.

$$n_3-n_2=\frac{hN}{6kT}\,\frac{\nu_{12}-\nu_{32}}{(1+2T_1/3T_{21})+T_1\cdot S_{32}} \tag{41}$$

where $T_L=T_{ad}=T$ is assumed. For the push-pull four level Masers as shown in Fig. 3, in the same way we have

$$n_3-n_2=\frac{Nh}{4kT}\,\frac{w'_{12}\nu_{12}+w'_{43}\nu_{43}+w'_{14}\nu_{14}-w'_{23}\nu_{23}}{w'_{12}+w'_{43}+w'_{14}+(w'_{23}+2\sum w_{ij})+S_{32}}$$

again using the notations

$$w'_{43}\sim w'_{21}\sim w'_{32}\sim w'_{12}\equiv w'=(2T_1)^{-1}\,,\quad (3\sum w_{ij})^{-1}=T_{21}\,,\quad \text{and}\quad w'_{41}/w'\equiv\eta\,,\quad \text{with}\quad 0<\eta<1\,,$$

we have

$$n_3-n_2=\frac{hN}{4kT}\,\frac{(\eta\nu_{41}+2\nu_{12})-\nu_{32}}{(\eta+3)+4\cdot T_1/3T_{21}+2T_1S_{32}} \tag{42}$$

where the cross relaxations are due to simultaneous flips $i(1\rightarrow 2)$, $j(3\rightarrow 2)$ and $i(3\rightarrow 4)$, $j(3\rightarrow 2)$.

It is well known that the spin-lattice relaxation time T_1 rapidly decreases with the increase of the temperature, but the cross relaxation time T_{21} is independent of the temperature. We see therefore from (41) and (42) that under certain conditions we would obtain a better Maser action in a relatively high temperatures. This presumption was verified by Maiman[7] using the ruby Maser with (nominal) 0.2 percent Cr ions operated at 77°K and further by Ditchfield.[8] The signals were in the X band and the root-gain-bandwidth products were 14 Mc/s and 22 Mc/s respectively. Maiman suggested that the success of the Maser is due to the effective control of the cross relaxation. For their push-pull scheme, the pump frequency ν_p is roughly related to the signal frequency ν_s as follows:

$$\nu_p=1.9\nu_s+5.8\quad(\text{kMc/s}).$$

Therefore for $\nu_s=9$ we have $\nu_p=22.9$ and hence

$$\nu_\beta(1\rightarrow 2)-\nu_\alpha(3\rightarrow 2)=4.9\quad(\text{kMc/s}).$$

It is surprising that the cross relaxation is effective for such a great difference of transition frequencies, therefore a close examination is needed. Maiman measured T_{21} and obtained the following values: $T_{21}=2\times 10^{-3}$ sec. and $\sim 10^{-6}$ sec for $f=\text{Cr/Al}=$(nominal) 0.2% and 0.6% respectively. In ruby the lattice sites of Al (and hence or Cr) have the near neighbors as shown in the following Table I.

According to Rimai[12] et al, the nearest neighbor is strongly coupled by the exchange interaction and they form rather the molecules and further other antiferromagnetically coupled pairs with smaller exchange constants appear to be present. In addition there is an evidence for the existence of ion pairs coupled by weaker ferromagnetic exchange. These will give rise to different spectrums from the ordinary resonance lines and should probably be omitted from our considerations. Thus we tentatively adopt Z ions at the distance of ρ Å as the effective nearest neighbors and ignor the exchange effect. The real concentrations of Cr are assumed to be one half the nominal.

Fortunately the η and f values do not greatly influence the T_{21} values. We obtain from (40) with $\eta=1$ the values of T_{21} shown in Table II. These values are very rough, however, it may be of interest to note that the values of the first two lines are intermediate of the observed values. It is likely that the cross relaxation would take place in

Table I. Distances and Numbers of the Near Neighbors.

Distance (Å)	2.73	2.81	3.13	3.50	3.78	4.77
Number	1	3	3	6	1	6

Table II. The Cross Relaxation Time T_{21} for the Assumed Nearest Z Neighbors at the Distance ρ.

ρ	Z	$f=10^{-3}$	$f=3\times10^{-3}$
3.50Å	6	3.4×10^{-6} sec	1.1×10^{-6} sec

4.77	6	$1.4\times10^{+6}$	$4.71\times10^{+5}$

this fashion. Further study is still necessary to confirm the present estimation.

§7. Concluding Remarks

The theory of cross relaxation has been discussed on the paramagnetic salts in general use for solid state Masers. To evaluate the rate of cross relaxation, it is necessary to determine the shape function. Under consideration of the crystalline electric field and the applied magnetic field we estimated the shape function in terms of the moment method. The obtained second and fourth moment for the diluted salt show that the shape function is nearly Gaussian but takes slightly less value in the wings. When the paramagnetic lattice sites are randomly populated the second moment is much greater than that deduced by the overlap integral of observed resonance shape functions. This was already suggested by BSPA on the supposition that the cross relaxation takes place mainly through the ions with one nearest neighbor. However our second moment is about one third of that suggested by BSPA and to some extent influenced by the orientation of the applied magnetic field. In this case the cross relaxation time will slowly decrease in proportion to the concentration of the paramagnetic ions.

On the other hand if the effect of the dilution were to expand the magnetic lattice uniformly the cross relaxation time rapidly decreases with the increase of the concentration of the paramagnetic ions.

The cross relaxation in the ruby Maser which is succesfully operated at the liquid nitrogen temperature is briefly discussed. In spite of various unknown factors it is likely that the process is effective also in this case.

Acknowledgements

The author would like to express his gratitude to Dr. Hiroyuki Uyeda director of the Radio Research Laboratories for his constant interest and to Prof. Kenjiro Kambe of the University of Electro-Communications for his valuable discussions. Many thanks are also due to Professor N. Bloembergen of Harvard University and Dr. P. S. Pershan of National Science foundation who read the manuscript and informed him their opinions.

"Non-Adiabatic" Behavior in a Low Frequency Beam-Type Maser

By Tadao SHIMIZU and Koichi SHIMODA

Department of Physics, Faculty of Science, University of Tokyo, Tokyo

(Received December 28, 1960)

Characteristics of a low frequency beam-type maser is discussed. A particularly interesting phenomenon is a breakdown of the adiabatic focusing approximation. Theories of electro-static focusing and the line-width of the low frequency transition are obtained by taking into consideration the effect of transition induced by the Stark field which changes with time on a moving molecule.

Saturation of the effective number of focused molecules with the focuser voltage is calculated. The induced radio-frequency transition of a molecule in a mixed state is calculated and the line shape is shown to be the same as for a molecule in a pure state.

§ 1. Introduction

An exploitation of a low frequency spectrometer has been carried out, because some interesting transitions of molecules fall in the megacycle frequency range. The low frequency spectroscopy has become feasible by using maser actions such as a three-level[1] or a beam-type[2] maser. In a conventional spectrometer the intensities of the spectral lines become weaker in the lower frequency range because they are nearly proportional to ν^2. In the maser spectrometer, however, the intensity does not decrease so much at lower frequencies and the noise figure of the amplifier is smaller than that in the microwave range. Thus, many of the low frequency transitions have detectable intensities due to the pumping action in the three-level maser or due to the focusing action in the two-level beam-type maser.

The beam-type maser seems to be more useful, since it can be operated on two levels. Moreover, the focusing efficiency in the beam-type maser is very good when the two levels are close. However, some unexpected phenomena have been found in the operation of a low frequency beam-type maser which have not been observed in the microwave frequency range.

A particularly interesting phenomenon which is found in the low frequency beam-type maser, is a breakdown of the so-called "adiabatic focusing approximation". It may be called a "non-adiabatic" effect. Some years ago a similar problem concerning an atomic orientation in a variable magnetic field was discussed.[3),4),5)]* It was solved, however, for a special case of the magnetic field and their solutions can not be adapted to our problem.

Another phenomenon is an effect of the transition field between the focuser and the resonator. Because of the strong perturbing field on the molecule, the adiabatic approximation that the molecule does not make transition during a flight in this region becomes poor when a low spectral frequency is studied.

Theories of the focusing and the spectral line-width have already been given on the assumption of adiabatic behavior. It is the purpose of this paper to discuss how the focusing and the line shape are affected by the breakdown of the adiabatic approximation. The experimental results on these problems in the case of K-type transitions of formaldehyde molecule will be compared with the present theories in the forthcoming paper.

§ 2. A Breakdown of the Adiabatic Focusing Approximation

A schematic diagram of a low frequency beam-type maser is shown in Fig. 1 of reference (2). Molecules issue from a beam source consisting of a number of fine tubes into the focusing region. High d.c. voltage is supplied on the focuser. The inhomogeneous field inside the focuser is formed so that the molecules in the upper state can be deflected towards the axis and those in the lower state away from the axis.

---

* The authors are grateful to Professors W. A. Nierenberg and W. E. Lamb for notifying these references.

The rf signal valtage $V_0 \cos \omega t = Ed \cos \omega t$ is applied between the electrodes of the parallel-plate condenser which corresponds to a resonant cavity in the microwave maser. Here E is the rf field strength and d is the separation of the electrodes. The molecules make transitions inside the condenser being stimulated by the rf electric field at a proper frequency. The theory of sensitivity of the low frequency beam-type maser spectrometer has already been discussed.[2)]

Now consider the states of molecules in the perturbing field of the focuser and that in the transition field between the focuser and the resonator. Because the gas pressure in the focusing region is low, the molecules do not collide with each other and it is assumed that the state of molecules is not disturbed by molecular collision.

The focuser was constructed from a even number of cylindrical rods. The electric field strength inside a $2n$-pole focuser can be approximated by an expression[7)],

$$E(r) = n \frac{r^{n-1}}{2R^n} V , \qquad (1)$$

where R is the radius of the focuser and V the total voltage applied on the focuser. Therefore, if the Stark effect is such that the energy increases with the electric field, the force acting on the molecule is directed toward the axis and proportional to the gradient of the Stark energy. It is dependent only on r and not on θ of the cylindrical coordinate. The direction of the electric field at any point in a meridional plane is same.

As shown in the following section, a simple analytical expression of the molecular trajectory can be obtained only for the case of a six-pole focuser. The components of the electric field in a six-pole focuser are

$$E_x = a(x^2 - y^2)$$
$$E_y = -a(2xy)$$
$$E_z = 0$$

in a cartesian coordinate, where z is the direction of the axis. Then the ratio of E_x and E_y (the direction of the electric field),

$$\frac{E_x}{E_y} = \frac{1-(y^2/x^2)}{2(y/x)} ,$$

is constant, since y/x is constant for the molecule in a meridional plane.

When the molecules move in the plane, the direction of the electric field seen from the molecules does not change. Therefore, the transition between different M states induced by the focusing field is not considered here.

When a molecule passes through a electrostatic focuser the electric field seen from the moving molecule changes with time during which the molecule takes from the start. A criterion for the adiabatic focusing approximation such that the molecule does not make any transition during the flight through the focuser and that the molecular state itself slowly varies according to the Stark field, can be expressed by

$$\frac{h}{(W_2 - W_1)^2} \left(\frac{\partial H'}{\partial t} \right)_{12} \ll 1 , \qquad (2)$$

where $(\partial H'/\partial t)_{12}$ is the matrix element of the time derivative of the interaction Hamiltonian between the two unperturbed levels. For the six-pole focuser this expression is reduced to a simple form after some manipulations.

$$\frac{\omega_\theta}{\omega_0} \cdot \frac{\Delta W}{\hbar \omega_0} \ll 1 , \qquad (3)$$

where ω_θ is the angular frequency of the perturbing field seen from the molecule and ω_0 the molecular transition frequency between the two unperturbed states. The value of the left-hand side of the formula takes an order of 10^{-7} to 10^{-6} at a microwave frequency near 20 Gc, while it takes a value from 1 to 10 at a radio-frequency of several megacycles. This shows that the adiabatic focusing approximation is not good in the low frequency region.

The perturbing term in the Hamiltonian depends on the trajectory of molecules in the focuser. Since the intensity of the electric field is a function of r, the time dependent perturbing Hamiltonian can be expressed by an explicit function of time from a solution of the molecular motion in a form $r(t)$. Strictly speaking, however, the Schrödinger equation and the equation of motion must be solved simultaneously, but it would be laborious to do so.

As a first approximation, the trajectory of molecules is solved using the potential function which is the Stark energy of the molecule in the "pure" (unmixed) rotational state. Subsequently with the perturbing Hamiltonian which is constructed from the molecular trajectory a time dependent Schrödinger equation of the molecule is worked out.

§ 3. Schrödinger Equation of the Molecule

Approximate solutions of the differential equation of the molecular state in the perturbing field are given in the case of the six-pole focuser.

i) *Schrödinger equation of the perturbed molecule*

In order to describe the molecular state under the time dependent Hamiltonian $H = H_0 - \mu E$, a set of convenient basic functions must be chosen.

Assume that only two levels* take part in the problem, and the wave function of the molecule may be expressed by a linear combination.

$$\psi = a_1(t)u_1(t)\exp\left[-\frac{i}{\hbar}\int_0^t W_1(t')dt'\right] + a_2(t)u_2(t)\exp\left[-\frac{i}{\hbar}\int_0^t W_2(t')dt'\right]. \tag{4}$$

This expression is very convenient in studying "non-adiabatic" behavior of the molecular state in the focuser.

In Eq. (4) $W_1(t)$ and $W_2(t)$ are solutions of the instantaneous stationary problems,

$$H(t)u_n(t) = W_n(t)u_n(t)\,. \tag{5}$$

They are written explicitly as follows:

$$\left.\begin{aligned} W_1(t) &= \frac{1}{2}[W_1^0 + W_2^0 - \sqrt{\delta^2 + 4\mu_{12}^2 E^2(t)}]\,,\\ W_2(t) &= \frac{1}{2}[W_1^0 + W_2^0 + \sqrt{\delta^2 + 4\mu_{12}^2 E^2(t)}]\,, \end{aligned}\right\} \tag{6}$$

where W_1^0 and W_2^0 are the rotational energies of the molecule at zero field and $\delta = W_2^0 - W_1^0$. Here μ_{12} is the dipole matrix element of the molecule and is proportional to the matrix element of the direction cosine, when the direction of the electric field seen from the molecule does not change. In Eqs. (5) and (6), t is not considered as a variable but a parameter which corresponds to the position of the molecule. The basic functions $u_1(t)$ and $u_2(t)$ are the solutions of Eq. (5) and are the instantaneous stationary wave functions of the molecule in the Stark field, including t as a parameter. In Eq. (4) $a_1(t)$ and $a_2(t)$ are the probability amplitudes of $u_1(t)$ and $u_2(t)$, respectively.

The Schrödinger equation of the molecule,

$$i\hbar\frac{\partial\psi}{\partial t} = H(t)\psi\,, \tag{7}$$

is reduced to simultaneous equation between the coefficients $a_1(t)$ and $a_2(t)$, on the assumption of two levels and with an additional condition concerning the phase of the wave functions given by

$$\int u_n^* \frac{\partial u_n}{\partial t} d\tau = 0\,. \tag{8}$$

Substitution of Eq. (4) into Eq. (7) gives after some manipulations

$$\dot{a}_1(t) = -\frac{1}{\hbar\omega}\left(\frac{\partial H}{\partial t}\right)_{12}\exp\left[-i\int_0^t \omega dt\right]\cdot a_2(t) \tag{9}$$

and

---

* For example, the nearest another K-type doublets lies 3×10^5 Mc apart from the $J=4$, $K_{-1}=3$, doublets in the case of formaldehyde molecule. If the perturbing field does not mix the different M states, only two levels are taken into consideration.

$$\dot{a}_2(t)=\frac{1}{\hbar\omega}\left(\frac{\partial H}{\partial t}\right)_{21}\exp\left[\,i\int_0^t \omega dt\,\right]\cdot a_1(t)\;, \tag{10}$$

where

$$\hbar\omega(t)=W_2(t)-W_1(t) \qquad \text{and} \qquad \left(\frac{\partial H}{\partial t}\right)_{12}=\int u_1{}^*\,\frac{\partial H}{\partial t}\,u_2 d\tau\;.$$

Basic functions $u_1(t)$ and $u_2(t)$ can be taken as real functions and written explicitly as functions of the field strength E by

$$u_1\{E(t)\}=a(E)u_1{}^0+b(E)u_2{}^0 \tag{11}$$

$$u_2\{E(t)\}=-b(E)u_1{}^0+a(E)u_2{}^0\;, \tag{12}$$

where $u_1{}^0$ and $u_2{}^0$ are wave functions at zero field and $a(E)$ and $b(E)$ can be written as real functions of E

$$\left.\begin{aligned} a(E)&=\left\{\frac{\sqrt{\delta^2+4\mu_{12}{}^2E^2}+\delta}{2\sqrt{\delta^2+4\mu_{12}{}^2E^2}}\right\}^{1/2}\\ b(E)&=\left\{\frac{\sqrt{\delta^2+4\mu_{12}{}^2E^2}-\delta}{2\sqrt{\delta^2+4\mu_{12}{}^2E^2}}\right\}^{1/2}\\ \{a(E)\}^2&+\{b(E)\}^2=1\;. \end{aligned}\right\} \tag{13}$$

It should be noted that Eq. (8) is satisfied with these basic functions as follows:

$$\begin{aligned}\int u_1{}^*\frac{\partial u_1}{\partial t}d\tau&=\int(au_1{}^0+bu_2{}^0)\left(\frac{\partial a}{\partial t}u_1{}^0+\frac{\partial b}{\partial t}\,u_2{}^0\right)d\tau\\ &=0\end{aligned}$$

Similarly, $\int u_2{}^*\frac{\partial u_2}{\partial t}d\tau=0$ is also satisfied.

By eliminating $a_2(t)$ from Eqs. (9) and (10) a linear differential equation of the second order for $a_1(t)$ is obtained:

$$\ddot{a}_1+\left(i\omega+\frac{\dot{\omega}}{\omega}-\frac{\partial/\partial t(\partial H/\partial t)_{12}}{(\partial H/\partial t)_{12}}\right)\dot{a}_1+\frac{(\partial H/\partial t)_{12}(\partial H/\partial t)_{21}}{\hbar^2\omega^2}a_1=0 \tag{14}$$

In order to obtain explicit expressions of $\left(\frac{\partial H}{\partial t}\right)_{12}$, $\left(\frac{\partial H}{\partial t}\right)_{21}$ and $\frac{\partial}{\partial t}\left(\frac{\partial H}{\partial t}\right)_{12}$, $\int u_1H'u_2d\tau$ is differentiated by t*.

$$\int u_1\frac{\partial H'}{\partial t}u_2d\tau=\frac{\partial}{\partial t}\int u_1H'u_2d\tau-\int\frac{\partial u_1}{\partial t}H'u_2d\tau-\int u_1H'\frac{\partial u_2}{\partial t}d\tau\;. \tag{15}$$

If the direction of the electric field seen from the molecule does not change,

$$\int u_1{}^0H'u_2{}^0d\tau=\int u_1{}^0(-\boldsymbol{\mu}\boldsymbol{E})u_2{}^0d\tau=-E\mu_{12}\;,$$

where μ_{12} is the dipole matrix element on the base of wave functions at zero field and is proportional to the direction cosine matrix element.

By differentiating Eqs. (11) and (12)

$$\frac{\partial u_1}{\partial t}=\dot{a}u_1{}^0+\dot{b}u_2{}^0$$

---

* Because H_0 is time independent, it is apparent that $\partial H/\partial t=\partial H'/\partial t$, where $H=H_0+H'$.

and

$$\frac{\partial u_2}{\partial t}=-\dot{b}u_1{}^0+\dot{a}u_2{}^0$$

are obtained. From these equations

$$\int\frac{\partial u_1}{\partial t}H'u_2d\tau=\int(\dot{a}u_1{}^0+\dot{b}u_2{}^0)(-\mu E)(-bu_1{}^0+au_2{}^0)d\tau$$

$$=(\dot{a}a-\dot{b}b)(-E\mu_{12}) \tag{16}$$

$$\int u_1H'\frac{\partial u_2}{\partial t}d\tau=(a\dot{a}-b\dot{b})(-E\mu_{12}) \tag{17}$$

and

$$\int u_1H'u_2d\tau=\int(au_1{}^0+bu_2{}^0)H'(-bu_1{}^0+au_2{}^0)d\tau$$

$$=(a^2-b^2)(-E\mu_{12}) \tag{18}$$

$$\frac{\partial}{\partial t}\int u_1H'u_2d\tau=(2a\dot{a}-2b\dot{b})(-E\mu_{12})+(a^2-b^2)(-\dot{E}\mu_{12})\ . \tag{19}$$

From Eqs. (16), (17), (18) and (19)

$$\int u_1\frac{\partial H'}{\partial t}u_2d\tau=(a^2-b^2)(-\dot{E}\mu_{12})=\int u_2\frac{\partial H'}{\partial t}u_1d\tau \tag{20}$$

are obtained. Then the explicit forms of functions $\left(\frac{\partial H}{\partial t}\right)_{12}$ and $\frac{\partial}{\partial t}\left(\frac{\partial H}{\partial t}\right)_{12}$ are written by

$$\left(\frac{\partial H}{\partial t}\right)_{12}=\frac{-\delta\mu_{12}\dot{E}}{\sqrt{\delta^2+4\mu_{12}{}^2E^2}} \tag{21}$$

$$\frac{\partial}{\partial t}\left(\frac{\partial H}{\partial t}\right)_{12}=\frac{4\delta\mu_{12}{}^3E\dot{E}^2}{(\delta^2+4\mu_{12}{}^2E^2)^{3/2}}-\frac{\delta\mu_{12}\ddot{E}}{(\delta^2+4\mu_{12}{}^2E^2)^{1/2}}\ , \tag{22}$$

where E is the electric field strength seen from the moving molecule in the focuser and is a function of time. Also, ω and $\dot{\omega}$ are functions of time as follow:

$$\hbar\omega=\sqrt{\delta^2+4\mu_{12}{}^2E^2} \tag{23}$$

$$\hbar\dot{\omega}=\frac{4\mu_{12}{}^2E\dot{E}}{\sqrt{\delta^2+4\mu_{12}{}^2E^2}}\ . \tag{24}$$

The differential equation of $a_1(t)$ is obtained from Eqs. (21), (22), (23) and (24)

$$\ddot{a}_1+\left(\frac{i}{\hbar}\sqrt{\delta^2+4\mu_{12}{}^2E^2}+\frac{8\mu_{12}{}^2E\dot{E}}{\delta^2+4\mu_{12}{}^2E^2}-\frac{\ddot{E}}{\dot{E}}\right)\dot{a}_1+\frac{\delta^2\mu_{12}{}^2\dot{E}^2}{(\delta^2+4\mu_{12}{}^2E^2)^2}a_1=0\ . \tag{25}$$

ii) *The trajectory of molecules in the focuser*

The Lagrangian of the molecular motion in the focuser is written in a cylindrical coordinate as

$$L=\frac{1}{2}m(\dot{r}^2+r^2\dot{\theta}^2+\dot{z}^2)-U(r)\ ,$$

where z is the direction of the axis of the focuser and r is perpendicular to z. The potential $U(r)$ is the Stark energy of the molecule in the focusing field. For a slightly asymmetric top molecule, when $h\nu_0$ is much smaller than the Stark energy*, the potential in the

---

* In more correct words the Stark energy is linearly proportional to the electic field strength.

$2n$-pole focuser is written by*

$$U(r)=\pm\beta_n r^{n-1}\ ,$$

where $\beta_n=\frac{MK}{J(J+1)}\frac{n\mu V}{2R^n}$ and μ the permanent electric dipole moment of the molecule. An upper sign is for the upper state of the molecular energy levels, and *vice versa.*

For the molecule in the upper state Lagrange equations are integrated and become

$$mr^2\dot{\theta}=\text{constant}\equiv j \tag{26}$$

$$m\dot{z}=\text{constant}\equiv mv_z \tag{27}$$

$$\dot{r}^2=v_0{}^2+\frac{2}{m}\left\{\frac{j^2}{m}\left(\frac{1}{r_0}-\frac{1}{r^2}\right)+\beta_n(r_0{}^{n-1}-r^{n-1})\right\}\ , \tag{28}$$

where v_0 is the r-component of the initial velocity of the molecule, and r_0 the initial value of r. Reverse the sign before β_n, and the equation for the lower state molecule is given. Eq. (26) shows a constant angular momentum motion around the z-axis, while Eq. (27) shows a constant velocity motion along the z-direction.

The integral of Eq. (28) can be written in a form,

$$t-t_0=\int\frac{dr}{g(r)}\ . \tag{29}$$

This integration can be expressed by a simple analytical function only for the case of six-pole focuser. In the case of eight- and ten-pole focuser the molecular trajectories are approximately expressed by eliptic functions. For the sake of analytical treatment of the differential equation, the molecular trajectory is discussed for the six-pole focuser as follows.

When $n=3$ (six-pole focuser), from Eq. (28) $g(r)$ is given by

$$g(r)=\frac{1}{r}\sqrt{-ar^4+br^2-c}\ , \tag{30}$$

where

$$\left.\begin{aligned} a&=\frac{2\beta_3}{m}\\ b&=v_0{}^2+\frac{j^2}{m^2r_0{}^2}+\frac{2\beta_3r_0{}^2}{m}\\ c&=\frac{j^2}{m^2}\ . \end{aligned}\right\} \tag{31}$$

Then, the integral of Eq. (29) becomes

$$r^2=\frac{b}{2a}\pm\frac{\sqrt{b^2-4ac}}{2a}\sin^2 2\sqrt{a}\,(t+t_0)\ . \tag{32}$$

The focusing criterion is expressed by

$$r^2_{\max}=\frac{2c}{b-\sqrt{b^2-4ac}}\leqq R^2\ . \tag{33}$$

In a usual experimental condition it may be assumed that the angular momentum of the molecule, j, and the initial value of r-component of the position vector of the molecule, r_0, are very small. When j and r_0 are negligible in the expression of b and c, Eq. (33) is rewritten by

---

* This expression is correct, when the direction of the electric field seen from the moving molecule does not change and the matrix element due to the perturbing interaction is proportional to the direction cosine matrix element.

$$\frac{1}{2}mv_0^2 \leq \frac{MK}{J(J+1)}\mu E_{\max},$$

where $E_{\max}=E(r=R)=\frac{3}{2}\frac{V}{R}$. Similarly, the solution for the lower state molecule is

$$r^2=\frac{\sqrt{b'^2+4ac}}{2a}\cosh 2\sqrt{a}\,(t+t_0)-\frac{b'}{2a}, \tag{34}$$

where

$$b'=v_0^2+\frac{j^2}{m^2r_0^2}-\frac{2}{m}\beta_3 r_0^2 .$$

For the molecule which satisfies the condition, $\frac{1}{2}mv_0^2=\bar{\mu}E_{\max}$, the trajectories are simply expressed by

$$\frac{r}{R}=\sin\sqrt{a}\,t \tag{35}$$

$$\frac{r}{R}=\sinh\sqrt{a}\,t . \tag{36}$$

Then the explicit form of the time dependent perturbation Hamiltonian can be constructed from the trajectory of the molecule.

When $n=3$, electric field strength and its derivatives can be written analytically by

$$\left.\begin{aligned} &E=E_1-E_0\cos\omega_\theta t=E_0(\rho-\cos\omega_\theta t)\\ &\dot{E}=\omega_\theta E_0\sin\omega_\theta t\\ &\ddot{E}=\omega_\theta^2 E_0\cos\omega_\theta t , \end{aligned}\right\} \tag{37}$$

where

$$\omega_\theta=2\sqrt{a}, \qquad E_0=\frac{3V}{2R^3}\frac{\sqrt{b^2-4ac}}{2a}, \qquad E_1=\frac{3V}{2R^3}\frac{b}{2a}\simeq\frac{mv_0^2}{4\bar{\mu}} \quad \text{and} \quad \rho=\frac{E_1}{E_0}\simeq 1 .$$

iii) *Approximate solution of the Schrödinger equation*

Now the differential equation is solved for the case of six-pole focuser. The electric field E is given by Eq. (37) from the trajectory of the molecule, so that the analytical expression of the differential equation can be obtained.

Substitution of Eq. (37) into (25) becomes

$$\frac{d^2a_1}{d\theta^2}+\left(i\frac{\sqrt{F}}{\omega_\theta}-\frac{8x_1^2\sin\theta(\cos\theta-\rho)}{F}-\cot\theta\right)\frac{da_1}{d\theta}+\frac{\omega_0^2x_1^2\sin^2\theta}{F^2}a_1=0 , \tag{38}$$

where

$$\theta=\omega_\theta t , \qquad x_1=E_0\bar{\mu}/\hbar , \qquad \text{and} \qquad F=\omega_0^2+4x_1^2(\cos\theta-\rho)^2 . \tag{39}$$

a) When θ is small so that the coefficient of a_1 in Eq. (38),

$$\omega_0^2x_1^2\sin^2\theta/F^2 ,$$

may be neglected compared with unity, Eq. (38) is reduced to a differential equation of the form

$$\frac{d^2a_1}{d\theta^2}+\left(i\frac{\omega_0}{\omega_\theta}-\cot\theta\right)\frac{da_1}{d\theta}=0 . \tag{40}$$

Here the second order terms of θ in Eq. (38), is neglected and it is taken that $F=\omega_0^2$ because for most of molecules ρ is nearly equal to unity. It should be noted that a_1 is still very small for a small value of θ in this approximation when the initial condition is $a_1=0$, while $da_1/d\theta$ or $d^2a_1/d\theta^2$ may have finite values even for a very small value of θ.

By integrating Eq. (40), one obtains

$$a_1=\frac{-B_1}{1-(\omega_0/\omega_\theta)^2}\left(\cos\theta+i\frac{\omega_0}{\omega_\theta}\sin\theta\right)\exp\left(-i\frac{\omega_0}{\omega_\theta}\theta\right)+B_1' \tag{41}$$

and a similar expression for a_2. With the determined constants from the initial condition, for a very small value of θ, the approximate expressions of a_1 and a_2 are

$$\left.\begin{aligned} a_1&=\frac{\bar{\mu}E_0}{\delta}\theta^2\\ a_2&=1-\frac{1}{2}\left(\frac{\bar{\mu}E_0}{\delta}\right)^2\theta^4\end{aligned}\right\} \tag{42}$$

or

$$\left.\begin{aligned} a_1{}^2&=\left(\frac{x_1}{\omega_0}\right)^2\theta^4\\ a_2{}^2&=1-\left(\frac{x_1}{\omega_0}\right)^2\theta^4+O(\theta^8)\end{aligned}\right\} \tag{43}$$

Since ω_θ is proportional to the square root of the focuser voltage V, $a_1{}^2$ increases in proportion to the square of the voltage V and to the fourth power of t.

$$a_1{}^2=16\left(\frac{x_1}{\omega_0}\right)^2\left(\frac{3MK}{J(J+1)}\frac{\mu}{mR^3}\right)^2V^2t^4 \tag{44}$$

The criterion that the above approximate solutions are applicable is roughly given by

$$\theta\ll\frac{\omega_0}{x_1} \tag{45}$$

A typical value of ω_0/x_1 takes an order of 10^{-3} for the $J=4$, $K_{-1}=3$ transition of formaldehyde molecule.

b) When the transition frequency is so low that $\omega_0\ll x_1$ but θ is not very small, the differential equation, Eq. (38), can be integrated, when

$$\frac{\omega_0{}^2\sin^2\theta}{16x_1{}^2(1-\cos\theta)^2}\ll 1$$

so that the third term in the differential equation can be neglected.

By taking $F=4x_1{}^2(1-\cos\theta)^2$, it becomes

$$a_1=A_1\int_{\theta_0}^{\theta}\frac{\sin\theta}{\sin^4(\theta/2)}\exp\left[-\frac{2ix_1(\theta-\sin\theta)}{\omega_\theta}\right]d\theta\,, \tag{46}$$

where $\theta_0\gg\theta_{00}$ and θ_{00} will be defined later.

Because the typical value of x_1/ω_θ is of the order of 10^6 or more, the second part in the integrand of Eq. (46) is a very rapidly varying function compared with the first part. It may be reasonable that the first part is replaced by its mean value in the interval of the integration and can be factored out from the integration. Then,

$$a_1=-\frac{\omega_\theta}{2ix_1}A_1\overline{f(\theta)}\left\{\exp\left[-\frac{2ix_1}{\omega_\theta}(\theta-\sin\theta)\right]-\exp\left[-\frac{2ix_1}{\omega_\theta}(\theta_0-\sin\theta_0)\right]\right\}, \tag{47}$$

where

$$\overline{f(\theta)}=\frac{\int_{\theta_0}^{\theta}f(\theta)d\theta}{(\theta-\theta_0)}\qquad\text{and}\qquad f(\theta)=\frac{4\sin\theta}{(1-\cos\theta)^3}\,.$$

Multiplied by a_1^* Eq. (47) becomes

$$|a_1|^2=\frac{\omega_\theta^2}{2x_1^2}|A_1|^2\overline{f(\theta)}^2\left\{1-\cos\frac{2x_1}{\omega_\theta}(\theta-\theta_0-\sin\theta+\sin\theta_0)\right\}. \tag{48}$$

Since the second term in the parenthesis is a rapidly varying function, even for a " short time " this term may be averaged out. Then it gives the " non-adiabatic " effect by the following expression.

$$|a_1|^2=\frac{\omega_\theta^2}{2x_1^2}|A_1|^2\overline{f(\theta)}^2. \tag{49}$$

Since ω_θ is proportional to $\sqrt{V}$, it is readily seen from Eq. (49) that $|a_1|^2$ is proportional to the focuser voltage V, when the value of θ is not small and $\omega_0 \ll x_1$.

The approximation is considered to be good when $\theta_0 \ll \theta_{00}$, where θ_{00} is given from

$$\frac{4x_1}{\omega_0}=\frac{\sin\theta_{00}}{(1-\cos\theta_{00})^2}. \tag{50}$$

For a typical condition that $4x_1/\omega_0=1.7\times10^3$ for the $J=4$, $K_{-1}=3$ line, a value of θ_{00} is about 1.0×10^{-1}.

§ 4. Effects of the Transition Field Between the Focuser and the Resonator

The transition field between the focuser and the condenser also disturbs the molecular states appreciably. When the molecular transition frequency is low, this effect is considerably large as shown below. A simple criterion of this effect is given by a comparison between ν_0 and $1/t_0$, where t_0, is a time of flight of the molecule from the end of the focuser to the entrance of the resonator.

i) *Sudden approximation.*

If the time-dependent term in the Hamiltonian of the molecule changes with time very rapidly compared with the molecular frequency, any appreciable change of the molecular wave function does not occur, so that ψ_{final} can be equated to ψ_{initial}, which is the wave function of the molecule at the end of the focuser,

$$\psi_{\text{initial}}=a_1(t_1)u_1(t_1)e^{-i\varphi_1}+a_2(t_1)u_2(t_1)e^{-i\varphi_2}, \tag{51}$$

where t_1 is the time of flight in the focuser. The coefficients a_1 and a_2 are taken as real quantities and their phases are included in φ_1 and φ_2.

When $\frac{\omega_\theta}{\omega_0}\cdot\frac{x_1}{\omega_0}\gg1$ is satisfied, φ_1 and φ_2 are approximatly written by

$$\left.\begin{aligned}\varphi_1&=\int_0^{t_1}\frac{1}{\hbar}W_1dt\\ \varphi_2&=\int_0^{t_1}\frac{1}{\hbar}W_2dt.\end{aligned}\right\} \tag{52}$$

The wave function of the molecule at the reasonator inlet $(t=0)$ is*

$$\psi_{\text{final}}=a_1^0u_1^0+a_2^0u_2^0, \tag{53}$$

where u_1^0 and u_2^0 are the molecular function at zero field.

Then on the assumption of sudden approximation

$$a_1(t_1)u_1(t_1)e^{-i\varphi_1}+a_2(t_1)u_2(t_1)e^{-i\varphi_2}=a_1^0u_1^0+a_2^0u_2^0, \tag{54}$$

---

* This is also the initial state of the molecule for the Schrödinger equation of the molecule in the rf field in the resonator.

where u_1 and u_2 are expressed using zero field functions by

$$\left.\begin{aligned} u_1&=a'u_1{}^0+b'u_2{}^0 \\ u_2&=-b'u_1{}^0+a'u_2{}^0 \end{aligned}\right\} \tag{55}$$

Here a' and b' are given by Eq. (13), when E is replaced by a value at the end of the focuser, E'. Multiplied by $u_1{}^0$ or $u_2{}^0$, Eq. (54) becomes after integration over the space coordinates*

$$\left.\begin{aligned} a_1{}^0&=a_1a'e^{-i\varphi_1}-a_2b'e^{-i\varphi_2}\equiv\mathcal{E}e^{i\theta_1} \\ a_2{}^0&=a_1b'e^{-i\varphi_1}+a_2a'e^{-i\varphi_2}\equiv\lambda e^{i\theta_2} \end{aligned}\right\} \tag{56}$$

or

$$\left.\begin{aligned} |a_1{}^0|^2&=a_1^2a'^2+a_2^2b'^2-a_1a_2a'b'2\cos(\varphi_2-\varphi_1)\equiv\mathcal{E}^2 \\ |a_2{}^0|^2&=a_1^2b'^2+a_2^2a'^2+a_1a_2a'b'2\cos(\varphi_2-\varphi_1)\equiv\lambda^2\,. \end{aligned}\right\} \tag{57}$$

For the case of a six-pole focuser, the field strength seen from the molecule is given approximately by

$$E=\frac{1}{2\bar{\mu}}\,mv_0{}^2\sin^2\frac{\theta}{2}\,.$$

The value at the end of the focuser is approximately

$$E'=\frac{1}{2\bar{\mu}}mv_0{}^2\,,$$

since the value of θ is approximately π near the end of the focuser for the typical values of molecular velocity and the focuser voltage.

The phase difference, $\varphi_2-\varphi_1$, is calculated approximately as follows:

$$\varphi_2-\varphi_1=\frac{1}{\hbar}\int_0^{t_1}(W_2-W_1)dt=\int_0^{t_1}\sqrt{\omega_0{}^2+4x_1{}^2\sin^4\frac{\theta}{2}}\,d\theta\gtrsim\frac{x_1}{\omega_\theta}\pi \tag{58}$$

Since this value is very large compared with π, $\cos(\varphi_2-\varphi_1)$ becomes nearly zero by averaging it over various molecules. Then Eq. (57) becomes

$$|a_2{}^0|^2=\frac{1}{2}\left\{1+\frac{\omega_0}{2x_1}(1-2\gamma^2)\right\}$$

and

$$|a_1{}^0|^2=\frac{1}{2}\left\{1-\frac{\omega_0}{2x_1}(1-2\gamma^2)\right\}$$

where

$$\gamma^2=\{a_1(t_1)\}^2 \qquad \text{and} \qquad 1-\gamma^2=\{a_2(t_1)\}^2\,.$$

It may be noted that as shown in the equation, the effect of the fringing field also occurs even when $\gamma^2=0$ such that the molecule can be focused adiabatically. The line intensity is proportional to

$$|a_2{}^0|^2-|a_1{}^0|^2=\frac{\omega_0}{2x_1}(1-2\gamma^2) \tag{59}$$

The line disappears when $\gamma^2=\frac{1}{2}$, that is, when the molecular state is completely mixed up in the focuser.

ii) *Corrections due to finite time of flight*

Because the time of flight in the transition region is not equal to zero, the wave function of the molecule changes with time during the flight and the wave function at the end of focuser, ψ_{initial}, is not equal to that at the inlet of resonator, ψ_{final}, but somewhat different.

---

* $|a_1{}^0|^2+|a_2{}^0|^2=a_1^2a'^2+a_2^2b'^2+a_1^2b'^2+a_2^2a'^2=(a_1^2+a_2^2)(a'^2+b'^2)=1\,.$

If the perturbing potential $V(t)$ is commutable with the unperturbed Hamiltonian H_0, this difference of the wave functions is expressed by a phase factor of

$$\exp\left[\frac{1}{i\hbar}\int_{t_1}^{t_2}V(t)dt\right].$$

Then Eq. (51) is replaced by

$$\psi_{\text{final}}=\exp\left[-\frac{i}{\hbar}\int_{t_1}^{t_2}V(t)\,dt\right]\cdot\psi_{\text{initial}}$$

and

$$a_1{}^0u_1{}^0+a_2{}^0u_2{}^0=a_1e^{-i(\varphi_1+\beta_1)}u_1+a_2e^{-i(\varphi_2+\beta_2)}u_2\,, \tag{60}$$

where

$$\beta_1=\frac{1}{\hbar}\int_{t_1}^{t_2}W^1(t)dt$$

$$\beta_2=\frac{1}{\hbar}\int_{t_1}^{t_2}W^2(t)dt$$

and $W^1(t)$ and $W^2(t)$ are the eigen values of*

$$\left.\begin{aligned}V(t)u_1&=W^1(t)u_1\\ V(t)u_2&=W^2(t)u_2\end{aligned}\right\} \tag{61}$$

It is readily seen from a comparison of Eqs. (51) and (60) that the expression revised by finite time correction is similar to Eq. (51), where φ_1 should be replaced by $\varphi_1+\beta_1$ and φ_2 replaced by $\varphi_2+\beta_2$.

In order to estimate the validity of sudden approximation, the electric field is assumed to change linearly in the transition region between the focuser and the resonator. Then the argument of cosine function in Eq. (57) becomes

$$(\varphi_2+\beta_2)-(\varphi_1+\beta_1)\simeq x_1\left(\frac{\pi}{\omega_\theta}+t_0\right)$$

The first term in the parenthesis is nearly a time of flight for the length of the focuser under a typical condition stated before, and the second term is that in the transition region. For the $J=4$, $K_{-1}=3$ line of formaldehyde molecule,

$$\frac{\pi}{\omega_\theta}\simeq 1.3\times10^{-3}\,\text{sec}$$

$$t_0\simeq 1.3\times10^{-5}\,\text{sec}\,.$$

This estimation shows that the sudden approximation is good in this case.

§ 5. Number of the Focused Molecules and Saturation Characteristics with the Focuser Voltage

If the upper state is mixed up with the lower state by the perturbation of focusing field, the trajectory of the molecule should deviate from that of the molecule on a pure state and hence the flux of the focused molecules differs somewhat from the expression obtained on the adiabatic approximation[7]. In other words, some molecules in the upper state make transitions to the lower state in the focuser and they are defocused. In addition, the number of molecules which interact with the rf field as the upper state molecules are effectively less than the number of focused molecules because molecular states are not pure at the resonator inlet. This reduced number of molecules is called hereafter an effective number of focused molecules.

---

* Strictly speaking, Eq. (61) can not always be solved as quasi-stationary problems in the similar way as in Eq. (5).

From a kinematical consideration on the adiabatic focusing approximation, the flux of focused molecules by a six-pole focuser can be calculated by using Eqs. (35) and (36)

$$n=\frac{A_i\alpha}{\sqrt{\pi}}N_2\left(1-\exp\left[-\frac{aR^2}{\alpha^2}\right]\right)\left(1-\exp\left[-\frac{4al^2}{\pi^2\alpha^2}\right]\right) \tag{62}$$

where A_i is the inlet area, N_2 the number density of the upper state molecules, and l the length of the focuser. This expression is essentially the same as Eq. (3.9) in reference (7).

In order to take the "non-adiabatic" effect into consideration of the focused molecules the focusing field is treated at first, and secondary the fringing field. Because of the mixing of states induced by the perturbation of Stark field in the focuser, the effective force which acts on the molecule differs from that in a pure state. The expectation value of the potential energy of the molecule in the mixed state can be expressed by

$$U_{\text{eff}}=|a_2(t)|^2U_2+|a_1(t)|^2U_1\ . \tag{63}$$

Since the Stark effect is approximately linear in the low frequency maser[2] the effect of mixing may be calculated by using the effective dipole matrix element which is obtained from Eq. (63) by

$$\mu_{\text{eff}}=\{1-2|a_1(t)|^2\}\mu_{12}\ . \tag{64}$$

This may be interpreted as the decrease of the number of molecules in the upper state and the increase of that in the lower state. It is seen from Eq. (64) that μ_{eff} decreases monotonously with time as the molecule proceeds in the focuser. It is too difficult to obtain $a_1(t)$ from the Schrödinger equation, because the perturbation field must be solved simultaneously with the equation of motion.

Since the argument of the exponential functions in Eq. (62) are small in a ordinary condition, the number of focused molecules is approximately proportional to μ_{eff}^2. Although μ_{eff} is not a constant during the flight of the molecule, a plausible estimate can be obtained by a certain average of μ_{eff}. As shown in Eqs. (44) and (49), $|a_1|^2$ is proportional to V^2 when θ is very small, while $|a_1|^2$ increases linearly with V when θ is not small. Then the rough estimate of the number of focused molecules is expressed by

$$n'=n\left\{1-\left(\frac{V}{V_N'}\right)^{\xi}\right\}^2 \tag{65}$$

where $1<\xi<2$. In a low frequency maser with $V\approx10$ kV, $\nu_0\lesssim10$ Mc and $\mu_{12}\approx1$ Debye, ξ is nearly equal to 1.

Since some of the upper state molecules make transitions to the lower state by the perturbation of the focuser and its fringing field, the effective number of focused molecules should decrease. This effect is supported by the experimental evidence that the saturation of the effective beam flux with the focuser voltage decreases considerably as the distance between the focuser and the resonator increases.

Because the focused molecule is partially in the lower state as given by Eq. (53), the effective number of upper state molecules in a unit time is given after some manipulations by

$$n_{\text{eff}}=n'(1-2\varepsilon^2)\ , \tag{66}$$

where

$$\varepsilon^2=\frac{1}{2}\left\{1-\frac{\omega_0}{2x_1}(1-2\gamma^2)\right\}$$

is the probability amplitude of $u_1{}^0$ in Eq. (53) at the resonator inlet. Since γ^2 is proportional to V near the end of the focuser Eq. (66) can be written by

$$n_{\text{eff}}=n'\frac{\omega_0}{2x_1}(1-2\gamma^2)=n'\frac{\omega_0}{2x_1}\left(1-\frac{V}{V_N}\right). \tag{67}$$

Therefore, from Eq. (65) and Eq. (67) the effective number of focused molecules in a unit time can be written by

$$n_{\text{eff}}=n\left(1-\left(\frac{V}{V_{N'}}\right)^{\xi}\right)\left(1-\frac{V}{V_N}\right), \tag{68}$$

where n is the beam flux on the adiabatic approximation. The expression shows a saturation characteristics with the focuser voltage.

§ 6. Line Shape of the Molecule in a Mixed State

In this section the transition probability of the molecule in the rf field in the resonator is discussed. The induced transition by the rf signal has a different transition probability from that on the adiabatic approximation, when the quantum mechanical state of the molecule is not pure but has been mixed by the perturbation of the focusing field.

As seen in the preceding sections, the molecular state at the resonator inlet is not pure but mixed to some extent. The initial molecular state at $t=0$ is expressed by

$$\psi_0=a_1{}^0u_1{}^0+a_2{}^0u_2{}^0\ .$$

The Hamiltonian of the molecule in the rf field, $E\cos(\omega t+\chi)$, is

$$H=H_0-\mu E\cos(\omega t+\chi)=H_0-\frac{\mu E}{2}\{e^{i(\omega t+\chi)}+e^{-i(\omega t+\chi)}\}\ . \tag{69}$$

Here χ is a phase of the rf field at $t=0$, when the molecule enters the resonator. Express the molecular state in the rf field by*

$$\psi(t)=a_1(t)u_1{}^0e^{i(W_1/\hbar)t}+a_2(t)u_2{}^0e^{i(W_2/\hbar)t}\ ,$$

and the Schrödinger equation is reduced to the differential equations for $a_1(t)$ and $a_2(t)$,

$$\left.\begin{aligned}\dot{a}_2&=\frac{i}{2}xe^{-i(\omega-\omega_0)t-i\chi}\cdot a_1\\ \dot{a}_1&=\frac{i}{2}xe^{i(\omega-\omega_0)t+i\chi}\cdot a_2\ .\end{aligned}\right\} \tag{70}$$

Here $x=E\mu_{12}/\hbar$ and non-resonance terms such as $\exp[\pm i(\omega+\omega_0)t]$ in the differential equations are neglected.

The solutions of the differential equations can be expressed by the following forms,

$$\left.\begin{aligned}a_1&=A_1\exp(i\alpha_+t)+B_1\exp(i\alpha_-t)\\ a_2&=A_2\exp(i\alpha_+'t)+B_2\exp(i\alpha_-'t)\ ,\end{aligned}\right\} \tag{71}$$

where

$$\alpha_\pm=\frac{1}{2}\{(\omega-\omega_0)\pm\sqrt{(\omega-\omega_0)^2+x^2}\}$$

$$\alpha_\pm'=\frac{1}{2}\{-(\omega-\omega_0)\pm\sqrt{(\omega-\omega_0)^2+x^2}\}\ .$$

---

* Though the same notations, a_1 and a_2, are used in the former section for the states in the focuser, they should not be confused.

Substituting Eq. (71) into Eq. (70), the coefficients in Eq. (71) are determined as follows:

$$A_1=\frac{xa_2{}^0\exp(i\chi/2)+2\alpha_-a_1{}^0\exp(-i\chi/2)}{2\sqrt{x^2+\delta\omega^2}}$$

$$B_1=\frac{-xa_2{}^0\exp(i\chi/2)+2\alpha_+a_1{}^0\exp(-i\chi/2)}{2\sqrt{x^2+\delta\omega^2}}$$

where $\delta\omega=\omega-\omega_0$. The expressions of A_2 and B_2 can be obtained similarly. Then, $|a_1|^2$ is given by

$$\begin{aligned}|a_1|^2&=A_1A_1{}^*+B_1B_1{}^*+2Re\,A_1B_1{}^*\exp i(\alpha_+-\alpha_-)t\\&=\frac{1}{2(x^2+\delta\omega^2)}\{x^2+2|a_1{}^0|^2\delta\omega^2-2x\delta\omega|a_1{}^0|\,|a_2{}^0|\cos\delta\\&\quad+[x^2(2|a_1{}^0|^2-1)+2x\delta\omega|a_1{}^0|\,|a_2{}^0|\cos\delta\cos\sqrt{x^2+\delta\omega^2}\,t\\&\quad-2x\sqrt{x^2+\delta\omega^2}\,|a_1{}^0|\,|a_2{}^0|\sin\delta\sin\sqrt{x^2+\delta\omega^2}\,t\}\,,\end{aligned}\tag{72}$$

where δ is the sum of χ and the phase difference between $a_1{}^0$ and $a_2{}^0$.

When $a_1{}^0$ and $a_2{}^0$ are written by Eqs. (56) and (57), $\delta=\chi+\theta_2-\theta_1$. Then

$$\tan(\theta_2-\theta_1)=\frac{a_1(t_1)a_2(t_1)(a'^2+b'^2)\sin\varphi}{a'b'\{a_1(t_1)^2-a_2(t_1)^2\}+a_1(t_1)a_2(t_1)(a'^2-b'^2)\cos\varphi}\,,$$

where $\varphi=\varphi_2-\varphi_1$ is the phase difference between the two states appeared in Eq. (51). Since φ is a very large quantity which depends on the molecular velocity and the field in the focuser, $\sin\varphi$ and $\cos\varphi$ average to zero by the velocity distribution, so that $\theta_2-\theta_1\simeq0$ and $\delta\simeq\chi$.

In ordinary cases when the molecule enters uniformly in the resonator, averages of $\sin\chi$ and $\cos\chi$ for all molecules are zero. Eq. (72) becomes

$$|a_1|^2=\frac{x^2(1-\cos\sqrt{x^2+\delta\omega^2}\,t)}{2(x^2+\delta\omega^2)}+\frac{2\mathcal{E}^2(\delta\omega^2+x^2\cos\sqrt{x^2+\delta\omega^2}\,t)}{2(x^2+\delta\omega^2)}\,,\tag{73}$$

and the emitted power from the molecules is expressed by

$$\Delta P=n'h\nu_0\{|a_1|^2-|a_1{}^0|^2\}=n'h\nu_0\frac{x^2}{x^2+\delta\omega^2}(1-2\mathcal{E}^2)\sin^2\frac{\sqrt{x^2+\delta\omega^2}}{2}t\,.\tag{74}$$

The optimum rf voltage for the maximum output signal is obtained by differentiating $(\Delta P)^2/P_i$, where $P_i\propto x$ is the input power for stimulation.

$$x_{\text{opt}}\frac{L}{2v}=\theta_0=1.1656\tag{75}$$

The saturation broadened line-width can also be calculated from Eq. (74).

$$2\Delta\omega_{\text{sat}}=2\sqrt{x^2+(\Delta\omega_0)^2}\tag{76}$$

Here $\Delta\omega_0/2\pi$ is the half half-width of the line at zero field. These are the same expressions as those derived on the adiabatic approximation, the only difference being that the intensity is $(1-2\mathcal{E}^2)$ times.

It can be concluded that the mixing of states (" non-adiabatic " effect) does not change the resonance width and the optimum voltage when the phase of the molecule is at random with respect to that of the applied rf field. However, when $\langle\sin\delta\rangle$ and $\langle\cos\delta\rangle$ are not zero but take some finite values, the saturation broadened line shape is expressed by

$$\begin{aligned}\frac{\Delta P}{n'h\nu_0}=&\frac{x^2}{x^2+\delta\omega^2}(1-2\mathcal{E}^2)\sin^2\sqrt{x^2+\delta\omega^2}\frac{t}{2}-\frac{2x\delta\omega}{x^2+\delta\omega^2}\mathcal{E}\lambda\langle\cos\delta\rangle\sin^2\sqrt{x^2+\delta\omega^2}\frac{t}{2}\\&-\frac{x}{\sqrt{x^2+\delta\omega^2}}\mathcal{E}\lambda\langle\sin\delta\rangle\sin\sqrt{x^2+\delta\omega^2}\,t\,.\end{aligned}\tag{77}$$

At resonace when $\omega=\omega_0$, the emitted power is

$$\Delta P=n'h\nu_0\left[(1-2\mathcal{E}^2)\sin^2\frac{xt}{2}-\mathcal{E}\lambda\langle\sin\delta\rangle\sin xt\right]. \tag{78}$$

The optimum amplitude for finite values of $\mathcal{E}$ and $\langle\sin\delta\rangle$ is given by

$$x_{\mathrm{opt}}\frac{L}{2v}\simeq\theta_0+\frac{4\theta_0{}^2+1}{4\theta_0{}^2-1}\,\frac{\mathcal{E}\lambda\langle\sin\delta\rangle}{1{-}{-}2\mathcal{E}^2}=1.1656+1.451\,\frac{\mathcal{E}\lambda\langle\sin\delta\rangle}{1-2\mathcal{E}^2}\,, \tag{79}$$

where higher order terms of $\mathcal{E}\lambda\langle\sin\delta\rangle/(1-2\mathcal{E}^2)$ are neglected.

The saturation broadened line-width due to the rf field can be calculated from Eq. (77). The transition probability or the power emitted from the beam is a function of the transit time through the resonator. The distribution of the transit time of molecules in the beam is not exactly but approximately expressed by an exponential function, $\exp(-\Delta\omega_0 t)$. The average of $\overline{\Delta P}$ is obtained from integration of Eq. (77) using this weight factor.

$$\overline{\Delta P}=n'h\nu_0\frac{x}{x^2+\delta\omega^2+\Delta\omega_0{}^2}\left\{\frac{1-2\mathcal{E}^2}{2}x-\mathcal{E}\lambda\langle\cos\delta\rangle\delta\omega-\mathcal{E}\lambda\langle\sin\delta\rangle\Delta\omega_0\right\} \tag{80}$$

Then the total half-width (times 2π) calculated from Eq. (80) is

$$2\Delta\omega_{\mathrm{sat}}=2\sqrt{x^2+(\Delta\omega_0)^2}\left\{1+\frac{\mathcal{E}^2\lambda^2\langle\cos\delta\rangle^2[x^2+(\Delta\omega_0)^2]}{[(1-2\mathcal{E}^2)x/2-\mathcal{E}\lambda\langle\sin\delta\rangle\Delta\omega_0]^2}\right\}^{1/2} \tag{81}$$

This reduces to Eq. (76), when $\mathcal{E}=0$ or when $\langle\cos\delta\rangle=0$.

(Received December 24, 1960)

Density (**D**)-*Exposure* (**E**) curves measured for Fuji Process Orthochromatic plates for electrons with energy 20~200 **kV** were given. Dependence of developing conditions on **D**–**E** curves was also examined. At a suitable developing condition, **D**–**E** curves for electrons with higher energy than 50 **kV** are linear over a wide range of density, and for electrons with lower energy they bend over at lower density.

§ 1. Introduction

For low exposures with fast electrons the photographic density of some emulsions is proportional to the amount of charge per unit area which has reached the emulsion during the exposure. Making use of this property Karle and Karle[1] proposed a method to determine the [*density* (**D**)] vs. [exposure (**E**)] curve, **D**–**E** curve, and their method has been applied by many investigators. For intensity measurement of electrons by the photographic method, the emulsions whose **D**–**E** curves are linear over a wide range of density are most suitable for use.

Some examples of the **D**–**E** curves for electrons in the earlier experiments are shown in Fig. 1. The extent of the linear portion depends on the emulsion. The curves bend over at low density for Agfa Extrarapid[2] and for Agfa Isochrom[3], at **D**=0.8 for Eastman Lantern Slide Medium[4], at **D**=1.3 for Ilford Thin Film Half Tone[5] and at a **D** value larger than 3 for Ilford Nuclear Research B2 plate[5]. The dependence of the extent of the linear portion on the energy of electrons has been studied. Digby et al[5] show that the extent increases as the energy of electrons increases from 25 **kV** to 60 **kV**. Baker et al[4] show that the extent is the same for 40 **kV**~212 **kV** electrons.

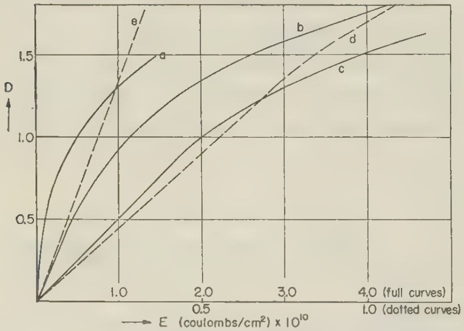

Fig. 1. **D**–**E** curves in the earlier experiments.

- **a**: Agfa Extrarapid, 72.9 **kV** (Backer and Kipphan [2])
- **b**: Agfa Isochrom, 75 **kV** (Borries and Knoll [3])
- **c**: Eastman Lantern Slide Medium, 67 **kV** (Baker, Ramberg and Hillier [4])
- **d**: Ilford Thin Film Half Tone, 66 **kV** (Digby, Firth and Hercock [5])
- **e**: Ilford Nuclear Research B 2,66 **kV** ([5])

Curves **a**, **b** and **c** were given in **D**-log **E** curves in the original papers.

§ 2. Experimental and Results

In this paper the results are given of measurements on **D**–**E** curves of Fuji Process Orthochromatic plate using a high voltage electron diffraction equipment containing two lenses and a rotating sector. The **D**–**E** curves are obtained from the two plates with different exposures applying the method proposed by Karle and Karle[1]. On this method an electron source with any intensity distribution can be used provided that it is stable during the two exposures. However, for precise measurements it is better to use an electron source whose intensity changes continuously with scattering angle. Such a source was obtained by the following method. By adjusting the projector lens current so as to give a large magnification, an almost uniform distribution of electrons is obtained. The electrons are partly masked by a rotating sector above the photographic plate, and the resultant intensity of electrons reaching the plate is nearly, but not exactly, proportional to the distance from the center of the rotating sector.

---

* Now at Ochanomizu University, Tokyo.

Photographic density was read by an optical balancing type microphotometer made by Narumi Mfg. Co. The reading of the density had been calibrated by a standard optical wedge made by Riken Co. The **D–E** curves are obtained from two plates with different exposures applying the method proposed by Karle and Karle[1]. Fig. 2 and Fig. 3 show **D–E** curves for Fuji Process Orthochromatic plates developed for 3 minutes at 20°C in Eastman D–72 developer diluted in ratio 1:1 with water. Fig. 2 is a curve for 80 **kV** electrons which is quite linear up to **D**=1.5. Fig. 3 is the curve for 20~200 **kV** electrons. For electrons with as low an energy as 20 **kV** the curves bend over at low density, and for electrons with higher energy than 50 **kV** the curves are quite linear over a wide range of **D**. This result accords with the earlier experiments[4,5].

Results with different developing conditions for 50 **kV** electrons are shown in Fig. 4. For this emulsion development for 3 minutes in Eastman **D**–72 developer diluted 1:1 with water gives the best result. Digby et al[5] concluded that the extent of the linear portion in **D–E** curves is mainly determined by the nature of the emulsions. The results shown in Fig. 4, however, show that it is also affected to a large extent by the developing conditions.

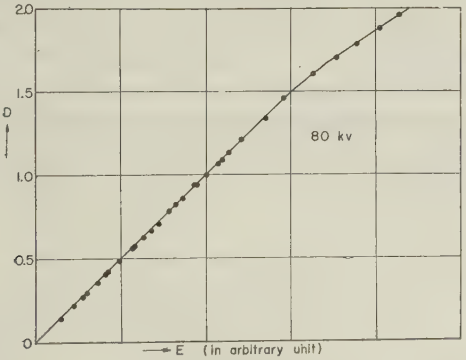

Fig. 2.

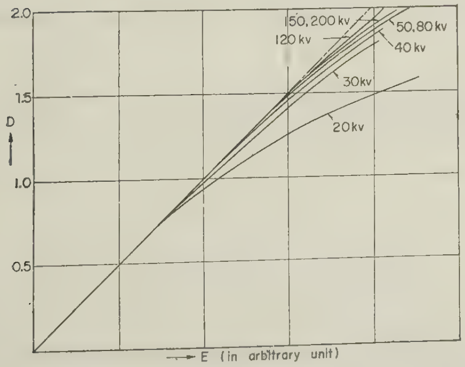

Fig. 3.

a: D-72 dilution 1:1 3 min.
b: D-72 1:1 5 min.
c: D-131 1:0 3 min.
d: D-131 1:1 5 min.
e: D-131 1:1 3 min.

Fig. 4.

On precise intensity measurement of electrons, it is required to control the exposure time so as to make the photographic density to be measured is in a linear range of the **D–E** curve. Hence, it is obvious that the precision will be greatly improved by using plates whose linear range is as wide as suitably developed Fuji Process Orthochromatic plates. Though we have shown only on the results for this emulsion in the above, probably it would be worth while to try various developing conditions for other emulsions to give **D–E** curves linear over a wide range of density.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 16, No. 4, APRIL, 1961

On the Steady Motion of an Indealized Elastico-Viscous Liquid Through Channels with Suction and Injection

By S. K. DATTA

The Calcutta Technical School 110, S. N. Banerjee Road,
Calcutta-13, India

(Received May 12, 1960, Revised December 8, 1960)

In this paper the steady flow of a certain type of elastico-viscous liquid in the annulus between two coaxial circular cylinders and between parallel plane boundaries has been considered. It is assumed that fluid is injected at one boundary and withdrawn at the other, both at the same rate and one of the boundaries is assumed to be moving with a constant velocity parallel to its generator. Numerical values have been given both for the annulus and for the parallel plates.

§1. Introduction

Attention has recently been drawn, due to experimental results on dilute suspensions and emulsions which cannot be explained on classical viscous theory, to the idealized incompressible elastico-viscous liquids. It is generally known that the behaviour of such liquids at small rates of shear is characterized by three constants, a coefficient of viscosity η_0, a relaxation time λ_1 and a retardation time λ_2 e.g., (Oldroyd, 1958)

$$p_{ik}=p'_{ik}-p''\delta_{ik}\ ,$$

$$p'_{ik}+\lambda_1\frac{d}{dt}p'_{ik}=2\eta_0\left(e_{ik}+\lambda_2\frac{d}{dt}e_{ik}\right)\ , \qquad (1)$$

$$e_{ik}=\frac{1}{2}(v_{k,i}+v_{i,k})\ ,$$

where $\delta_{ik}=0,\ i\neq k;\ =1,\ i=k,\ i,\ k=1,2,3$ and e_{ik} is the rate of strain tensor, p_{ik} is the stress tensor, and all these equations are referred to orthogonal cartesian system of axes. It has been shown by Oldroyd (1950, 1951) that among the possible generalizations of equation (1), which are valid for all conditions of motion and stress, and which reduce to (1) for small rates of shear and shear stresses, the simplest are linear in the stresses and include terms of the second degree in stresses and velocity gradients taken together. Thus assuming isotropy and incompressibility, a possible generalization of the second equation of (1) is

$$p'_{ik}+\lambda_1\frac{\mathscr{D}}{\mathscr{D}t}p'_{ik}+\mu_0 p'_{jj}e_{ik}-\mu_1(p'_{ij}e_{jk}+p'_{jk}e_{ij})+\nu_1 p'_{jl}e_{jl}\delta_{ik}$$
$$=2\eta_0\left(e_{ik}+\lambda_2\frac{\mathscr{D}}{\mathscr{D}t}e_{ik}-2\mu_2 e_{ij}e_{jk}+\nu_2 e_{jl}e_{jl}\delta_{ik}\right)\ , \qquad (2)$$

with the equation of incompressibility $e_{ii}=0$, where $\mu_0,\ \mu_1,\ \mu_2,\ \nu_1,\ \nu_2$ are material constants, each of the dimension of time and

$$\frac{\mathscr{D}}{\mathscr{D}t}p'_{ik}\equiv\frac{\partial}{\partial t}p'_{ik}+v_j p'_{ik,j}+\omega_{ij}p'_{jk}+\omega_{kj}p'_{ij}\ ,$$
$$\omega_{ik}\equiv\frac{1}{2}(v_{k,i}-v_{i,k})\ . \qquad (3)$$

Now it was shown by Oldroyd (1950) that for

$$\eta_0>0\ ,\ \lambda_1=\mu_1>\lambda_2=\mu_2\geq 0\ ,\ \mu_0=\nu_1=\nu_2\ ,$$

the liquid will exhibit Weissenberg climbing effect when sheared at a uniform rate between rotating coaxial cylinders. So this may be possible set of values of the constants for a liquid showing Weissenberg climbing effect. In particular, we choose

$$\eta_0>0\ ,\ \lambda_1=\mu_1\ ,\ \lambda_2=\mu_2=\mu_0=\nu_1=\nu_2=0\ .$$

With this choice of constants equation (2) together with (3) gives

$$p'_{ik}+\lambda_1\left(\frac{\partial}{\partial t}p'_{ik}+v_j p'_{ik,j}-v_{i,j}p'_{jk}-v_{k,j}p'_{ij}\right)=2\eta_0 e_{ij}\ . \tag{4}$$

§ 2. Coaxial Circular Cylinders

We choose cylindrical polar coordinates (r, θ, x) with x-axis along the axis of the cylinder. Then from symmetry and when the motion is steady,

$$u_1=u_x=u(r)\ ,\ u_2=u_r=v(r)\ ,\ u_3=u_\theta=0\ ,$$

if we consider the flow at a sufficient distance from the entrance end so that the quantities u_1, u_2, u_3 may be taken as independent of x, and then equation (4) takes the form

$$\begin{gathered}
p'_{rr}+\lambda_1\left[v\frac{\partial p'_{rr}}{\partial r}-2\frac{\partial v}{\partial r}p'_{rr}\right]=2\eta_0\frac{\partial v}{\partial r}\ ,\\
p'_{rx}+\lambda_1\left[v\frac{\partial p'_{rx}}{\partial r}-\frac{\partial u}{\partial r}p'_{rr}-\frac{\partial v}{\partial r}p'_{rx}\right]=\eta_0\frac{\partial u}{\partial r}\ ,\\
p'_{xx}+\lambda_1\left[v\frac{\partial p'_{xx}}{\partial r}-2\frac{\partial u}{\partial r}p'_{rx}\right]=0\ ,\\
p'_{\theta\theta}+\lambda_1\left[v\frac{\partial p'_{\theta\theta}}{\partial r}-2\frac{v}{r}p'_{\theta\theta}\right]=2\eta_0\frac{v}{r}\ ,\\
p'_{r\theta}=p'_x\theta=0\ .
\end{gathered} \tag{5}$$

The equation of continuity is

$$\frac{\partial v}{\partial r}+\frac{v}{r}=0 \tag{6}$$

and the equation of momentum gives

$$\begin{gathered}
\rho v\frac{\partial v}{\partial r}=-\frac{\partial p''}{\partial r}+\frac{\partial p'_{rr}}{\partial r}+\frac{p'_{rr}-p'_{\theta\theta}}{r}\ ,\\
\rho v\frac{\partial u}{\partial r}=\frac{\partial p'_{rx}}{\partial r}+\frac{1}{r}p'_{rx}\ ,
\end{gathered} \tag{7}$$

The boundary conditions are

$$\begin{aligned}
v&=v_a\ , & r&=a\\
&=v_b\ , & r&=b\\
u&=U\ , & r&=b\\
&=0\ , & r&=a
\end{aligned} \tag{8}$$

where a, b are the radii of the outer and inner cylinders respectively.

Integrating (6) and using the first two equations of (8)

$$v=\frac{v_a a}{r}=\frac{v_b b}{r}=\frac{v_a}{\zeta},\quad \zeta==r/a\ . \tag{9}$$

Assuming λ_1 to be small, we eliminate p'_{rr} from the first two equations (5) neglecting squares of λ_1,

$$\lambda_1 v\frac{dp'_{rx}}{dr}+\left(1-3\lambda_1\frac{dv}{dr}\right)p'_{rx}=\eta_0\frac{du}{dr}\ . \tag{10}$$

Substituting v from (9) in the second equation of (7) and integrating

$$rp'_{rx}=\rho v_a a(u+D)\ , \tag{11}$$

where D is a constant of integration. Substituting this in (10) we integrate (10) using the last two equations of (8) and get

$$\frac{u}{U}=\left(\frac{\sigma}{\zeta}\right)^2\frac{\zeta^2(1-KR)^{(R+2)/2}-(\zeta^2-KR)^{(R+2)/2}}{\sigma^2(1-KR)^{(R+2)/2}-(\sigma^2-KR)^{(R+2)/2}}\ ,$$

where

$$K=\frac{\lambda_1 v_a}{a}\ ,\quad R=\frac{v_a a}{\eta_0/\rho}\ ,\quad \sigma=b/a\ .$$

From (12) we may deduce the expression for u for an ordinary viscous liquid by making $\lambda_1=0$,

$$\frac{u}{U}=\frac{1-\zeta^R}{1-\sigma^R}\ . \tag{13}$$

Further, if the walls are rigid having no porosity, $u_a=0$ and then

$$\frac{u}{U}=\frac{\log\zeta}{\log\sigma}\ , \tag{14}$$

which agrees with the expression for laminar flow of a viscous fluid in an annulus when the inner cylinder is moving parallel to its axis.

Table I. (for u/U)
$K=0.05$

R / ζ	1	2	4
.4	1.00	1.00	1.00
.5	0.81	0.91	1.00
.8	0.31	0.45	0.74
1.0	0.00	0.00	0.00

$K=0.00$

R / ζ	1	2	4
.4	1.00	1.00	1.00
.5	0.83	0.89	0.96
.8	0.33	0.43	0.60
1.0	0.00	0.00	0.00

We give in the following table the values of u/U for $K=0.00$, 0.05 when $R=1$, 2, 4 and $\sigma=0.4$. The above table shows that for this particular choice of σ the radius ratio, u/U decreases at a particular position with increase in K if $R<2$ and if $R>2$, u/U increasese with increase in K. It is also noted that as ζ increases u/U decreases and it appears that for a particular choice of radius ratio, if $KR<1$*, then u/U will decrease with increase in K for some values of R and increase for some other values of R. It can also be seen that increase in R increases u/U at any distance.

§ 3. Parallel infinite plates

In this case we choose rectangular cartesian coordinates with x-axis along the upper plate which is fixed and y-axis perpendicular to the plates directed into the fluid. The flow is assumed to be in the x-direction and liquid is injected at the lower plate and withdrawn at the upper one. Then, if we assume the flow to be steady and fully developed,

$$u_x=u(y)\ ,\ u_y=v(y)\ ,\ u_z=0\ .$$

The boundary conditions are

$$\begin{aligned} v&=-V\ ,\quad y=0 \text{ and } h\\ u&=0\ ,\qquad y=0\\ &=U\ ,\qquad y=h\ . \end{aligned} \tag{15}$$

The equation of continuity gives

$$v=-V$$

everywhere. So equation (4) will give

$$\begin{gathered} p_{xx}+\lambda_1\left[v\frac{\partial p'_{xx}}{\partial y}-2\frac{\partial u}{\partial y}p'_{xy}\right]=0\ ,\\ p'_{yy}+\lambda_1 v\frac{\partial p'_{yy}}{\partial y}=0\ ,\\ p'_{xy}+\lambda_1\left[v\frac{\partial p'_{xy}}{\partial y}-\frac{\partial u}{\partial y}p'_{yy}\right]=\eta_0\frac{\partial u}{\partial y}\ ,\\ p'_{zz}=p'_{zx}=p'_{zy}=0\ , \end{gathered} \tag{16}$$

and the equation of momentum gives

---

* By our choice, since λ_1 in small, we may take $KR<1$ ordinary purposes, under the velocity of injection is very large.

$$\rho v\frac{\partial u}{\partial y}=\frac{\partial p'_{xy}}{\partial y}\,,$$
$$0=-\frac{\partial p''}{\partial y}+\frac{\partial p'_{yy}}{\partial y}\,. \tag{17}$$

Eliminating p'_{yy} from the second and third equations of (16) and retaining only first power of λ_1, we have as before

$$p'_{xy}-K_1\frac{dp'_{xy}}{d\eta}=\frac{\eta_0}{h}\frac{du}{d\eta}\,,$$
$$K_1=\frac{\lambda_1 V}{h}\,,\quad \eta=\frac{y}{h}\,. \tag{18}$$

Integrating the first equation of (17) we will obtain

$$p'_{xy}=-\rho V(u+D)\,,\quad \text{where } D \text{ is constant.}$$

Substituting this in (18) and integrating, we have with the help of (15),

$$\frac{u}{U}=\frac{1-e^{-R\eta/(1-K_1R)}}{1-e^{-R/(1-K_1R)}}\,, \tag{19}$$

where

$$R=\frac{vh}{\eta_0/\rho}\,.$$

If $K_1=0$, we obtain the expression for an ordinary viscous fluid as

$$\frac{u}{U}=\frac{1-e^{-R\eta}}{1-e^{-R}}\,. \tag{20}$$

Further if the plates are rigid having no porosity,

$$\frac{u}{U}=\eta \tag{21}$$

which is the known expression for an ordinary viscous fluid without suction or injection.

Table II. (for u/U)

$K_1=0.05$

η \ R	1	2	4
0.0	0.00	0.00	0.00
0.5	0.63	0.75	0.92
1.0	1.00	1.00	1.00

$K_1=0.00$

η \ R	1	2	4
0.0	0.00	0.00	0.00
0.5	0.62	0.73	0.88
1.0	1.00	1.00	1.00

The values of u/U are given in Table II for $K_1=0.00$ and 0.05 when $R=1$, 2, and 4.

So here also we note that when R and K_1 increase, u/U increases, at any particular distance.

The expression (19) can also be deduced from (12) if we make $\sigma\rightarrow 1$.

In conclusion I express my thanks to Prof. B. Sen, D. Sc., for his kind help in the preparation of this paper.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 16, No. 4, APRIL, 1961

Flow of Condensing Vapour with Temporary Supersaturated State due to Heat-Removal Effect

By Keishiro NIU

Department of Physics, Faculty of Science,
Tokyo Metropolitan University, Tokyo

(Received November 4, 1960)

This paper deals with the flow of a condensing vapour. The vapour flow in a pipe of constant cross-sectional area with heat-removal effect through the pipe walls has the temporary supersaturated state in the supersonic flow by the effect of surface tension of the droplets which are born in the vapour. In case when the fluid is maintained continually in the supersaturated state, the ratio of the increase in relative humidity to the increase in Mach number or to the decrease in pressure is greater in the flow with heat-removal than in the adiabatic flow. Numerical calculations have been carried out for an example of the flow with definite initial conditions and the region where the condensation shock takes place is predicted theoretically.

§ 1. Introduction

Some studies have been made on the condensation phenomena of the fluid caused by the adiabatic expansion in diverging nozzles[1)-4)], but only few have been done on the same phenomena caused by the heat-removal effect[5)].

In a previous paper[6)], the writer has analysed the flow pattern in the case when the water vapour flows through a pipe of constant cross-sectional area, assuming that there occurs the heat-exchange between the vapour and the pipe wall and that the vapour is kept always in the thermodynamical equilibrium state. The phase change from gas to liquid of the vapour occurs after the fluid reaches the saturated state. In reality, however, a supersaturated state appears in the supersonic flow, since the surface tension of the droplets born in the vapour acts to obstruct the rapid transition of phase. Such a supersaturated state continues for a while, but, owing to the successive heat-removal the temperature of the vapour goes on to decrease and the degree of supersaturation of the fluid reaches ultimately a critical value. Then this unstable state breaks down abruptly and the considerable amount of vapour in the flow changes its phase from gas to liquid. We call the region where this abrupt change occurs the "condensation shock".

In the present paper, we shall investigate the flow pattern in the supersonic flow, by taking account of the appearance of supersaturated state.

§ 2. Flow in Thermodynamical Equilibrium State

For the sake of reference we shall first recapitulate briefly the results obtained in the previous paper[6)]. If we suppose that the fluid is kept always in the thermodynamical equilibrium state, the conservation equations of mass, momentum and energy can be written down for the inviscid vapour flow through a pipe of constant cross-sectional area in case when the heat-exchange occurs between the fluid and the pipe wall. If, then, we take into account the equation of state as well as the proportionality-relation between the enthalpy and the temperature for the ideal gas, the solutions of these conservation equations for the case where the condensation does not occur in the fluid are given by

$$U=\frac{\mu C_P(P_e+m'U_e)\pm\sqrt{\mu^2C_P{}^2(P_e+m'U_e)^2+m'^2R(2\mu C_P-R)(2h'-2H_e-U_e{}^2)}}{m'(2\mu C_P-R)}\,, \tag{1}$$

$$T=(2H_e+U_e{}^2-2h'-U^2)/2C_P\,, \tag{2}$$

$$P=m'RT/\mu U\,. \tag{3}$$

Here, U is the velocity, T the temperature, P the pressure, H the enthalpy, C_P the specific heat at constant pressure, μ the molecular weight of the fluid, R the universal gas constant (R in the previous paper having been replaced here by μR), m' the rate of mass flow through the unit sectional area and h' the removed heat quantity divided by the rate of mass flow. The subscript e refers to the values at the entrance section.

When a part of the vapour condenses so that both the gas and liquid phases coexist in the flow, we can obtain the solutions of the conservation equations by taking into account the following conditions, in addition to the ones for the non-condensing case, that the pressure at the section under consideration is equal to the saturated one, the density of the liquid phase is a known function of the temperature and the enthalpy of the liquid is a linear function of the temperature. Thus we have

$$\begin{aligned}&\frac{\mu\kappa_0 P_S(T)^2}{m'^2RT}+\left\{1+\frac{P_e\rho_L(T)}{m'^2}-\frac{U_e\rho_L(T)}{m'}\right\}\frac{\mu\kappa_0 P_S(T)}{RT\rho_L(T)}+\left\{\frac{1}{2m'^2}-\frac{\mu(C_P-\kappa)}{m'^2R}\right\}P_S(T)^2\\&\qquad-\left[\frac{P_e}{m'^2}+\frac{U_e}{m'}+\left\{1-\frac{P_e\rho_L(T)}{m'^2}-\frac{U_e\rho_L(T)}{m'}\right\}\frac{\mu(C_P-\kappa)}{R\rho_L(T)}\right]P_S(T)+\kappa T\\&\qquad=H_e-\frac{P_e^2}{2m'^2}-\frac{P_eU_e}{m'}-\kappa_0-h'\,,\end{aligned}\tag{4}$$

$$P=P_S(T)\,,\tag{5}$$

$$U=U_e+(P_e-P)/m'\,,\tag{6}$$

where $P_S(T)$ is the saturated vapour pressure, $\rho_L(T)$ the density of liquid phase and κ_0, κ are the coefficients of the zeroth and the first orders of the temperature in the linear relation of the enthalpy of liquid phase, respectively.

Thus, for the equilibrium flow, T, P, U and etc. can be obtained in terms of the parameter h'. When we take into account the appearance of supersaturated state in the flow, however, the variables characterizing the flow depend on the time and cannot be settled by the numerical value of h' only. Consequently, the flow pattern cannot be analysed unless h' is given as a function of the distance measured along the pipe axis from the entrance section.

In this paper, first we assume the pressure distribution in the fluid which is considered to flow down continuously without condensation regardless of the amount of heat-removal, instead of giving h' as a function of the distance defined above. In this case, it is convenient to use, instead of Eqs. (1), (2) and (3), the following equation:

$$h'=\left(\frac{\mu C_P}{R}-\frac{1}{2}\right)\frac{P^2}{m'^2}+\left(\frac{P_e}{m'}+U_e-\frac{\mu C_PU_e}{R}-\frac{\mu C_PP_e}{Rm'}\right)\frac{P}{m'}+H_e-\frac{P_e}{2m'^2}-\frac{P_eU_e}{m'}\,,\tag{7}$$

$$U=U_e+(P_e-P)/m'\,,\tag{8}$$

$$T=\mu PU/m'R\,,\tag{9}$$

then, h' can be obtained from Eq. (7) as a function of the said distance through the known distribution of P.

§ 3. Relation between Relative Humidity and Mach Number or Pressure

If the vapour is in the saturated or supersaturated state and has not sufficient nuclei for condensation, the gaseous molecule must combine with each other so as to form a cluster which develops to a nucleus. Namely, the vapour has to self-nucleate. However, Gibbs' free energy of the cluster is increased by the effect of the surface tension, and the smaller the cluster is, the greater is the rate of increase of the free energy due to the surface tension. Consequently, even if the vapour be in the supersaturated state of rather high degree, the rapid phase transition from gas to liquid would be forbidden by the barrier of high free energy of the clusters which are very small in the early stage of condensation process. Thus we can observe the appearance of supersaturated state in the supersonic flow where all phenomena must be changed during a very short time-duration.

In this section, we shall investigate the relation between the relative humidity and the Mach number or pressure, assuming that the supersaturated state is maintained continuously in the flow as long as we concern.

The Clausius-Clapeyron relation between the temperature T and the saturated vapour pressure P_S is given by

$$\frac{P_S}{P_S{}^*}=\exp\left\{\frac{\mu L}{RT^*}\left(1-\frac{T^*}{T}\right)\right\}, \tag{10}$$

where L is the latent heat of vaporization which is assumed to be constant, and the superscript $*$ refers to the values at the sonic state.

On the other hand, the relation between the Mach number M and the temperature T for the one-dimensional flow in a pipe of constant cross-sectional area in case when there occurs heat-exchange between the fluid and the pipe wall is given by Howarth[7] as follows:

$$\frac{T^*}{T}=\frac{(1+\gamma M^2)^2}{(1+\gamma)^2M^2}, \tag{11}$$

where γ is the adiabatic exponent of the vapour. Accordingly, the relation between the relative humidity and the Mach number for this case is given by

$$\frac{\varphi}{\varphi^*}\equiv\frac{P/P_S}{P^*/P_S{}^*}=\frac{P}{P^*}\exp\left[\frac{\mu L}{RT^*}\left\{\frac{(1+\gamma M^2)^2}{(1+\gamma)^2M^2}-1\right\}\right], \tag{12}$$

The corresponding relation for the one-dimensional flow whose change is caused exclusively by the adiabatic expansion or compression is given by Wegener and Mack[3] as follows:

$$\frac{\varphi}{\varphi^*}=\frac{P}{P^*}\exp\left\{\frac{\mu L(\gamma-1)}{RT^*(\gamma+1)}(M^2-1)\right\}. \tag{13}$$

From these two relations (12) and (13) it will be seen that the ratio of the increase in relative humidy to the increase in Mach number is greater in the flow with heat-exchange than in the adiabatic flow, provided that the change in P is neglected.

As described in § 2, we first employ the pressure distribution along the pipe axis, and enquire after in either case of the above two the change in relative humidity is larger for the same pressure distribution. To this end we shall discuss the relation between M and P, instead of the direct one between φ and P, for the two cases.

According to Howarth[7] we have

$$\frac{P^*}{P}=\frac{1+\gamma M^2}{1+\gamma} \quad \text{namely} \quad M^2=\frac{(1+\gamma)P^*}{\gamma P}-\frac{1}{\gamma} \tag{14}$$

for the one-dimensional flow with heat-exchange, and

$$\frac{P^*}{P}=\left\{\frac{2}{\gamma+1}\left(1+\frac{\gamma-1}{2}M^2\right)\right\}^{\gamma/(\gamma-1)} \quad \text{namely} \quad M^2=\frac{\gamma+1}{\gamma-1}\left(\frac{P^*}{P}\right)^{(\gamma-1)/\gamma}-\frac{2}{\gamma-1} \tag{15}$$

for the corresponding adiabatic flow. From these relations we obtain the values of $dM^2/d(P/P^*)$ as:

$$\frac{1+\gamma}{\gamma} \quad \text{and} \quad \frac{1+\gamma}{\gamma}\frac{1}{(P^*/P)^{1/\gamma}}, \tag{16}$$

respectively. The inequality $P^*/P>1$ holds always in the supersonic flow, so that we can infer from (16) that the ratio of the increase in M^2 to the increase in P^*/P or to the decrease in P itself is larger in the flow with heat-removal than in the flow with adiabatic expansion. Thus this conclusion, together with the result obtained from the relations (12) and (13), implies that in case when the same uniformly decreasing pressure distribution is supposed, the high degree of supersaturation is realized faster in the flow with heat-removal than in the flow with adiabatic expansion.

§ 4. Conservation Equation

In § 3, we have studied the relation between the relative humidity and the Mach number or pressure, assuming that the vapour does not condense after it had been in the supersaturated state. In reality, however, if the degree of supersaturation of the fluid exceeds a certain critical value, this unstable state will be ultimately broken down and consequently the appearance of the considerable amount of liquid phase can be observed by sudden condensation. The mass fraction of the condensed phase of the fluid immediately before and after this abrupt change must be quite different from the one for the equilibrium case. Accordingly, the variables which characterize the flow pattern cannot be obtained from Eqs. (4), (5) and (6) for such a case in our problem.

Here we use the mass fraction of condensed phase q defined as:

$$q=m_L'/m' , \tag{17}$$

where m_L' is the rate of mass flow of condensed phase through the unit sectional area. Then q would increase in company with the increase in h' when the fluid flows downstream. If this q can be known by some considerations of the flow which deviates from the equilibrium one, we can easily obtain the flow variables by solving the conservation equations, instead of using Eqs. (4), (5) and (6). The conservation equations involving q of the mass, momentum and energy in the form of differential equations for the one-dimentional flow which passes through a pipe of constant cross-sectional area with heat-removal effect are written down respectively as

$$\frac{d\rho'}{\rho'}+\frac{dU}{U}=0 , \tag{18}$$

$$-\rho' U dU=dP , \tag{19}$$

$$UdU+C_P dT-d(qL)=-dh' , \tag{20}$$

and the equation of state is also given by

$$\frac{dP}{P}=\frac{d\rho'}{\rho'}+\frac{dT}{T}-\frac{dq}{1-q} . \tag{21}$$

Here, ρ' is the mean fluid density of the gaseous and liquid phases and L the latent heat of vaporization which is given by the difference of the enthalpy of gaseous phase from that of liquid phase as

$$L=(C_P-\kappa)T-\kappa_0 . \tag{22}$$

From the above five equations, we have

$$dU=\frac{1}{\dfrac{U}{\{C_P-(C_P-\kappa)q\}T}+\dfrac{1}{U}-\dfrac{m'}{P}}\left[\frac{\{(C_P-\kappa)T-\kappa_0\}dq-dh'}{\{C_P-(C_P-\kappa)q\}T}-\frac{dq}{1-q}\right] , \tag{23}$$

$$dT=\frac{\{(C_P-\kappa)T-\kappa_0\}dq-UdU-dh'}{C_P-(C_P-\kappa)q} , \tag{24}$$

$$dP=-m'dU , \tag{25}$$

and by successive uses of these equations, we can calculate the values of U, T and P step by step.

§ 5. Mass Fraction of Condensed Phase

In the supersonic flow in which the condensation phenomena are obliged to occur during a very short time-duration, the number of dusts in ordinary vapours is too small to form the nuclei for condensation which play an essential role to break out the supersaturated state. Owing to this result, the nuclei must be supplied by the self-nucleation of vapour. Then the mass fraction of condensed phase q is changed by the following two reasons: first by the self-nucleation and secondly by the growth of the droplets which were born at the preceding sections. In the fluid flow between the interval x and $x+dx$ which are measured from a standard section along the pipe-axis, these changes of mass fraction of condensed phase, described by dq_1 and dq_2 respectively, are given by

$$dq_1=\frac{4}{3m'}\pi\rho_L r_*^3 J dx\ , \tag{26}$$

$$dq_2=\frac{4}{3m'}\pi\rho_L \sum_k \{(r_k+dr_k)^3-r_k^3\}J_k dx_k\ , \tag{27}$$

$$dq=dq_1+dq_2\ , \tag{28}$$

where J is the number of self-nucleation per unit time and unit volume, J_k is the mean rate of self-nucleation in the flow between x_k and x_k+dx_k, r_* is the radius of nucleus of condensation, r_k is the radius of a droplet at x which was born at x_k and grew up during its movement from x_k to x and dr_k is the increase in the radius of the same droplet during its movement along a distance of dx. The radius of nucleus is expressed by[3),8)]

$$r_*=\frac{2\sigma\mu}{\rho_L RT\ln P/P_S}\ , \tag{29}$$

where σ is the surface tension which is given by a semi-empirical expression due to Eötvös and Ramsay-Schield[3),8)] as:

$$\sigma=\frac{\text{const}}{(\mu/\rho_L)^{2/3}}(T_c-T)\ . \tag{30}$$

Here, T_c is the critical temperature of the vapour.

Volmer[9)], Becker and Döring[10)], Frenkel[8)] and others proposed the expressions for the rate of self-nucleation respectively, but these expressions were proved to be practically equivalent to each others.[11,12)] In this paper, we employ Frenkel's one:

$$J=\left(\frac{2}{\pi}\right)^{1/2}\frac{A^{3/2}(\sigma\mu)^{1/2}}{R^2\rho_L}\left(\frac{P}{T}\right)^2\exp\left\{-\frac{16\pi}{3kR^2}\left(\frac{\mu}{\rho_L}\right)^2\left(\frac{\sigma}{T}\right)^3\frac{1}{\ln^2 P/P_S}\right\}\ , \tag{31}$$

where A is the Avogadro number and k is the Boltzmann constant.

So far some investigations have also been made on the growth of the droplet. Oswatitsch ingeniously analysed the adiabatic flow by calculating the growth velocity of the droplet on the basis of the temperature gradient at its surface[13)]. But the density gradient of the vapour due to the absorption of vapour molecules at the droplet surface gives rise directly to the growth of the droplet, though the temperature gradient is buit up conversely by the rate of condensation of the vapour on the droplet. Therefore, with a little modification, we shall follow Wilde's reasoning that the growth velocity of the droplet depends upon the concentration gradient[14)]. Namely, we suppose that the surface of the droplet which exists in the supersaturated vapour is surrounded by the saturated vapour with the pressure $P_S(T)$. Then, Wilde's first approximation is modified to

$$dr_k=\frac{\mu D}{\rho_L RT}\{P-P_S(T)\}\frac{dx}{Ur_k}\ . \tag{32}$$

The coefficient of self-diffusion D is given by[15)]

$$D=\frac{3(RT)^{3/2}}{8(\pi\mu)^{1/2}A\omega^2P}\,, \tag{33}$$

where ω is the effective diameter of molecular collision. Substituting Eq. (33) into Eq. (32), we get the expression for the growth of the droplet as follows:

$$dr_k=\frac{3(\mu R)^{1/2}}{8\pi^{1/2}A\rho_L\omega^2}\left\{1-\frac{P_S(T)}{P}\right\}\frac{T^{1/2}dx}{Ur_k}\,. \tag{34}$$

§ 6. Numerical Discussion

Making use of the results in the preceding two sections, we can analyse the flow in the region where the fluid is not in the equilibrium state. Thus, carrying out numerical calculations, we shall investigate how the flow pattern obtained in the writer's previous paper is altered in the supersonic branch. Water vapour has been chosen as the fluid, and as in the previous paper the following initial values for the flow have been adopted: $P_e=152$ cm Hg $=2.02\times10^6$ dyne cm^{-2}, $T_e=200°\text{C}=473°\text{K}$ and $M_e=1$, from which we have obtained $U_e=5.39\times10^4$ cm sec^{-1}, $\rho_e=9.27\times10^{-4}$ gram cm^{-3}, $m'=5.00\times10$ gram cm^{-2} sec^{-1}. The thermodynamic relations and constants used in this paper are: $P_S(T)=4.98\times10^{11}\exp(-4.89\times10^3/T)$ dyne cm^{-2}, $\kappa=4.19\times10^7$ erg gram^{-1} deg^{-1}, $\kappa_0=-3.13\times10^{10}$ erg gram^{-1}, $\rho_L=\text{const}=1$ gram cm^{-3}, $R=8.31\times10^7$ erg deg^{-1} mol^{-1}, $k=1.37\times10^{-16}$ erg deg^{-1}, $C_P=1.86\times10^7$ erg gram deg^{-1}, $\gamma=1.33$ and $\omega=3.26\times10^{-8}$ cm. Values of the surface tension have been obtained from the existing table[16], instead of calculating them by the use of Eq. (30).

With these values and relations, Eqs. (23)~(25), (27)~(29), (31) and (34) are now reduced respectively to

$$dU=\frac{1}{\dfrac{U}{(1.86\times10^7+2.33\times10^7q)T}+\dfrac{1}{U}-\dfrac{500}{P}}\left\{\frac{(3.13\times10^{10}-2.33\times10^7T)dq-dh'}{(1.86\times10^7+2.33\times10^7q)T}-\frac{dq}{1-q}\right\},$$

$$dT=\frac{(3.13\times10^{10}-2.33\times10^7T)dq-UdU-dh'}{1.86\times10^7+2.33\times10^7q}\,,$$

$$dP=-50.0\times dU\,,$$

$$dq_1=8.38\times10^{-2}r_*^3Jdx\,,$$

$$dq_2=8.38\times10^{-2}\sum_k\{(r_k+dr_k)^3-r_k^3\}J_kdx_k\,,$$

$$r_*=\frac{1.88\times10^{-7}\sigma}{T\log P/P_S}\,,$$

$$\log J=20.36+\frac{1}{2}\log\sigma+2\log P-2\log T-\frac{4.69\times10^2\sigma^3}{T^3\log^2 P/P_S}\,,$$

$$(r_k+dr)^2=r_k^2+2.53\times10^{-5}\left\{1-\frac{P_S(T)}{P}\right\}\frac{\sqrt{T}}{U}dx\,.$$

As described in the preceding sections, we have first given the pressure distribution of the non-condensing vapour and then h' has been determined as a function of x. The pressure distribution used in the present paper is that given by Winnie and Wood's wind tunnel experiment[17]. In Fig. 1 are plotted this pressure P and the corresponding removed heat quantity h' which has been calculated from Eq. (7). The distance x in this figure has been measured from the sonic section. P, T and U for both the equilibrium flow and the non-condensing one are shown in Fig. 2 corresponding to the distribution of h' in Fig. 1. From this figure it will readily be seen that the condensation starts at $x=2.6$ cm in equilibrium flow.

If we take account of the appearance of supersaturated state in the condensing flow, the rate of self-nucleation J, the total number of droplets per unit volume n and the mass fraction of condensed phase q are obtained as shown in Fig. 3. The resulting pressure P, temperature T and velocity U become as shown in Fig. 4, from which it will be seen that, in a very narrow region of 0.2 cm length whose center is at $x=4.8$ cm, the supersaturated state, which has been held from $x=2.6$ cm, is broken down abruptly and a considerable amount of the mass of gaseous phase changes to liquid phase discontinuously. For this region, the term "condensation shock" is used ordinarily. The fluid which behaved as if it were the non-candensing vapour after it was fallen in the supersaturated state is brought back to the nature of equilibrium flow by passing through this condensation shock.

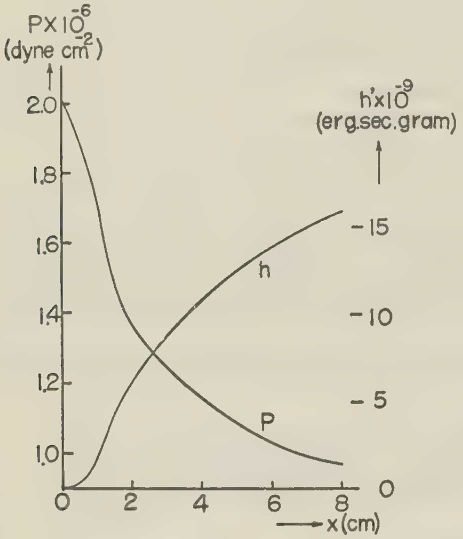

Fig. 1. The pressure distribution given by Winnie and Wood's wind tunnel experiment and the removed heat quantity as calculated from this pressure distribution.

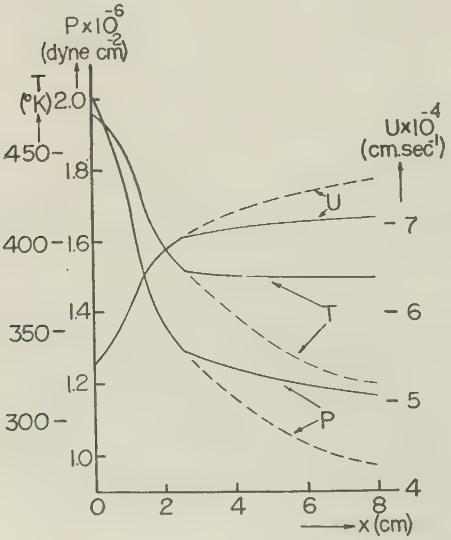

Fig. 2. The pressure, temperature and velocity for the equilibrium flow (continuous line) and for the non-condensing flow (broken line).

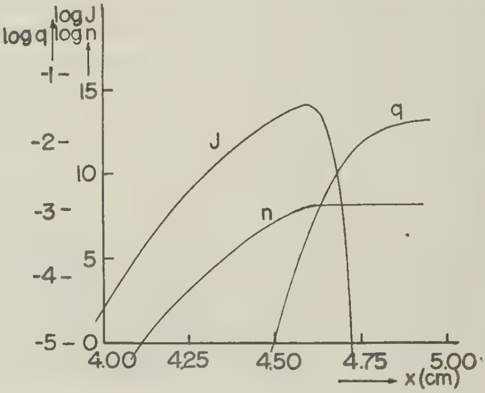

Fig. 3. The rate of self-nucleation, total number of droplets per unit volume and mass fraction of condensed phase.

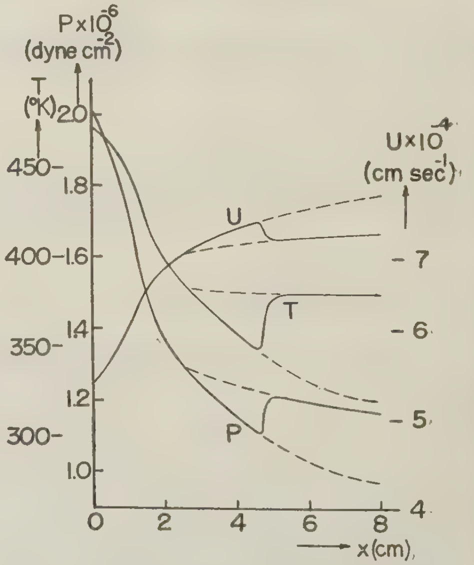

Fig. 4. The resulting pressure, temperature and velocity curves.

A Simplified Method Calculating The Laminar Boundary Layer

By Shin KAWAMATA

The Aeronautical Research Institute, University of Tokyo

(Received December 1, 1960)

A somewhat simplified method calculating the steady and incompressible laminar boundary layer flow is developed basing on the idea of the "local similarity". The analysis is performed by using the variables proposed by Goertler[1]. The calculated results are utilized to predict the separation points in some decelerated flows and the comparison with other exact solutions shows that the value of the "similar parameter" may be taken as -0.224 at the separation points in this method.

The fundamental equations for the steady incompressible laminar boundary layer flow with an arbitrary pressure gradient in two-dimensions are:

Equation of continuity

$$\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}=0\,, \tag{1}$$

and Equation of motion

$$u\frac{\partial u}{\partial x}+v\frac{\partial u}{\partial y}=u_1\frac{du_1}{dx}+\nu\frac{\partial^2 u}{\partial y}\,, \tag{2}$$

where x, y are the Cartesian coordinates measured along and normal to the body surface, and u, v the velocity components in x- and y-directions, respectively, u_1 the velocity outside the boundary layer, and ν is the kinematic viscosity which is constant. The boundary conditions are

$$\left.\begin{array}{lll} u=v=0\,, & \text{at} & y=0\,, \\ u\to u_1 & \text{at} & y\to\infty\,. \end{array}\right\} \tag{3}$$

Eq. (1) can be satisfied by the introduction of the stream function $\overline{\Psi}$ which is defined as follows:

$$u=\frac{\partial\overline{\Psi}}{\partial y}\,, \qquad v=-\frac{\partial\overline{\Psi}}{\partial x} \tag{4}$$

Then the following non-dimensional variables are introduced:

$$\left.\begin{aligned} &\xi=\frac{1}{\nu}\int_0^x u_1dx\ , \quad \eta=\frac{u_1y}{\nu}\ , \quad \psi=\frac{1}{\nu}\overline{\Psi}\ , \\ &\zeta=\frac{\eta}{\sqrt{2\xi}}\ , \qquad f(\xi,\eta)=\frac{\psi}{\sqrt{2\xi}} \end{aligned}\right\} \tag{5}$$

With these variables, Eq. (2) and the boundary conditions (3) are transformed into the form

$$f_{\zeta\zeta\zeta}+ff_{\zeta\zeta}+g(\xi)(1-f_\zeta{}^2)=2\xi(f_\zeta f_{\xi\zeta}-f_\xi f_{\zeta\zeta})\ , \tag{6}$$

and

$$\left.\begin{aligned} &f(\xi,0)=f_\zeta(\xi,0)=0\ , \\ &f_\zeta(\xi,\infty)\rightarrow 1\ , \end{aligned}\right\} \tag{7}$$

where $g(\xi)=2\xi d\log u_1/d\xi$.

With the conditions (7), the integration of (6) with respect to ζ from 0 to ∞ gives

$$2\xi\frac{d\Theta}{d\xi}+[1+g(1+H)]\Theta=(f_{\zeta\zeta})_{\zeta=0}\ , \tag{8}$$

where

$$\Theta=\int_0^\infty f_\zeta(1-f_\zeta)d\zeta\ , \text{ and } H\Theta=\int_0^\infty(1-f_\zeta)d\zeta\ .$$

Now, in the case of similar flow, f is the function of ζ only, the right-hand side of Eq. (6) vanishes, and $g(\xi)$ is reduced to a constant independent of ξ, which is called the Falkner-Skan parameter[2], hereafter denoted by β in this paper. For more general flows, the Falkner-Skan parameter does not exist in the strict sense, but it seems reasonable to treat β as a parameter varying slowly with x or ξ.

In this approximation, the Eq. (6) may still be written in the form

$$f_{\zeta\zeta\zeta}+ff_{\zeta\zeta}+\beta(1-f_\zeta{}^2)=0\ , \tag{9}$$

or upon integration

$$[1+\beta(1+H)]\Theta=(f_{\zeta\zeta})_{\zeta=0}\ . \tag{9$'$}$$

Equating Eqs. (8) and (9′), we have

$$2\xi\frac{d\Theta}{d\xi}+(1+H)(g-\beta)\Theta=0\ . \tag{10}$$

Solving for β, we obtain

$$\beta=g+\xi\frac{d\log\Theta^2}{d\xi}\Big/(1+H)\ . \tag{11}$$

Now, the quantity, Θ is a slowly varying function of x, and can be calculated in good approximation by the formula[3]

$$\Theta^2=0.22\,u_1{}^{-4}\int_0^x u_1{}^5dx\Big/\int_0^x u_1dx \tag{12}$$

Then the modified Pohlhausen parameter

$$m=-\frac{\theta^2}{\nu}\frac{du_1}{dx}$$

is calculated in terms of Θ and u_1, where Θ is the momentum thickness, and H is found as a function of m by using the table given by Curle and Skan[4]. Finally we get β from Eq. (11). Once β is determined as a function of x, the velocity profile and skin friction are given numerically by using Howarth's tables[5].

With a view to determining the condition at separation point, the present method of calculation has been applied to some retarded flows, and the value of β are calculated for which the exact or approximate solutions are available. The results are shown in the following table.

u_1/U	separation point x/L	$-\beta$
$1-x/L$	0.120 (H., T.)	0.220
	0.125 (G.)	0.227
$1-(x/L)^2$	0.268 (T.)	0.225
	0.271 (G.)	0.226
$1-(x/L)^4$	0.451 (T.)	0.227
	0.462 (G.)	0.254
$1-(x/L)^8$	0.640 (T.)	0.284
	0.630	0.224
$(1+x/L)^{-1}$	0.159 (G.)	0.222

Here U and L are the reference velocity and length, and the capital letters H, T and G denote the positions of separation point calculated by L. Howarth[5], I. Tani[3] and H. Goertler[1], respectively. It is noticed from these results that the values of β at the separation point are almost the same except the flow of the fourth case of the above table. Omitting this case and taking the arithmetical mean, we have the average value -0.224 for β at the separation point. This result can be utilized for rapidly determining the separation point for a given velocity distribution $u_1(x)$. First, g and Θ are determined as functions of x. Then, they are substituted in Eq. (11), where the value $\beta=-0.224$, and $H=3.55$ which is nearly constant in the vicinity of separation point, are used. The solution of the resulting equation gives the value of x for the separation point. The accuracy of this method determining the separation point seems to be very good. Even when applied to the fourth case of the foregoing table, it gives $(x/L)_{\text{sep}}=0.630$, which is in error of only 1.5 per cent compared with the exact value.

The author is indebted to Dr. Itiro Tani, Professor of Aeronautical Research Institute, University of Tokyo, for his supervision and encouragement during the course of the study.

Refractive Index and Pore Structure of Acid-Leached Surface Layer of Glass

By Koreo KINOSITA

Department of Physics and Chemistry, Gakushuin University,
Mejiro, Tokyo

(Received December 22, 1960)

It is known that acids leach out metal ions from the outermost layer of glass, leaving a skeleton film. We found that the refractive index of such a film n_f changes with the relative humidity p/p_0, and studied n_f *vs.* p/p_0 relations for some dense flint and dense crown glasses. The following conclusions are derived from the analysis of n_f *vs.* p/p_0 curves: (1) The refractive index of the skeleton n_s ($>n_f$) is always greater than that of fused silica, indicating that metal ions are still contained in the skeleton. (2) The porosity of the film ranges from 0.05 to 0.21, and the mean pore radius from 6Å to 23Å, depending on the composition of glass as well as the leaching conditions.

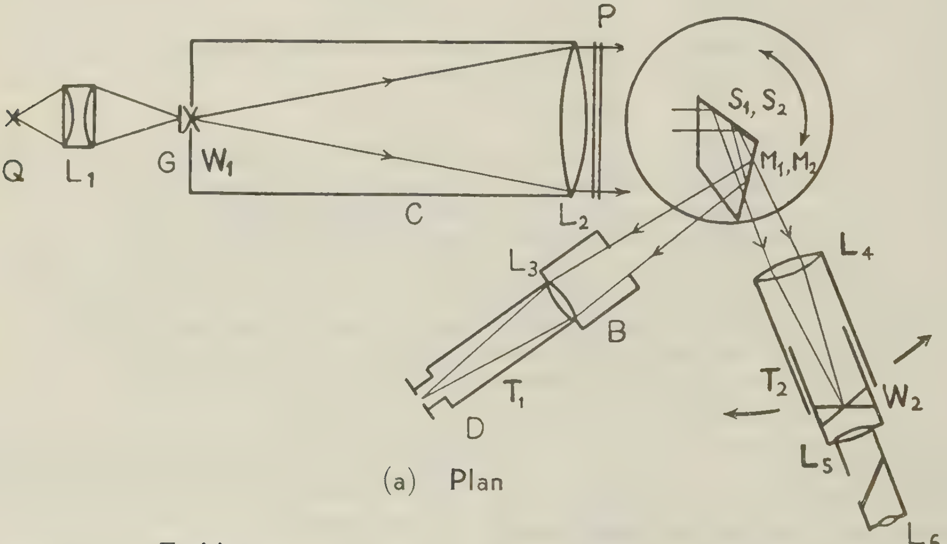
§ 1. Introduction

According to the widely accepted view[1], the action of acid and alkaline solutions and water on glass can be summarized, in the main, as follows. Acids leach out the alkali and other metal ions from the outermost layer of glass, leaving a porous film of silica skeleton. This surface layer is often recognized by the interference of light, because its index of refraction is lower than that of the bulk of the glass. The reaction of glass with alkaline solution, on the other hand, resembles that with diluted hydrofluoric acid. NaOH, for instance, breaks the existing –Si–O–Si– bond in glass by forming –Si–O–Na, HO–Si– units. Thus the surface layer of glass as a whole is dissolved into the solution. The action of plenty of water is similar to that of acids: it leaches out alkali (and sometimes other metal) ions from the surface layer, only to a lesser extent. If, however, a water droplet is left on the glass surface, the leached out alkali ions remain on the surface and the reaction assumes the characteristics of an alkaline attack.

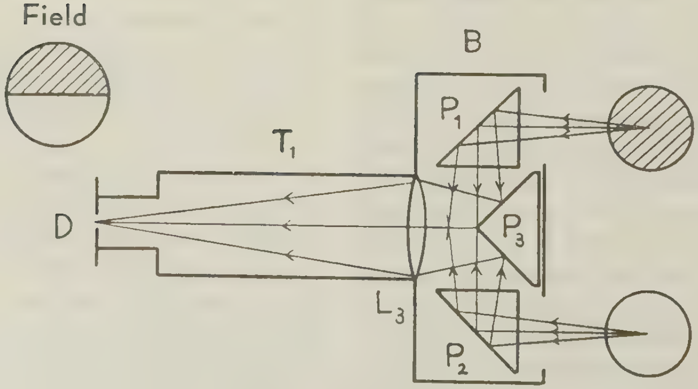
These phenomena are in close relation with what is known as *yake* (pronounced yah-keh) among the Japanese opticians. *Yake* is a general term for those spontaneously deteriorated areas of a glass surface which differ in reflectivity, scattering power and other properties from the original surface. English word for *yake* would be *stain* (*s*) or *tarnishing*. Frequent outbreak of *yake* on lenses in the manufacturing process, especially in the warm and humid summer season, has been an obstacle to the optical industry of this country.

Yake is classified into two categories: *aoyake* (ah-oh-yah-keh) and *shiroyake* (shee-roh-yah-keh). The former denotes the stains, coloured often amber or purple-blue by the interference of light, which actually are the patches on the glass surface where a surface layer similra to that obtained by acid or water leaching has been formed. The latter represents the white stains which are the patches where light is scattered by small crystallites adhering to the glass surface or by minute irregularities of the surface. It has been found that these crystallites are carbonates, hydroxides and/or other salts of the metals leached out from the glass[2),3),4)].

An extensive study of *yake* by collaboration of a number of physicists and chemists was started around 1955 upon request of the Japan Camera Research Association. As it seemed to me that the most promising approach to the elucidation of the nature of spontaneously developed *yake* was the systematic re-examination by newer techniques of the corrosion of glass by liquid etchants, the work in this laboratory was decided to proceed along this line[5)-8)]. Some workers followed the same line[3),4),9)-14)], some wrestled with the problem of atmospheric attack directly[15)], some looked for sensitive methods for detecting the slightest *aoyake*[16)-18)], and others were engaged in more practical investigations including the search for an effective protecting film to be applied to lens surfaces during the manufacturing process for the prevention of *yake*[19)]. This collaboration was finished in 1959 after making valuable contributions to the optical industry of this country, but still there are many problems left unsolved. Some of these are now being investigated in this laboratory.



(a) Plan



(b) Elevation of B and T_1

Fig. 1. Apparatus for studying relation between n_f and p/p_0. Q: sodium lamp. C: collimator (G: diffuser, W_1: cross wires). P: polarizer. S_1: reference test piece. S_2: test piece with *aoyake* layer. M_1, M_2: plane mirrors. B: prism box (P_1, P_2: rectangular prisms, P_3: aluminized roof prism (field splitter), T_1: tubing with viewing lens L_3). T_2: telescope for reading angle of incidence (W_2: cross wires).

The present paper deals with a recent experiment on the variation with relative humidity of the refractive index of surface layers artificially produced by acid treatment on some dense flint and dense crown glasses. For brevity, such layers shall be called the *aoyake* layers in the following. This variation in refractive index is ascribed to the multilayer adsorption of water vapour on the pore walls of the *aoyake* layer; and the *porosity* (fractional pore volume) as well as the *mean pore radius* are estimated from the refractive index *vs.* relative humidity relations.

§ 2. Experimental Procedures

a) *Measurement of refractive index*

According to the polarimetric study by Tsunekane and Doi[11], the refractive index of the *aoyake* layer is quite uniform throughout its depth. This justifies the application of Abelès's method[20] to the measurement of the refractive index of the *aoyake* layer, n_f. We carried out in 1958 a series of measurements by this method[8], when we found that n_f underwent an observable change if the sample was desiccated or moistened. At once we decided on undertaking a systematic investigation of the humidity dependence of n_f.

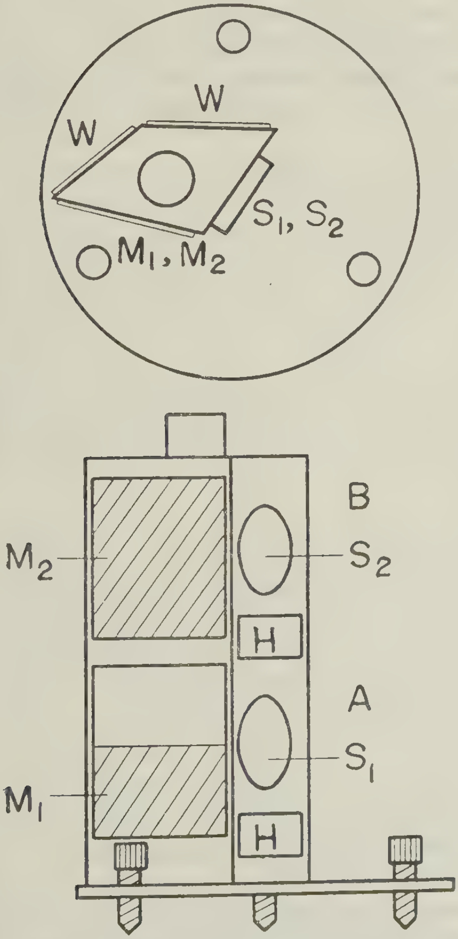


Fig. 2. Sample chamber with air-tight compartments A and B. S_1: reference test piece. S_2: test piece with *aoyake* layer. W: plan-parallel windows. M_1, M_2: plane mirrors. H: gate for inserting humidity controlling agent.

In the experiment cited above our specimen was of the form usually employed in this type of measurement–a glass disk, one half of the surface of which had been subjected to acid attack while the other half was left as freshly polished, with a clear line of demarcation between the two halves. But this was apparently inadequate for the new project, in which it was required to keep the conditions of the reference, or uncoated, surface constant while we change at our will the humidity of the ambient atmosphere of the *aoyake* layer. So we determined on separating the test piece into two, a reference piece S_1 without any surface layer and another piece S_2 of the same kind of glass coated by the *aoyake* layer; and for carrying out the measurement according to Abelès's principle we constructed a new double-head instrument[21]. Later we improved it adopting Traub and Osterberg's idea[22]. A brief description of the improved instrument is given below (see Figs. 1 and 2).

Monochromatic light from a sodium lamp Q, after being collimated and polarized in the *p*-direction*, is allowed to fall on the test pieces S_1 and S_2 which are stored in airtight compartments A and B of the sample chamber (Fig. 2). The sample chamber is mounted on the prism disk of an old spectrometer. Compartment A in which the reference piece S_1 is stored is desiccated throughout the experiment by means of anhydrous phosphoric acid. The test piece on which the *aoyake* layer has been formed, S_2, is enclosed in the other compartment B, and the humidity in this compartment is controlled by keeping appropriate chemicals in it (see § 2 *c*). It is essential to keep the surfaces to be examined of S_1 and S_2 in one and the same plane which is parallel to the revolving axis of the spectrometer. The beams reflected by S_1 and S_2 are again reflected by plane mirrors M_1 and M_2. The last beams take a fixed direction irrespective of the angle of incidence to S_1 and S_2 of the beam from the collimator, and can enter the fixed prism box B. It was found convenient to set M_1 and M_2 at an angle of 110° with S_1 and S_2. The aluminized mirrors M_1 and M_2 are protected by SiO_2 coating. The upper half of M_1 is left transparent, so that a part of the beam from S_1 can go right on and enter a movable telescope T_2. T_2 serves for the precise determination of the angle of incidence. The sample chamber is furnished with plan-parallel windows W, faced at right angles to the beams which fall on and are reflected by S_1 and S_2 at an angle of 56° ($\tan^{-1} 1.483$).

---

* The transmission axis of the polarizer was set within **1′** of the *p*-direction with the aid of Kinosita-Nomura's half-shade device[23].

The beams which enter the prism box B, after being reflected by small rectangular prisms P_1 and P_2, fall on an aluminized *roof prism* P_3 which works as a field splitter. Thus if one observes through a pinhole D at the end of the tubing T_1 the lower and upper halves of the field are seen illuminated by the beams reflected from S_1 and S_2 respectively, with a clear line of demarcation between the two halves. The viewing lens L_3 is focussed on S_1 and S_2.

The method of measurement is quite simple. Observing through D, one adjusts the angle of incidence of the beam from C to S_1 and S_2 by rotating the prism disk until no difference can be recognized in the brightness of the two halves of the field. The angle of incidence φ at this stage can be accurately determined by means of the movable telescope T_2. It is known that[20])

$$\tan\varphi = n_f\,. \tag{1}$$

b) *Preparation of test pieces*

Chemical compositions and refractive indices of the glasses under test are given in Table I. A1 and B1 are commercial optical glasses*, while A2 and A3 are test glasses specially prepared for the study of *yake*.

Table I. Compositions (wt %) and refractive indices (n_D) of glasses under test.

Glass	Composition									n_D
	SiO_2	B_2O_3	Na_2O	K_2O	BaO	PbO	Al_2O_3	Bi_2O_3	As_2O_3	
A1 (analyzed*)	32.4		0.6	1.6		64.6	0.2	0.33		1.760
A2 (calc. from batch)	29.7					70.0			0.3	1.777
A3 (calc. from batch)	29.7			1.0		69.0			0.3	1.771
B1 (analyzed*)	37.1	15.7	0.4		39.5		6.1			1.589

* By the courtesy of Prof. S. Tsuchihashi, University of Kobe.

Test pieces are freshly polished disks, 32 mm in diameter and 3~5 mm in thickness. The top and back surfaces of the test piece make an angle of 2° with each other, in order that the back reflection can be avoided in the measurement of n_f. Techniques for the preservation of the test pieces as well as the cleaning and the leaching treatments have been described previously[5]) (see also Kinosita[24])). The leaching was stopped when the *aoyake* layer showed the sensitive colour of the first order ($n_f d \sim 145\,\text{m}\mu$, where d is the thickness). As was discussed previously[21]), the sensitivity of Abelès's method reaches its maximum at this optical thickness. The test pieces were then rinsed with water, dehydrated with distilled alcohol, and were set in the sample chamber.

c) *Humidity control*

The relative pressure p/p_0 of water vapour in the compartment B, in which the leached test piece S_2 is stored, is controlled by enclosing one of the agents given below in it (see International Critical Tables, Vol. I, p. 67 (1926)):

H_2O $NaCO_3 \cdot 10H_2O$ $NaCl$
NH_4NO_3 $K_2CO_3 \cdot 2H_3O$ $MgCl_2 \cdot 6H_2O$
$ZnCl_2 \cdot 1\frac{1}{2}H_2O$ P_2O_5

It takes some considerable time (of the order of an hour) for the equilibrium value of p/p_0 to be reached in the compartment. For later reference, the variation of p/p_0 with the lapse of time was investigated with the aid of the humidity- and temperature-pick-up of a "Minima" Electric Hygrometer* sealed in the compartment. The time lag of the indication of the hygrometer is believed to be of the order of minutes.

---

* A1 and B1 correspond to Schott SF3 and SK5 respectively.

§ 3. Dependence of n_f on p/p_0

a) Preliminary experiment

The test piece on which an *aoyake* layer had been formed and another test piece of the same glass free from *aoyake* were enclosed in the compartments B and A respectively, one of the humidity controlling agents was inserted in B, and the change with time of n_f was observed. It took some time, say several tens of minutes, for n_f to reach the equilibrium value. A part of this time lag may possibly be attributed to the time required for the completion of adsorption, but the greater part can be ascribed to the time required for the equilibrium in p/p_0 to be established in the compartment B (see the end of § 2 *c*)).

A series of such experiments lead to the conclusion that a wait of one and a half hours was enough for obtaining the equilibrium value of n_f for all agents but H_2O (equil. $p/p_0=1.00$), which needed a longer wait.

On the basis of these preliminary experiments, the equilibrium values of n_f for respective values of p/p_0 between 0.00 and 1.00 were systematically investigated.

b) Experiments with the glasses A1, A2 and A3

The results for the glasses A1, A2 and A3 are illustrated in Fig. 3.

The test pieces were attacked by 0.001 *N* NHO_3, at 60°C. The measurement was started at $p/p_0=0.00$. The relative vapour pressure was then raised step by step up to 1.00 ((1)→), after which it was lowered again step by step down to 0.00 (←(2)). The second (down) run did not follow the path of the first (up) run, but n_f for $p/p_0=0.00$ at the end of the second run was identical with the initial value of n_f for $p/p_0=0.00$. Further up and down runs ((3)→, ←(4)) followed the path of the second run. It took about a week to complete these four runs for one sample.

The observation described above suggests that some structural change had occurred in the first and the second runs which took about four days, after which the layer was stabilized. In this stabilized or *aged* state, the change in the equilibrium value of n_f with the change in p/p_0 was remarkably reversible.

As was reported previously[8)], the absolute values of n_f of the samples prepared in one and the same way are accompanied by some individual fluctuations. But the general trends of the n_f *vs.* p/p_0 relations for the glasses A1, A2 and A3 are well represented by the curves shown in Fig. 3. They are strikingly similar.

c) Experiments with the glass B1

Two experiments were carried out with the glass B1. In the first experiment, the test piece was attacked by 0.001 *N* HNO_3 at 60°C, and in the second by 0.01 *N* HNO_3 at 60°C.

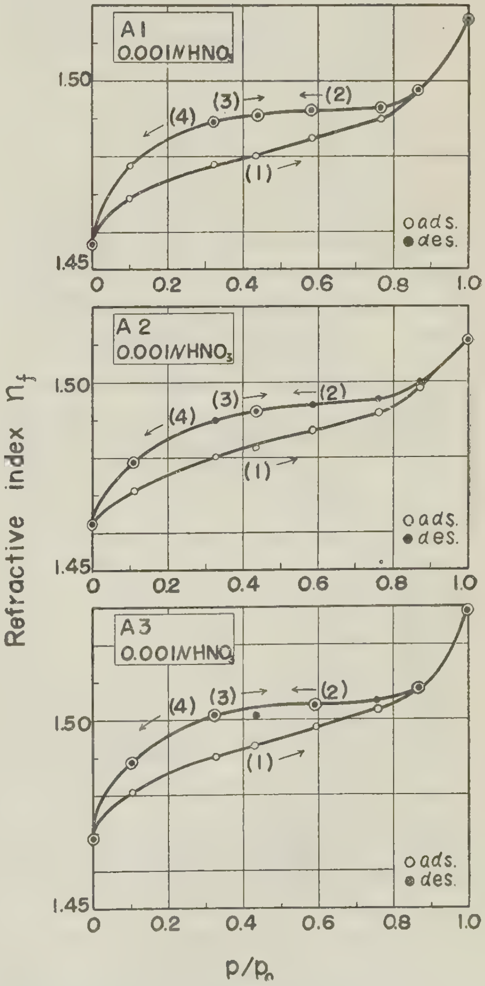

Fig. 3. n_f *vs.* p/p_0 relations for *aoyake* layers on dense flint glasses A1, A2 and A3. Attacked by 0.001 *N* HNO_3, 60°C. $n_f d \sim 145\,m\mu$.

---

* Originally devised by Prof. K. Shiba.

The n_f vs. p/p_0 relations for respective cases are shown in Fig. 4.

Fig. 4 again shows that the path of the second (down) run lies above that of the first (up) run. The third (up) and the fourth (down) runs were found to trace the path of the second run, just as was the case in *b*). One of the differences from the results for the glasses A1, A2 and A3 is that the value of n_f for $p/p_0=0.00$ at the end of the second run is higher than the initial value of n_f for $p/p_0=0.00$. Another difference is found in the form of the n_f vs. p/p_0 curves. The two curves in Fig. 4 are similar in general trends; but they are quite different from those of Fig. 3.

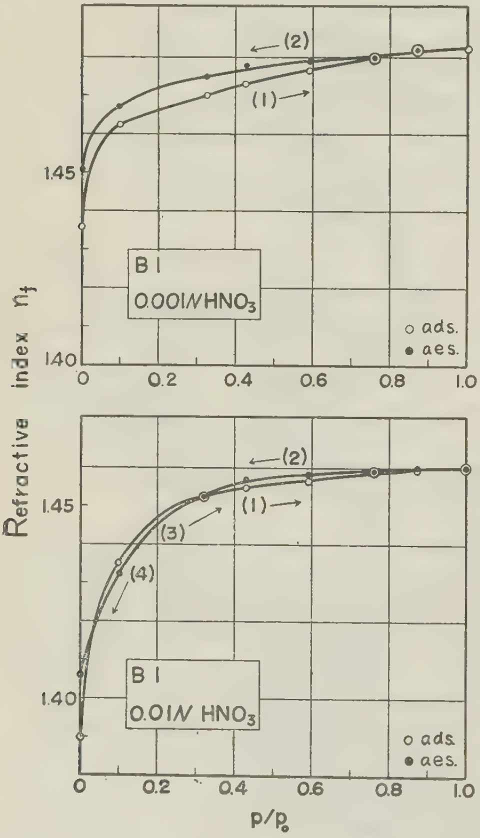

Fig. 4. n_f vs. p/p_0 relations for *aoyake* layers on dense crown glass B1. Attacked by 0.001 *N* HNO_3, 60°C and 0.01 *N* HNO_3, 60°C, resp. $n_f d \sim 145$ mμ.

§4. Estimation of the Parameters of the Pore Structure of the *Aoyake* Layer

It has been discussed[1),7)etc.] that the *aoyake*, from which the alkali and other metal ions have been leached out, is a porous skeleton layer. If this is admitted, the natural consequence will be to suppose that the above described variation in n_f is due to the change in the amount of water adsorbed on the walls of the pores as p/p_0 is varied. The resemblance of the n_f vs. p/p_0 curves in Figs. 3 and 4 to the adsorption isotherms of Type II and Type I (Brunauer, Deming, Deming and Teller's classification[25)]) also supports this view.

According to this idea, the *porosities*, the *refractive indices of the skeletons*, and the *mean pore radii* of the *aoyake* layers we have studied in §3 will be estimated below.

a) *Porosity q and the refractive index of the skeleton* n_s

The skeleton of the *aoyake* layer on a silicate glass has been believed[1)etc.] to be composed almost exclusively of silicic acid which contains some –Si–OH groups besides the original –Si–O–Si– bonds. According to our semi-quantitative spectral analysis[7)], however, it still contains some amount of metal ions which are the constituents of the original glass. Moreover, the skeleton may very probably contain some water, which cannot be desorbed even when p/p_0 is reduced to zero. *The mean refractive index of the skeleton as such* shall be denoted by n_s.

According to the idea mentioned above, the number of water molecules in the pore space will increase as p/p_0 is increased. If v is the volume in the pore space occupied by water at a given value of p/p_0 and v_0 is the total volume of the pores (for convenience' sake, v and v_0 shall be referred to the unit area of the *aoyake* layer), then the mean refractive index of the pore space n_p at that relative pressure will be given by

$$n_p=n_w\frac{v}{v_0}+n_a\left(1-\frac{v}{v_0}\right). \tag{2}$$

Here n_w stands for the refractive index of water, and n_a for that of air.

If V is the volume of the *aoyake* layer per unit area, the following equation will be derived by similar reasoning:

$$n_f=n_s\left(1-\frac{v_0}{v}\right)+n_p\frac{v_0}{v}, \tag{3}$$

or, in terms of the *porosity* of the layer $q=v_0/V$,

$$n_f=n_s(1-q)+n_p q. \tag{4}$$

Now, if we assume that

$$v=0 \quad \text{or} \quad n_p=n_a \quad \text{in case} \quad p/p_0=0.00$$

and

$$v=v_0 \quad \text{or} \quad n_p=n_w \quad \text{in case} \quad p/p_0=1.00\,,$$

we can calculate n_s and q from the observed values of n_f at $p/p_0=0.00$ and 1.00. The results are given in Table II, together with some other data. The numerical values under the headings F and A are those obtained from the lower and upper branches of the curves in Figs. 3 and 4 respectively, and are supposed to represent the properties of the "fresh" and "aged" *aoyake* layers respectively.

In the evaluation of n_s and q described above, it has been tacitly assumed that the *aoyake* layer does not swell nor contract ($V=$ const.) throughout the range of p/p_0. In order to see if it is the case, we examined the change with p/p_0 of the interference colour exhibited by the *aoyake* layer, which is determined by the optical thickness of the layer $n_f d$. It did change as p/p_0 was varied, but quantitative examination proved that this variation can be explained by the change in n_f (Figs. 3 and 4) alone. The interference method is fairly reliable if $n_f d \sim 145\,\mathrm{m}\mu$, which fortunately was the case in our samples. Hence it could be concluded that d, and consequently $V(=d\,\mathrm{cm}^3$ by definition), remains constant throughout the range of p/p_0.

b) *Mean pore radius* $\bar{r}$

As is seen from Eqs. (2) and (4), the relation between n_f and v (the volume of adsorbed water) is linear:

$$n_f=n_a q+n_s(1-q)+(n_w-n_a)\frac{v}{v_0}\,. \tag{5}$$

All parameters included in the right side are known except v_0. The last parameter is at once obtained as*

$$v_0=qV=qd\,. \tag{6}$$

If we plot v as calculated from Eq. (5) against p/p_0, we get the *adsorption isotherms***. (Note that v is the volume as liquid). Figs. 5 and 6 show the adsorption isotherms obtained in this way from Figs. 3 and 4 respectively. The isotherms in Fig. 5 belong to Type II, and those in Fig. 6 to Type I.

Now, let us estimate the total area of the pore walls s by the method of Brunauer, Emmett and Teller[26]. For this, we assume that the adsorption in these cases is multimolecular and obeys the BET equation of multimolecular physical adsorption on a free surface

$$\frac{p}{v(p_0-p)}=\frac{1}{v_m c}+\frac{c-1}{v_m c}\frac{p}{p_0} \tag{7}$$

at low pressures. Eq. (7) includes two parameters, v_m and c: v_m is the so-called monolayer capacity, *i.e.*, the volume of vapour adsorbed when the entire surface of the pores is covered with a complete unimolecular layer; and

$$c=\exp.(E_1-E_L)/RT\,, \tag{8}$$

where E_1 is the heat of adsorption of the first layer, E_L is the latent heat of condensation of vapour, and R and T are the usual constants.

Table II. Properties of acid-leached *aoyake* layers on glasses A1, A2, A3 and B1, as estimated from n_f vs. p/p_0 relations. As for headings F and A, see text.

Glass		Leaching treatment		Index of film n_f at $p/p_0=0.7$	Index of skeleton n_s	Porosity q	Mean pore radius $\bar{r}$ (Å)
Notation	n_D						
A1	1.760	0.001 N HNO_3, 60°C	F A	1.489 1.492	1.558 1.558	0.183 0.183	23 11
A2	1.777	0.001 N HNO_3, 60°C	F A	1.490 1.495	1.541 1.541	0.144 0.144	18 12

B1	1.589	0.01 N HNO_3, 60°C	F A	1.458 1.459	1.494 1.464	0.213 0.123	9 6

---

* The value of d was obtained by dividing the optical thickness $n_f d$, as determined by the interference colour method, by n_f.

** To be exact, it must be admitted that our sample chamber was not thermostatted. But the temperature fluctuation in it seldom exceeded 1°.

If we transform the v *vs.* p/p_0 curves in Figs. 5 and 6 into $p/v(p_0-p)$ *vs.* p/p_0 curves, we find that these can be well approximated by straight lines at low pressures, as demanded by the Brunauer, Emmett and Teller procedure. From these straight lines c and v_m can be found for respective cases*; and from the values of v_m, s can be calculated taking the adsorption cross section of a water molecule as 10.5Å².

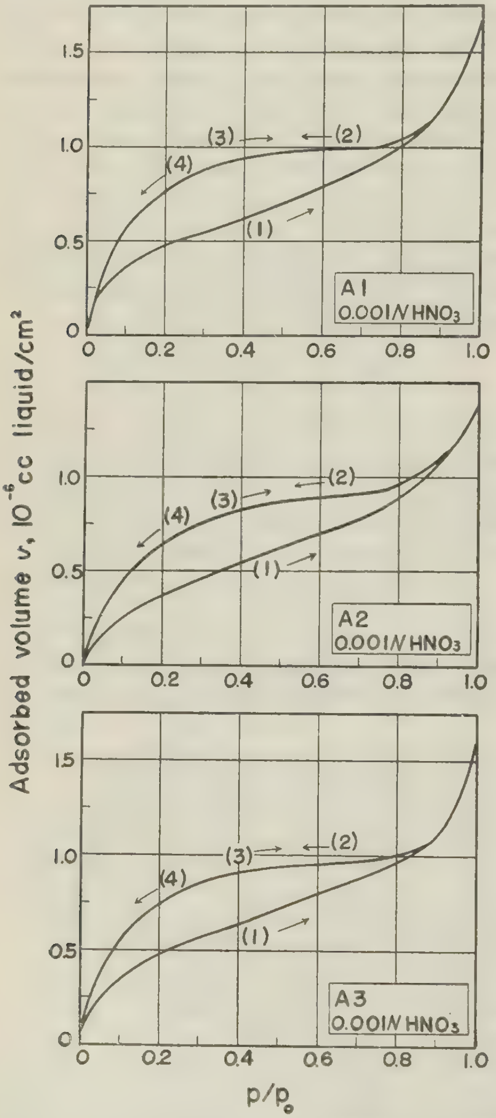

Fig. 5. Adsorption isotherms for *aoyake* layers on glasses A1, A2 and A3. Obtained from Fig. 3.

Now, if we assume for simlicity that the pores are of cylindrical form, s and v_0 are given by

$$s=2\pi\bar{r}l \quad \text{and} \quad v_0=\pi\bar{r}^2l\,, \tag{9}$$

where $\bar{r}$ is the *mean radius*, and l the *total length* of the pores. From the above relations it follows that

$$\bar{r}=2v_0/s\,. \tag{10}$$

The values of the mean pore radius evaluated in this way are given in the last column of Table II.

c) Distribution of pore radius

There is a quite different approach to the evaluation of the pore size, which is based on the capillary condensation theory. The equilibrium vapour pressure p over the meniscus of a liquid filling a capillary of radius r is lower than the normal vapour pressure of the liquid p_0, and is given by the Kelvin equation

$$\log(p/p_0)=-2\sigma V_L/rRT\,, \tag{11}$$

where σ and V_L represent the surface tension and the molar volume of the liquid respectively. Let us assume that at pressure p all capillaries whose radii are smaller than r as

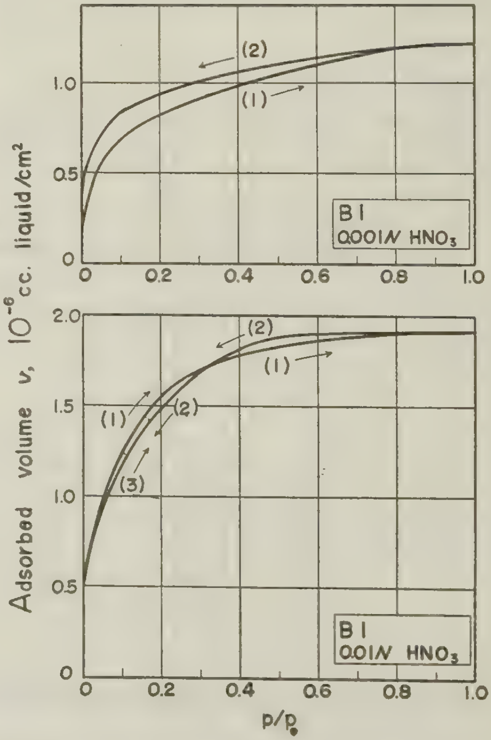

Fig. 6. Adsorption isotherms for *aoyake* layers on glass B1. Obtained from Fig. 4.

---

* The obtained values of v_m (as liquid) range from 0.41 to 1.30×10^{-6} cm³ per unit area of the *aoyake* layer. The values of c range from 11 to 56, which corresponds to $E_1-E_L=1.4\sim2.4$ kcal/mole.

given by Eq. (11) are filled with condensed adsorbate, while larger capillaries are left empty. Then we can transform the adsorption isotherm into a v *vs.* r curve, the ordinate of which represents the volume of liquid condensed in the pores of radii smaller than r. It is more convenient to plot v/v_0 against log r, according to Kubelka[27]. If we differentiate the v/v_0 *vs.* log r curve (the *integral structural curve*) by log r, we get the *differential structural curve*, the ordinate of which is proportional to the frequency of occurrence of the capillaries having radii whose natural logarithms lie between $\log r$ and $\log r + d\log r$.

Our measurements are not so minute as to allow the exact differentiation of the integral structure curves, but if we venture, we get Figs. 7 and 8. The results can be no more than qualitative, but we can get some idea of the pore size distribution from these curves.

The agreement with the estimation of the mean pore radii described in *b*) is not satisfactory, but we would have to be satisfied at this degree of agreement if we consider that the two estimates are based on quite different premises, not to mention the poor reliability of Figs. 7 and 8.

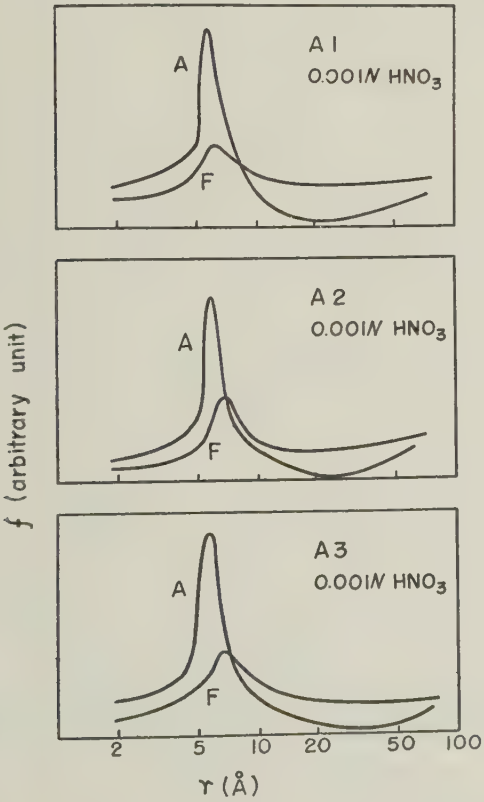

Fig. 7. Differential structural curves for glasses A1, A2 and A3. Obtained from Fig. 5. $f = d(v/v_0)/d(\log r)$.

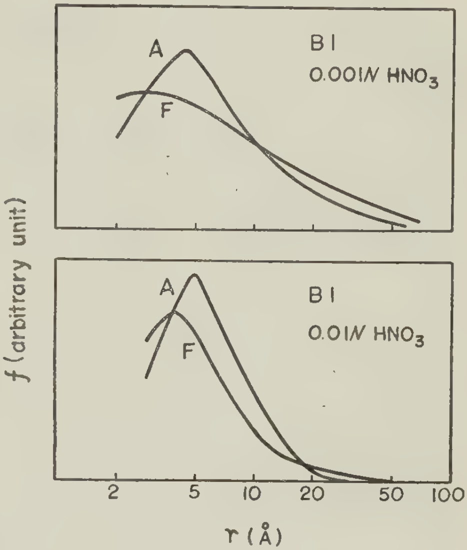

Fig. 8. Differential structural curves for glass B1. Obtained from Fig. 6. $f = d(v/v_0)/d(\log r)$.

§ 5. Discussions

a) n_s and n_f

The present work is believed to be the first attempt to determine n_s, the *refractive index of the skeleton* of an acid-leached surface layer of glass (*aoyake* layer). This has to be distinguished from n_f, the refractive index of the layer as a whole.

The values of n_f of well-developed *aoyake* layers hitherto published[28]–[32]etc.*, as well as the published[11],[13],[17] and unpublished data obtained in our collaboration 1955–59, are scattered between 1.42 and 1.58, most of which being concentrated around 1.47. As the last value is very close to the refractive index of fused silica, 1.46, this has been regarded as evidence in favour of the theory that the well-developed *aoyake* layer is a silica skeleton film, from which the metal ions contained in the original glass has been leached out almost completely. The present work has revealed that this is misinterpretation. The fact is that the refractive index of the material of the *aoyake* layer, or the skeleton, is much higher (see Table II), indicating that a considerable amount of metal ions are still present in the skeleton. The usual method of measurement of the refractive index of the *aoyake* layer gives nothing but the *mean index of the skeleton and the pore space*, which in most cases is close to 1.47. This is demonstrated by the values of n_f at $p/p_0=0.70$ given in Table II.

---

* As regards the interpretation of Bishop's[30] and Hara's[32] results, see Kinosita[33].

This view is consistent with the results of our semi-quantitative spectral analysis of *aoyake* layers[7]. It seems that Anderson and Kimpton's measurement[31] of the infrared spectral reflectivity of the *aoyake* layer also supports this view.

b) *Estimation of the pore structure*

Much has been discussed about the porous nature of the *aoyake* layer. Few, if any, measurements of porosity and pore size have been attempted, in so far as the *aoyake* layer on the polished surface is concerned.

The only data which are to be compared with ours would be those of Russian workers. They seem to have done much in this field, but little is known in this country. In a paper contributed to the Conference on the Structure of Glass, Leningrad, 1953[34], Zhdanov quotes a few estimations of porosities and predominant pore radii of acid-leached surface layers on optical glasses. These are cited in Table III. The estimation is based on "adsorption methods" (volumetric or gravimetric measurements with powdered samples ?). The *predominant radius* is conjectured to have been evaluated from the *differential structural curve*. His values seem to be consistent with ours.

Table III. Porosities and pore radii of acid-leached surface layers on optical glasses estimated by adsorption methods. Zhdanov[34].

Glass	Porosity q	Predominant pore radius (Å)
F3	0.07	<8
BK10	0.12	<8
K1	0.26	<8

Recently Watanabe, Noake and Aiba[35], in their study on microphases in glass, tried an electron microscopic study of the surfaces of some borosilicate glasses which had been subjected to acid attack after heat treatment, and observed small cavities which are believed to have come into existence because of local differences in solubility. The size of the cavities is increased by heat treatment: in air-cooled samples they are of a size of 100Å or less and only a few can be recognized in the electron micrograph*, while in the samples subjected to prolonged heat treatment they are larger and are seen scattered all over the the surface. In our opinion, these "cavities" are the same in their nature as the openings of the "pores" we have been discussing. It is desirable to observe by electron microscopy the openings of the pores in the *aoyake* layers on ordinary polished glass surfaces. For this, however, an essential improvement in the resolving power would be indispensable.

Before concluding this sub-section, an estimate of the area covered by openings of the pores will be given. From either of Eqs. (9) we can calculate l, the total length of the pores. The pores are supposed to form a most complicated labyrinth in the *aoyake* layer, but if we venture to assume that the mean length of a pore is twice the thickness of the layer, we can evaluate the number of pores, and hence the area covered by openings of the pores in the unit area of the surface. This turns out to be 0.03~0.11—not unreasonable.

c) *Further discussions on the pore structure*

It is remarkable that the adsorption isotherms for the dense flint glasses A1, A2 and A3 (Fig. 5) are of the same type, while those for the dense crown glass B1 (Fig. 6) belong to another type. The two isotherms for B1 are much alike notwithstanding the dfference in leaching conditions. These features suggest that the type of the adsorption isotherm is primarily determined by the composition of glass.

This assumpion certainly needs further experimental verifications**, but seems to be highly probable if one admits that the skeletonization of the surface layer of glass is caused by selective dissolution of those microphases in the glass which are easily attacked by acid. The presence of such microphases in the glass, or the microheterogeneous structure of glass, has been keenly discussed by Russian workers[34]; Watanabe's work[35] is also concerned in this problem. According to these workers, the composition and the thermal history of glass determine the chemical nature and the size of soluble (and insoluble) microphases. It will be natural to consider that these in turn will determine the structure characteristics of the *aoyake*. It is known that the adsorption isotherm is highly sensitive to variations in structure characteristics of porous adsorbents.

---

* The resolution of the replicas was of the order of 100Å.

** The adsorption isothem of the *aoyake* on a lantern crown glass, which is now under investigation, seems to belong to Type V isotherm.

The branching of the isoterm (Figs. 5 and 6) is another point to be discussed. The second (down) run goes along a path which differs from that of the first (up) run; further runs follow the path of the second run. This suggests, as was mentioned previously, that some irreversible change—aging—has occurred during the first and the second runs. According to the analysis (Table II), $\bar{r}$ is smaller in the aged layer than in the fresh one. In the glasses A1, A2 and A3 q and n_s are not affected by aging, while in the glass B1 the values of both parameters (especially q) are decreased. Corresponding to these situations, the total length of pores l increases by a factor of 2∼4 in the former glasses, while in the latter the increase of l is not marked.

What kind of irreversible process would have occurred in the *aoyake*, which results in in such structure changes? One of the possible answers would be the following. There are numerous Si–OHg roups in the *aoyake* which have been formed by the hydrolysis of Si–O–X bonds, where X is either an alkali or an alkali earth ion. Whenever two Si–OH groups react with the liberation of water, a strong Si–O–Si bond will be formed which draws two SiO_4 groups closer together. According to Weyl[1], this process can take place at room temperatures*. If it does, the consequent irregular shrinkage of the skeleton may give birth to numerous finer cracks, which will decrease the mean pore radius $\bar{r}$. The total shrinkage of the layer could possibly be so small that the resulting decrease in d cannot be recognized by observation of the interference colour. In some situations it might happen that some water is trapped in the skeleton in the process of deformation, which cannot escape even at $p/p_0=0.00$. Such trapped water will decrease n_s.

Another possible irreversible change which might have occurred in the *aoyake* layers of our samples is the acid attack by NO_3^- ions still left in the layers after rinsing.

There was particular reason why we carried out two experiments on the glass B1, one with the test piece attacked by 0.001 N HNO_3 and another by 0.01 N HNO_3. In our study of the growth rate of the *aoyake* layer[8], we found for this glass that d increases in proportion to $t^{0.4}$ (t is the duration of acid treatment) if the sample is attacked by 0.001 N HNO_3, while d increases in proportion to t if attacked by 0.01 N HNO_3**. This suggested that there would be a substantial difference between the structures of the *aoyake* layers developed by respective treatments. The result, however, was rather contrary to our expectation. The adsorption isotherms were of the same type; and the mean pore radii were almost identical. The only difference was found in that the porosity q and the fractional area covered by pore openings (see the end of § 5 *b*)) were twice as large in the latter case (attack by 0.01 N HNO_3) as in the former case (0.001 N).

It need hardly be said that the study of the growth mechanism of the *aoyake* layer should be based on the knowledge of its pore structure. We have to do much, however, before we can put the study on the right track. At the present status of our knowledge we cannot so much as estimate the resistance experienced by a metallic ion when it goes through a pore of a radius of the order of 10Å.

d) *Application of the method to other fields*

We have developed in this work a method of estimation of the pore structure of a transparent porous film, which is based on the observation of the change in its refractive index due to adsorption of vapour. This method may find applications in other fields, *e.g.*, in the study of the pore structures of evaporated films of transparent materials.

Cordial thanks are due to Mr. Kohzo Natsume, who used to be my assistant, for his collaboration in a series of studies of *yake* on which the present work is founded; and to

---

* It is well known that this aging process can be greatly accelerated by baking the *aoyake*[36].

** If the rate determining process is diffusion of ions through the layer, it is expected that $d \propto t^{0.5}$.

Miss Mizuko Yoshida, Mr. Kiyoshi Ito and Mr. Mitsuo Sasaki who assisted me in the experimental part of this work.

Diffraction of Plane Sound Wave by Many Equal Circular Holes Arbitrarily Distributed in an Infinitely Large Rigid Plane Plate

By Yûkichi NOMURA
Department of Applied Science, Tôhoku University,
and Tadao OSANAI
Department of Education, Tôhoku University

(Received December 28, 1960)

The solution of the problem, when the holes do not overlap but are distributed arbitrarily in one plane, is obtained by the method of expansion in hypergeometrical polynomials. Formulae of some physical quantities concerned are given. In the case of normal incidence, we also give approximate formulae which are valid when the wave length is large in comparison with the radius.

§ 1. Introduction

The problem of diffracttion of plane wave by a circular plate or circular hole has been solved by Meixner and Andrejewsky[1], Bouwkamp[2], Nimura[3], and other authors by making use of spheroidal coordinates and spheroidal wave functions. One of the present authors[4),5] has succeeded in solving the same problem by using cylindrical coordinates, the discontinuous integral of Weber-Schafheitlin, and the expansion by hypergeometrical polynomials. Following this method, in the familiar coordinate system, and utilizing the addition theorem of Bessel function, we can also solve by perturbation the case of many circular plates or circular holes. In the previous paper[6], we have treated the case of two equal non-overlapping circular holes made in a rigid plane plate. Now we show that the calculation can be easily adapted to the case of any number of non-overlapping equal circular holes arbitrarily distributed in one plane.

By the results, we know that the series of successive approximation, being the functions of wave length and its ratios to the distances between the centres of the holes, has good convergency if the wave length is large.

§ 2. General Solution

Let x, y-axes of rectangular coordinates lie in the rigid plane, origin being arbitrarily taken in this plane. The centres of the circular holes with the same radius a, can be denoted by x_l, y_l ($l=1, 2, 3, \cdots, \mathrm{N}$), or more conveniently by polar coordinates ϖ_l, ψ_l. We denote the distance from the centre x_l, y_l to any other centre $x_{l'}$, $y_{l'}$ by $aq_{l'l}$, its direction from the x-axis being indicated by the angle $\psi_{l'l}$. Cf. Fig. 1.:

$$aq_{l'l}=\sqrt{(x_{l'}-x_l)^2+(y_{l'}-y_l)^2}>2a\ ,$$

$$\cos\psi_{l'l}=\frac{x_{l'}-x_l}{aq_{l'l}}\ ,\qquad \sin\psi_{l'l}=\frac{y_{l'}-y_l}{aq_{l'l}}\ .$$

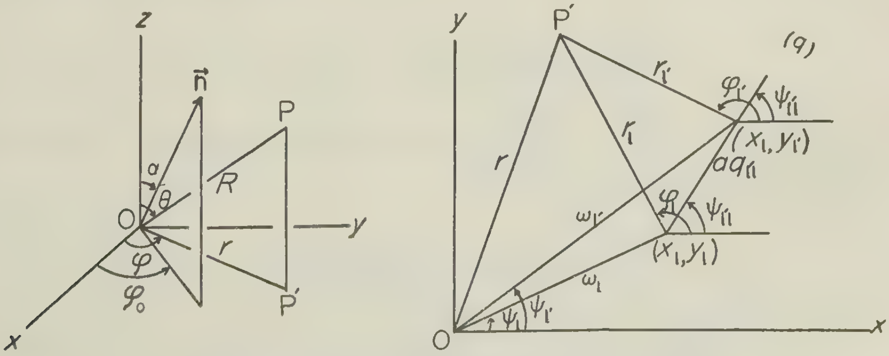

Fig. 1.

Any point P shall be indicated by the polar coordinates R, θ, φ, or more conveniently by the cylindrical ones r, φ, z. The distance from the l-th centre to the point $P'(r, \varphi, 0)$ shall be denoted by r_l. We shall suppose that a plane sound wave comes, whose normal is expressed by unit vector

$$\vec{n}(\sin\alpha\cos\varphi_0, \sin\alpha\sin\varphi_0, \cos\alpha) \ .$$

When the velocity potential for the acoustic field is expressed by $\Phi e^{i\omega t}$, Φ must satisfy the following wave equation:

$$(\nabla^2+k^2)\Phi=0 \ , \tag{1}$$

where $k=(\omega/c)=(2\pi/\lambda)$ in which c is the propagation velocity of sound and λ the wave length.

In the present case, we can put

$$\Phi=\begin{cases} \Phi_0+\overline{\Phi}_0+\sum\limits_{l=1}^{N}\Phi_l \ , & z<0 \\ \sum\limits_{l=1}^{N}\Phi_l \ , & z>0 \end{cases} \tag{2}$$

where Φ_0 and $\overline{\Phi}_0$ are the velocity potential of the incident and the reflected wave respectively,

$$\begin{aligned}\Phi_0&=C\exp\{-ikz\cos\alpha-ikr\sin\alpha\cos(\varphi-\varphi_0)\}\\ &=C\exp\{-ikz\cos\alpha-ik\varpi_l\sin\alpha\cos(\psi_l-\varphi_0)-ikr_l\sin\alpha\cos(\varphi_l-\varphi_0)\}\\ &=C\exp(-ikz\cos\alpha)\sum_{m=0}^{\infty}(2)_m(-i)^m J_m(kr\sin\alpha)\cos m(\varphi-\varphi_0)\\ &=C\exp\{-ikz\cos\alpha-ik\varpi_l\sin\alpha\cos(\psi_l-\varphi_0)\}\sum_{m=0}^{\infty}(2)_m(-i)^m J_m(kr_l\sin\alpha)\cos m(\varphi_l-\varphi_0) \ ,\end{aligned} \tag{3}$$

$$\begin{aligned}\overline{\Phi}_0&=C\exp\{ikz\cos\alpha-ikr\sin\alpha\cos(\varphi-\varphi_0)\}\\ &=C\exp\{ikz\cos\alpha-ik\varpi_l\sin\alpha\cos(\psi_l-\varphi_0)-ikr_l\sin\alpha\cos(\varphi_l-\varphi_0)\} \ ,\end{aligned} \tag{4}$$

and $\sum\limits_{l=1}^{N}\Phi_l$ is that of the scattered wave,

$$\Phi_l=\sum_{s=0}^{\infty}\Phi_l^{(s)} \ , \tag{5}$$

$$\Phi_l^{(s)}=\pm C\sum_{m=0}^{\infty}\sum_{n=0}^{\infty}({}_lA_{mn}^{(s)}\cos m\varphi_l+{}_lB_{mn}^{(s)}\sin m\varphi_l)S_{mn}(r_l, \mp z) \ , \qquad z\gtrless 0 \tag{6}$$

$$S_{mn}(r_l, \mp z)=\int_0^{\infty}\frac{\sqrt{\xi}\,J_m((r_l/a)\xi)\,J_{m+2n+(1/2)}(\xi)}{\sqrt{\xi^2-(ka)^2}}\exp\left\{\mp\sqrt{\xi^2-(ka)^2}\frac{z}{a}\right\}d\xi \tag{7}$$

in which $\Phi_l^{(0)}$ represents the scattered potential due to the l-th hole only, and $\sum\limits_{l=1}^{N}\Phi_l^{(s)}$ the s-th perturbed potential.

§ 3. Boundary Conditions

On the plate where $z=0$ and $r_l>a$ (for all $l=1, 2, 3, \cdots, N$), $\partial\Phi/\partial z$ must vanish. And, in the holes where $z=0$ and $r_l<a$ (for any $l=1, 2, 3, \cdots, N$), $\partial\Phi/\partial z$ and Φ must be continuous.

Since

$$\left[\frac{\partial S_{mn}(r_l, \mp z)}{\partial z}\right]_{z=0}=0 \ , \qquad r_l>a \tag{8}$$

we see that $[\partial\Phi/\partial z]_{z=0}=0$, provided that $r_l>a$. And since $\pm(\partial S_{mn}/\partial z)$ is continuous for $z=0$, we see that $\partial\Phi/\partial z$ is continuous in the holes.

The condition of the continuity of Φ is

$$[\Phi_0+\overline{\Phi}_0]_{z=0}+\left[\sum_{l=0}^{N}\Phi_l\right]_{z=-0}=\left[\sum_{l=1}^{N}\Phi_l\right]_{z=+0} \ ,$$

i.e.

$$[\Phi_0]_{z=0}=\left[\sum_{l=1}^{N}\Phi_l\right]_{z=+0}=\left[\sum_{l=1}^{N}\sum_{s=0}^{\infty}\Phi_l^{(s)}\right]_{z=+0} \ , \tag{9}$$

which shall be satisfied, provided

$$r_l<a: \qquad [\Phi_l{}^{(0)}]_{z=+0}=[\Phi_0]_{z=0}\ , \tag{10}$$

$$[\Phi_l{}^{(s)}]_{z=+0}=-\sum_{l'=1}^{N}{}' \,[\Phi_{l'}^{(s-1)}]_{z=+0}\ , \qquad s=1,2,3,\cdots \tag{11}$$

where Σ' means the summation excluding $l'=l$.

§4. Determination of the Constants

From the condition (10), we have

$$\begin{aligned}&C\sum_{m=0}^{\infty}\sum_{n=0}^{\infty}({}_lA_{mn}^{(0)}\cos m\varphi_l+{}_lB_{mn}^{(0)}\sin m\varphi_l)S_{mn}(r_l,0)\\ &=C\exp\{-ik\varpi_l\sin\alpha\cos(\psi_l-\varphi_0)\}\sum_{m=0}^{\infty}(2)_m(-i)^m J_m(kr_l\sin\alpha)\cos m(\varphi_l-\varphi_0)\ .\end{aligned} \tag{12}$$

If we utilize the hypergeometrical polynomials(7)

$$\left.\begin{aligned}u_n{}^m(x)&=x^{-m/2}\int_0^{\infty}\frac{J_m(\sqrt{x}\,\xi)J_{m+2n+(1/2)}(\xi)}{\sqrt{\xi}}\,d\xi\\ &=\frac{\Gamma(m+n+(1/2))}{n!\sqrt{2}\,\Gamma(m+1)}F(m+n+(1/2),-n,m+1;x)\\ &=\frac{\Gamma(m+n+(1/2))}{n!\sqrt{2}\,\Gamma(m+n+1)}x^{-m}(1-x)^{1/2}\frac{d^n}{dx^n}\{x^{m+n}(1-x)^{n-(1/2)}\}\ ,\end{aligned}\right]\quad 0<x<1 \tag{13}$$

we can expand any function $f_m(x)$ as follows;

$$f_m(x)=x^{m/2}\sum_{n=0}^{\infty}C_n{}^m u_n{}^m(x)\ , \tag{14}$$

where

$$C_n{}^m=\frac{\sqrt{2}\,(m+2n+(1/2))}{\Gamma(n+(1/2))}\int_0^1 x^{-(m/2)}f_m(x)\frac{d^n}{dx^n}\{x^{m+n}(1-x)^{n-(1/2)}\}\,dx\ . \tag{15}$$

Thus, we get

$$(2)_m(-i)^m J_m(kr_l\sin\alpha)=x^{m/2}\sum_{n=0}^{\infty}\beta_n{}^m u_n{}^m(x)\ , \tag{16}$$

$$S_{mn}(r_l,0)=x^{m/2}\sum_{\nu=0}^{\infty}G_{n\nu}^{m}u_\nu{}^m(x)\ , \tag{17}$$

where

$$x=\left(\frac{r_l}{a}\right)^2, \tag{18}$$

$$\beta_n{}^m=(2)_m(-i)^m(2m+4n+1)\frac{J_{m+2n+(1/2)}(ka\sin\alpha)}{\sqrt{ka\sin\alpha}}\ , \tag{19}$$

$$G_{n\nu}^{m}=(2m+4\nu+1)\int_0^{\infty}\frac{J_{m+2\nu+(1/2)}(\xi)J_{m+2n+(1/2)}(\xi)}{\sqrt{\xi^2-(ka)^2}}\,d\xi\ . \tag{20}$$

Therefore, (12) becomes

$$\begin{aligned}&C\sum_{m=0}^{\infty}\sum_{n=0}^{\infty}({}_lA_{mn}^{(0)}\cos m\varphi_l+{}_lB_{mn}^{(0)}\sin m\varphi_l)x^{m/2}\sum_{\nu=0}^{\infty}G_{n\nu}^{m}u_\nu{}^m(x)\\ &=C\exp\{-ik\varpi_l\sin\alpha\cos(\psi_l-\varphi_0)\}\sum_{m=0}^{\infty}x^{m/2}\sum_{n=0}^{\infty}\beta_n{}^m u_n{}^m(x)\{\cos m\varphi_l\cos m\varphi_0+\sin m\varphi_l\sin m\varphi_0\}\ ,\end{aligned}$$

from which we get, by interchanging the letters n and ν in the left hand side,

$$\sum_{\nu=0}^{\infty} G_{\nu n}^{m} \begin{matrix} {}_{l}A_{m\nu}^{(0)} \\ {}_{l}B_{m\nu}^{(0)} \end{matrix} = \beta_n^m \exp\{-ik\varpi_{l}\sin\alpha\cos(\psi_l-\varphi_0)\} \begin{matrix}\cos m\varphi_0 \\ \sin m\varphi_0\end{matrix} \equiv \begin{matrix} {}_{l}a_n^m \\ {}_{l}b_n^m \end{matrix} . \tag{21}$$

Using the solution X_{sn}^{m}, whose numerical tables are already given[4], of the equations

$$\sum_{\nu=0}^{\infty} X_{\nu s}^{m} G_{\nu n}^{m} = \delta_{ns} , \tag{22}$$

we obtain

$$ {}_{l}A_{mn}^{(0)} = \sum_{\nu=0}^{\infty} {}_{l}a_{\nu}^{m} X_{n\nu}^{m} , \qquad {}_{l}B_{mn}^{(0)} = \sum_{\nu=0}^{\infty} {}_{l}b_{\nu}^{m} X_{n\nu}^{m} . \tag{23}$$

By the addition theorem, we have

$$J_m\left(\frac{r_{l'}}{a}\xi\right)\cos m(\varphi_{l'}-\psi_{l'l})$$
$$=(-1)^m \sum_{h=0}^{\infty} \frac{(2)_h}{2} J_h\left(\frac{r_l}{a}\xi\right)\{J_{m+h}(q_{l'l}\xi)+(-1)^h J_{m-h}(q_{l'l}\xi)\}\cos h(\varphi_l-\psi_{l'l}) , \tag{24}$$

$$J_m\left(\frac{r_{l'}}{a}\xi\right)\sin m(\varphi_{l'}-\psi_{l'l})$$
$$=(-1)^{m+1} \sum_{h=0}^{\infty} \frac{(2)_h}{2} J_h\left(\frac{r_l}{a}\xi\right)\{J_{m+h}(q_{l'l}\xi)-(-1)^h J_{m-h}(q_{l'l}\xi)\}\sin h(\varphi_l-\psi_{l'l}) , \tag{25}$$

from which we get

$$J_m\left(\frac{r_{l'}}{a}\xi\right)\cos m\varphi_{l'}$$
$$=(-1)^m \sum_{h=0}^{\infty} \frac{(2)_h}{2} J_h\left(\frac{r_l}{a}\xi\right)\{J_{m+h}(q_{l'l}\xi)\cos(h+m)\psi_{l'l}+(-1)^h J_{m-h}(q_{l'l}\xi)\cos(h-m)\psi_{l'l}\}\cos h\varphi_l$$
$$+(-1)^m \sum_{h=0}^{\infty} \frac{(2)_h}{2} J_h\left(\frac{r_l}{a}\xi\right)\{J_{m+h}(q_{l'l}\xi)\sin(h+m)\psi_{l'l}+(-1)^h J_{m-h}(q_{l'l}\xi)\sin(h-m)\psi_{l'l}\}\sin h\varphi_l , \tag{26}$$

$$J_m\left(\frac{r_{l'}}{a}\xi\right)\sin m\varphi_{l'}$$
$$=(-1)^m \sum_{h=0}^{\infty} \frac{(2)_h}{2} J_h\left(\frac{r_l}{a}\xi\right)\{J_{m+h}(q_{l'l}\xi)\sin(h+m)\psi_{l'l}-(-1)^h J_{m-h}(q_{l'l}\xi)\sin(h-m)\psi_{l'l}\}\cos h\varphi_l$$
$$+(-1)^m \sum_{h=0}^{\infty} \frac{(2)_h}{2} J_h\left(\frac{r_l}{a}\xi\right)\{-J_{m+h}(q_{l'l}\xi)\cos(h+m)\psi_{l'l}+(-1)^h J_{m-h}(q_{l'l}\xi)\cos(h-m)\psi_{l'l}\}\sin h\varphi_l . \tag{27}$$

Putting (26), (27) into (6), (7), we obtain

$$\Phi_{l'}^{(s-1)}=\pm C\sum_{m=0}^{\infty}\sum_{n=0}^{\infty}(-1)^m\sum_{h=0}^{\infty}\frac{(2)_h}{2}\cos h\varphi_l$$
$$\times\int_0^{\infty}J_h\left(\frac{r_l}{a}\xi\right)\Big[\{J_{m+h}(q_{l'l}\xi)\cos(h+m)\psi_{l'l}+(-1)^h J_{m-h}(q_{l'l}\xi)\cos(h-m)\psi_{l'l}\}{}_{l'}A_{mn}^{(s-1)}$$
$$+\{J_{m+h}(q_{l'l}\xi)\sin(h+m)\psi_{l'l}-(-1)^h J_{m-h}(q_{l'l}\xi)\sin(h-m)\psi_{l'l}\}{}_{l'}B_{mn}^{(s-1)}\Big]$$
$$\times\frac{\sqrt{\xi}\,J_{m+2n+(1/2)}(\xi)\exp\{\mp\sqrt{\xi^2-(ka)^2}\,(z/a)\}}{\sqrt{\xi^2-(ka)^2}}d\xi$$
$$\pm C\sum_{m=0}^{\infty}\sum_{n=0}^{\infty}(-1)^m\sum_{h=0}^{\infty}\frac{(2)_h}{2}\sin h\varphi_l$$
$$\times\int_0^{\infty}J_h\left(\frac{r_l}{a}\xi\right)\Big[\{J_{m+h}(q_{l'l}\xi)\sin(h+m)\psi_{l'l}+(-1)^h J_{m-h}(q_{l'l}\xi)\sin(h-m)\psi_{l'l}\}{}_{l'}A_{mn}^{(s-1)}$$

$$
\begin{aligned}
&+\{-J_{m+h}(q_{l'l}\xi)\cos(h+m)\psi_{l'l}+(-1)^h J_{m-h}(q_{l'l}\xi)\cos(h-m)\psi_{l'l}\}\,{}_{l'}B_{mn}^{(s-1)}\Big]\\
&\times\frac{\sqrt{\xi}\,J_{m+2n+(1/2)}(\xi)\exp\{\mp\sqrt{\xi^2-(ka)^2}(z/a)\}}{\sqrt{\xi^2-(ka)^2}}\,d\xi\;,
\end{aligned}
$$

which becomes, by interchanging the letters m and h,

$$
\begin{aligned}
\Phi_{l'}^{(s-1)}=&\pm C\sum_{m=0}^{\infty}\cos m\varphi_l\sum_{h=0}^{\infty}\sum_{n=0}^{\infty}(-1)^h\\
&\times\Big[{}_{l'}A_{hn}^{(s-1)}\{S_{m,n}^{h}(r_l,q_{l'l},\mp z)\cos(m+h)\psi_{l'l}+(-1)^m S_{-m,n}^{h}(r_l,q_{l'l},\mp z)\cos(m-h)\psi_{l'l}\}\\
&+{}_{l'}B_{hn}^{(s-1)}\{S_{m,n}^{h}(r_l,q_{l'l},\mp z)\sin(m+h)\psi_{l'l}-(-1)^m S_{-m,n}^{h}(r_l,q_{l'l},\mp z)\sin(m-h)\psi_{l'l}\}\Big]\\
&\pm C\sum_{m=0}^{\infty}\sin m\varphi_l\sum_{h=0}^{\infty}\sum_{n=0}^{\infty}(-1)^h\\
&\times\Big[{}_{l'}A_{hn}^{(s-1)}\{S_{m,n}^{h}(r_l,q_{l'l},\mp z)\sin(m+h)\psi_{l'l}+(-1)^m S_{-m,n}^{h}(r_l,q_{l'l},\mp z)\sin(m-h)\psi_{l'l}\}\\
&+{}_{l'}B_{hn}^{(s-1)}\{-S_{m,n}^{h}(r_l,q_{l'l},\mp z)\cos(m+h)\psi_{l'l}+(-1)^m S_{-m,n}^{h}(r_l,q_{l'l},\mp z)\cos(m-h)\psi_{l'l}\}\Big]\,,
\end{aligned}
\tag{28}
$$

where

$$
\begin{aligned}
&S_{\pm m,n}^{h}(r_l,q_{l'l},\mp z)\\
&\quad=\frac{(2)_m}{2}\int_0^\infty\frac{\sqrt{\xi}\,J_m((r_l/a)\xi)J_{h\pm m}(q_{l'l}\xi)J_{h+2n+(1/2)}(\xi)}{\sqrt{\xi^2-(ka)^2}}\exp\left\{\mp\sqrt{\xi^2-(ka)^2}\,\frac{z}{a}\right\}d\xi\;.
\end{aligned}
\tag{29}
$$

Utilizing $u_n{}^m(x)$, we get

$$
S_{\pm m.n}^{h}(r_l,q_{l'l},0)=x^{m/2}\sum_{\nu=0}^{\infty}G_{n\nu}^{\pm m,h}(q_{l'l})u_\nu{}^m(x)\;,\qquad x=\left(\frac{r_l}{a}\right)^2
\tag{30}
$$

$$
G_{n\nu}^{\pm m,h}(q_{l'l})=\frac{(2)_m}{2}(2m+4\nu+1)\int_0^\infty\frac{J_{h\pm m}(q_{l'l}\xi)J_{m+2\nu+(1/2)}(\xi)J_{h+2n+(1/2)}(\xi)}{\sqrt{\xi^2-(ka)^2}}\,d\xi\;.
\tag{31}
$$

Thus, from the condition (11) we have

$$
\begin{aligned}
&\sum_{n=0}^{\infty}{}_lA_{mn}^{(s)}\sum_{\nu=0}^{\infty}G_{n\nu}^{m}u_\nu{}^m(x)\\
&=-\sum_{l'=1}^{N}{}'\sum_{\nu=0}^{\infty}u_\nu{}^m(x)\sum_{h=0}^{\infty}\sum_{n=0}^{\infty}\Big[\{G_{n\nu}^{m,h}(q_{l'l})\cos(m+h)\psi_{l'l}+(-1)^m G_{n\nu}^{-m\ h}(q_{l'l})\cos(m-h)\psi_{l'l}\}(-1)^h\,{}_{l'}A_{hn}^{(s-1)}\\
&\qquad+\{G_{n\nu}^{m,n}(q_{l'l})\sin(m+h)\psi_{l'l}-(-1)^m G_{n\nu}^{-m,h}(q_{l'l})\sin(m-h)\psi_{l'l}\}(-1)^h\,{}_{l'}B_{hn}^{(s-1)}\Big]\,,
\end{aligned}
$$

i.e., interchanging the letters n and ν,

$$
\begin{aligned}
&\sum_{\nu=0}^{\infty}G_{\nu n}^{m}\,{}_lA_{m\nu}^{(s)}\\
&\quad=-\sum_{l'=0}^{N}{}'\sum_{h=0}^{\infty}\sum_{\nu=0}^{\infty}\Big[\{G_{\nu n}^{m,h}(q_{l'l})\cos(m+h)\psi_{l'l}+(-1)^m G_{\nu n}^{-m,h}(q_{l'l})\cos(m-h)\psi_{l'l}\}(-1)^h\,{}_{l'}A_{h\nu}^{(s-1)}\\
&\qquad+\{G_{\nu n}^{m,h}(q_{l'l})\sin(m+h)\psi_{l'l}-(-1)^m G_{\nu n}^{-m,h}(q_{l'l})\sin(m-h)\psi_{l'l}\}(-1)^h\,{}_{l'}B_{h\nu}^{(s-1)}\Big]\,,
\end{aligned}
\tag{32}
$$

and similarly,

$$\sum_{\nu=0}^{\infty} G_{\nu n}^{m}\,{}_{l}B_{m\nu}^{(s)}$$

$$=-\sum_{l'=1}^{N}{}' \sum_{h=0}^{\infty} \sum_{\nu=0}^{\infty} \Big[\{G_{\nu n}^{m,h}(q_{l'l}) \sin (m+h)\psi_{l'l}+(-1)^{m} G_{\nu n}^{-m,h}(q_{l'l}) \sin (m-h)\psi_{l'l}\}(-1)^{h}\,{}_{l'}A_{h\nu}^{(s-1)}$$

$$+\{-G_{\nu n}^{m,h}(q_{l'l}) \cos (m+h)\psi_{l'l}+(-1)^{m}G_{\nu n}^{-m,h}(q_{l'l}) \cos (m-h)\psi_{l'l}\}(-1)^{h}\,{}_{l'}B_{h\nu}^{(s-1)}\Big]. \tag{33}$$

Put

$$\begin{matrix} a_{mn}^{(s-1)}(q_{l'l}) \\ \bar{a}_{mn}^{(s-1)}(q_{l'l}) \end{matrix}$$

$$=-\sum_{h=0}^{\infty} \sum_{\nu=0}^{\infty} \left\{G_{\nu n}^{m,h}(q_{l'l}) \begin{matrix}\cos\\ \sin\end{matrix} (m+h)\psi_{l'l}+(-1)^{m} G_{\nu n}^{-m,h}(q_{l'l}) \begin{matrix}\cos\\ \sin\end{matrix} (m-h)\psi_{l'l}\right\}(-1)^{h}\,{}_{l'}A_{h\nu}^{(s-1)}\ , \tag{34}$$

$$\begin{matrix} b_{mn}^{(s-1)}(q_{l'l}) \\ \bar{b}_{mn}^{(s-1)}(q_{l'l}) \end{matrix}$$

$$=\pm\sum_{h=0}^{\infty} \sum_{\nu=0}^{\infty} \left\{G_{\nu n}^{m,h}(q_{l'l}) \begin{matrix}\cos\\ \sin\end{matrix} (m+h)\psi_{l'l}-(-1)^{m} G_{\nu n}^{-m,h}(q_{l'l}) \begin{matrix}\cos\\ \sin\end{matrix} (m-h)\psi_{l'l}\right\}(-1)^{h}\,{}_{l'}B_{h\nu}^{(s-1)}\ , \tag{35}$$

then

$${}_{l}A_{mn}^{(s)}=\sum_{l'=1}^{N}{}' \sum_{\nu=1}^{\infty} \{a_{m\nu}^{(s-1)}(q_{l'l})+\bar{b}_{m\nu}^{(s-1)}(q_{l'l})\}X_{n\nu}^{m}\ , \tag{36}$$

$${}_{l}B_{mn}^{(s)}=\sum_{l'=1}^{N}{}' \sum_{\nu=0}^{\infty} \{\bar{a}_{m\nu}^{(s-1)}(q_{l'l})+b_{m\nu}^{(s-1)}(q_{l'l})\}X_{\nu n}^{m}\ . \tag{37}$$

Thus, we see that ${}_{l}A_{mn}^{(s)}$ and ${}_{l}B_{mn}^{(s)}$ can be calculated if $G_{n\nu}^{\pm m,h}(q_{l'l})$ is evaluated.

§ 5. Evaluation of $G_{n\nu}^{\pm m,h}(q)$

We shall evaluate the integral $G_{n\nu}^{\pm m,h}(q)$. Putting $ka=\gamma$, we have

$$G_{n\nu}^{\pm m,h}(q)=\frac{(2)_m}{2}(2m+4\nu+1)\int_0^{\infty}\frac{J_{h\pm m}(q\xi)J_{m+2\nu+(1/2)}(\xi)J_{h+2n+(1/2)}(\xi)}{\sqrt{\xi^2-\gamma^2}}\,d\xi$$

$$=\frac{(2)_m}{2}(2m+4\nu+1)\{R_{n\nu}^{\pm m,h}-iI_{n\nu}^{\pm m,h}\}\ ,$$

where

$$R_{n\nu}^{\pm m,h}=\int_{\gamma}^{\infty}\frac{J_{h\pm m}(q\xi)J_{m+2\nu+(1/2)}(\xi)J_{h+2n+(1/2)}(\xi)}{\sqrt{\xi^2-\gamma^2}}\,d\xi\ ,$$

$$I_{n\nu}^{\pm m,h}=\int_{0}^{\gamma}\frac{J_{h\pm m}(q\xi)J_{m+2\nu+(1/2)}(\xi)J_{h+2n+(1/2)}(\xi)}{\sqrt{\gamma^2-\xi^2}}\,d\xi\ .$$

These integrals can be calculated as shown in the appendices I, II, III and IV of our previous paper[6]. The results are as follows: When $h\pm m\geqq 0$,

$$R_{n\nu}^{\pm m,h}=\frac{\sqrt{\pi}}{2}\sum_{\mu=0}^{\infty}\frac{(-1)^{\mu}}{\mu!}\frac{(\gamma/2)^{2\mu}}{\Gamma(-\mu+(1/2))}q^{2\mu-h-2\nu-m-2n-1}\sum_{l=0}^{\infty}\frac{(-1)^{l}}{l!}$$

$$\times\frac{q^{-2l}\Gamma\{h+\nu+((1\pm1)/2)m+n-\mu+l+(1/2)\}\Gamma(h+2\nu+m+2n+2+2l)}{\Gamma\{\mu-\nu-((1\mp1)/2)m-n-l+(1/2)\}\Gamma(h+2\nu+m+2n+2+l)\Gamma(m+2\nu+(3/2)+l)\Gamma(h+2n+(3/2)+l)} \tag{I}$$

$$=\left(\frac{\gamma}{2}\right)^{h+m+2\nu+2n+1}\sum_{s=0}^{\infty}\frac{(-1)^{s}\Gamma\{h+((1\pm1)/2)m+\nu+n+s+1\}\Gamma(h+m+2\nu+2n+2+2s)}{s!\,\Gamma(h+m+2\nu+2n+2+s)\Gamma(m+2\nu+(3/2)+s)\Gamma(h+2n+(3/2)+s)}\left(\frac{\gamma}{2}\right)^{2s}$$

$$\times\sum_{\mu=0}^{h+((1\pm1)/2)m+\nu+n+s}\frac{1}{\{h+((1\pm1)/2)m+\nu+n+s-\mu\}!}\frac{(2\mu)!}{(\mu!)^2 2^{\mu}}(q\gamma)^{-\mu}\sqrt{\frac{\pi}{2q\gamma}}\,J_{h\pm m-\mu-(1/2)}(q\gamma)\ , \tag{II}$$

and when $h-m<0$, we can reduce it to the former case by the general relation

$$R_{n\nu}^{-m,h}=(-1)^{h-m}R_{\nu n}^{-h,m}\,.$$

And, we have in general

$$\begin{aligned}
I_{n\nu}^{\pm m,h}&=\frac{\sqrt{\pi}}{2}q^{h\pm m}\left(\frac{\gamma}{2}\right)^{2h+(1\pm1)m+2\nu+2n+1}\\
&\times\sum_{s=0}^{\infty}\frac{(-1)^s}{s!}\frac{\Gamma(h+m+2\nu+2n+2+2s)}{\Gamma(h+m+2\nu+2n+2+s)\Gamma(m+2\nu+(3/2)+s)\Gamma(h+2n+(3/2)+s)}\left(\frac{\gamma}{2}\right)^{2s}\\
&\times\sum_{\mu=0}^{\infty}\frac{(-1)^\mu}{\mu!}\frac{q^{2\mu}}{\Gamma(h\pm m+1+\mu)}\frac{\Gamma\{h+((1\pm1)/2)m+\nu+n+s+1+\mu\}}{\Gamma\{h+((1\pm1)/2)m+\nu+n+s+(3/2)+\mu\}}\left(\frac{\gamma}{2}\right)^{2\mu} \qquad \text{(III)}\\
&=\left(\frac{\gamma}{2}\right)^{h+m+2\nu+2n+1}\\
&\times\sum_{s=0}^{\infty}\frac{(-1)^s\Gamma\{(1\mp1)/2)m+\nu+n+s+1\}\Gamma(h+m+2\nu+2n+2+2s)}{s!\,\Gamma(h+m+2\nu+2n+2+s)\Gamma(m+2\nu+(3/2)+s)\Gamma(h+2n+(3/2)+s)}\left(\frac{\gamma}{2}\right)^{2s}\\
&\times\sum_{\mu=0}^{((1\mp1)/2)m+\nu+n+s}(-1)^\mu\frac{1}{\{(1\mp1)/2)m+\nu+n+s-\mu\}!}\frac{(2\mu)!}{(\mu!)^2 2^\mu}(q\gamma)^{-\mu}\sqrt{\frac{\pi}{2q\gamma}}J_{h\pm m+\mu+(1/2)}(q\gamma)\,. \qquad \text{(IV)}
\end{aligned}$$

In the formulae (II) and (IV), when γ is small and the value of $q\gamma$ is not so small, we see that the term of the order $\gamma/2$ occurs only when $h=m=\nu=n=0$, $s=0$, and that the two terms of the order $(\gamma/2)^2$ occur when $h=1$, $m=\nu=n=s=0$ and $m=1$, $h=\nu=n=s=0$; in this way, we can have expressions of $R_{n\nu}^{\pm m,h}$, $I_{n\nu}^{\pm m,h}$ in power series of $\gamma/2=\beta$. And making use of the expressions[4] of X_{sn}^{m} in power series of β, we can get those of ${}_lA_{mn}^{(s)}$ and ${}_lB_{mn}^{(s)}$ (Cf. § 8.).

§ 6. Diffracted Field at Great Distance

For the scattered wave, we have

$$\Phi=\pm CV=\pm C\sum_{l=1}^{N}V_l\,, \qquad (38)$$

$$V_l=\sum_{m=0}^{\infty}\sum_{n=0}^{\infty}({}_lA_{mn}\cos m\varphi_l+{}_lB_{mn}\sin m\varphi_l)S_{mn}(r_l,\mp z)\,, \qquad (39)$$

where

$${}_lA_{mn}=\sum_{s=0}^{\infty}{}_lA_{mn}^{(s)}\,,\qquad {}_lB_{mn}=\sum_{s=0}^{\infty}{}_lB_{mn}^{(s)}\,. \qquad (40)$$

We use the Kirchhoff solution of the wave equation (1)

$$V=\frac{1}{4\pi}\iint\left\{\frac{\exp(-ikR')}{R'}\frac{\partial V}{\partial n}-V\frac{\partial}{\partial n}\left(\frac{\exp(-ikR')}{R'}\right)\right\}dS_l \qquad (41)$$

to obtain the value of V at a distant point. Here, R' is the distance R_l' between the point Q_l lying in the l-th hole and the distant point P. Cf. Fig. 2.* The integration is to be performed on both sides S_l^+ and S_l^- enclosing the l-th hole:

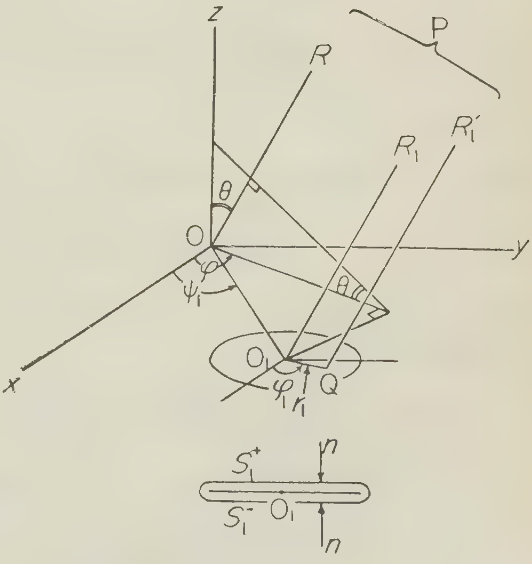

Fig. 2.

---

* Notice that the meanings of the symbols r_l, φ_l in Fig. 2 are just those in the right hand one of Fig. 1, if we identify Q_l and P′.

$$S_l = S_l^+ + S_l^- \,, \qquad l = 1, 2, 3, \cdots, \mathrm{N}\,. \tag{42}$$

Evidently

$$\left(\frac{\partial V_l}{\partial n}\right)_{S_l^+} = -\left(\frac{\partial V_l}{\partial z}\right)_{S_l^+} = \left(\frac{\partial V_l}{\partial z}\right)_{S_l^-} - \left(\frac{\partial V_l}{\partial n}\right)_{S_l^-}\,, \tag{43}$$

$$\left(\frac{\partial V}{\partial z}\right)_{S_l^-} = \left(\frac{\partial V_l}{\partial z}\right)_{S_l^-}\,, \tag{44}$$

$$\left(\frac{\partial}{\partial n}\frac{\exp(-ikR')}{R'}\right)_{S^+} = -\left(\frac{\partial}{\partial n}\frac{\exp(-ikR')}{R'}\right)_{S^-}\,. \tag{45}$$

Therefore

$$V = \frac{1}{2\pi}\sum_{l=1}^{\mathrm{N}}\int \frac{\exp(-ikR_l')}{R_l'}\frac{\partial V_l}{\partial z}\,dS_l^-\,. \tag{46}$$

Now, P being sufficiently distant, we may put

$$R_l = R - \varpi_l \sin\theta\cos(\varphi-\psi_l)\,, \tag{47}$$

$$R_l' = R_l - r_l \sin\theta\cos(\varphi-\varphi_l)\,. \tag{48}$$

And so, we get

$$\begin{aligned} V_l &= \frac{1}{2\pi}\int \frac{\exp(-ikR_l')}{R_l'}\frac{\partial V_l}{\partial z}\,dS_l^- \\ &= \frac{1}{2\pi}\frac{\exp(-ikR_l)}{aR}\sum_{m=0}^{\infty}\sum_{n=0}^{\infty}\int_0^a r_l\,dr_l\int_0^{\infty}\sqrt{\xi}\,J_m\!\left(\frac{r_l}{a}\xi\right)J_{m+2n+(1/2)}(\xi)\,d\xi \\ &\quad\times\int_0^{2\pi}\exp\{ikr_l\sin\theta\cos(\varphi-\varphi_l)\}({}_lA_{mn}\cos m\varphi_l + {}_lB_{mn}\sin m\varphi_l)\,d\varphi_l \qquad (49) \\ &= \sqrt{\frac{2}{\pi}}\,a\,\frac{\exp\{-ikR+ik\varpi_l\sin\theta\cos(\varphi-\psi_l)\}}{R} \\ &\quad\times\sum_{m=0}^{\infty}\sum_{n=0}^{\infty}(i)^m({}_lA_{mn}\cos m\varphi + {}_lB_{mn}\sin m\varphi)\,j_{m+2n}(ka\sin\theta)\,. \qquad (50) \end{aligned}$$

Thus, we obtain

$$\begin{aligned} \varPhi &= \pm\sqrt{\frac{2}{\pi}}\,aC\,\frac{\exp(-ikR)}{R}\sum_{m=0}^{\infty}\sum_{n=0}^{\infty}(i)^m j_{m+2n}(ka\sin\theta) \\ &\quad\times\sum_{l=1}^{\mathrm{N}}\exp\{ik\varpi_l\sin\theta\cos(\varphi-\psi_l)\}({}_lA_{mn}\cos m\varphi + {}_lB_{mn}\sin m\varphi)\,. \end{aligned} \tag{51}$$

At great distance from the holes, the energy flow (mean value about time) per unit solid angle in the direction θ, φ is

$$\begin{aligned} P(\theta,\varphi) &\equiv \frac{1}{2}\mathscr{R}_e\, i\omega\sigma\tilde{\varPhi}\frac{\partial\varPhi}{\partial R}R^2 = \frac{1}{2}\omega\sigma k\tilde{\varPhi}\varPhi R^2 \\ &= \frac{\omega\sigma k a^2|C|^2}{\pi}\sum_{l=1}^{\mathrm{N}}\left|\sum_{m=0}^{\infty}\sum_{n=0}^{\infty}({}_lA_{mn}\cos m\varphi + {}_lB_{mn}\sin m\varphi)\,j_{m+2n}(ka\sin\theta)\right|^2 \\ &\quad+\frac{\omega\sigma k a^2|C|^2}{\pi}\sum_{l=1}^{\mathrm{N}}\sum_{l'=1}^{\mathrm{N}}{}'\exp\{ik\varpi_l\sin\theta\cos(\varphi-\psi_l) - ik\varpi_{l'}\sin\theta\cos(\varphi-\varphi_{l'})\} \\ &\quad\times\sum_{m,n}\sum_{m',n'}(i)^m(-i)^{m'}({}_lA_{mn}\cos m\varphi + {}_lB_{mn}\sin m\varphi)({}_{l'}\tilde{A}_{m'n'}\cos m'\varphi + {}_{l'}\tilde{B}_{m'n'}\sin m'\varphi) \\ &\quad\times j_{m+2n}(ka\sin\theta)\,j_{m'+2n'}(ka\sin\theta)\,, \end{aligned} \tag{52}$$

where $\tilde{\Phi}$ is the conjugate of Φ, and σ the density of the air.

§ 7. Acoustic Impedance and Transmission Coefficient

If we denote by $(p)_l e^{i\omega t}$ the pressure at the l-th hole, we get

$$(p)_l = i\omega\sigma\Big[\sum_{l=1}^{\mathrm{N}} \Phi_l\Big]_{z=+0} = i\omega\sigma[\Phi_0]_{z=0}$$

$$= i\omega\sigma C \exp\{-ik\varpi_l \sin\alpha \cos(\psi_l - \varphi_0)\} \sum_{m=0}^{\infty} (2)_m (-i)^m J_m(kr_l \sin\alpha) \cos m(\varphi_l - \varphi_0)$$

$$= i\omega\sigma C \sum_{m=0}^{\infty} x^{m/2} \sum_{n=0}^{\infty} ({}_l a_n{}^m \cos m\varphi_l + {}_l b_n{}^m \sin m\varphi_l) u_n{}^m(x) \;, \tag{53}$$

conferring (9), (3), (21). Proceeding similarly as in the previous paper[6)], we obtain as to the l-th hole:

mean pressure
$$(p_m)_l = \frac{i\omega\sigma}{2\sqrt{2}} \sqrt{\pi}\, C \sum_{n=0}^{\infty} \frac{\Gamma(n+(1/2))}{n!\,(n+1)!\,\Gamma((3/2)-n)}\, {}_l a_n{}^0 \;, \tag{54}$$

mean velocity
$$(v_m)_l = \frac{2C}{a} \sqrt{\frac{2}{\pi}}\, {}_l A_{00} \;, \tag{55}$$

acoustic impedance
$$(Z_{ac})_l \equiv (R_{ac})_l + i(X_{ac})_l \equiv \frac{(p_m)_l}{(v_m)_l}$$

$$= \frac{i\pi\omega\sigma a}{8\, {}_l A_{00}} \sum_{n=0}^{\infty} \frac{\Gamma(n+(1/2))}{n!\,(n+1)!\,\Gamma((3/2)-n)}\, {}_l a_n{}^0 \;, \tag{57}$$

$$(R_{ac})_l = -\frac{\pi\omega\sigma a}{8} \sum_{n=0}^{\infty} \frac{\Gamma(n+(1/2))}{n!\,(n+1)!\,\Gamma((3/2)-n)}\, \mathscr{Im}\, \frac{{}_l a_n{}^0}{{}_l A_{00}} \;, \tag{58}$$

$$(X_{ac})_l = +\frac{\pi\omega\sigma a}{8} \sum_{n=0}^{\infty} \frac{\Gamma(n+(1/2))}{n!\,(n+1)!\,\Gamma((3/2)-n)}\, \mathscr{Re}\, \frac{{}_l a_n{}^0}{{}_l A_{00}} \;; \tag{59}$$

energy flow (mean value about time)

$$(W)_l = \omega\sigma |C|^2 a \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \frac{\pi}{(2)_m} \frac{1}{2m+4n+1}\, \mathscr{Im}\, ({}_l A_{mn}\, {}_l \tilde{a}_n{}^m + {}_l B_{mn}\, {}_l \tilde{b}_n{}^m) \;. \tag{60}$$

Energy flow from the whole holes:

$$W = \sum_{l=1}^{\mathrm{N}} (W)_l = \omega o |C|^2 a \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \frac{\pi}{(2)_m} \frac{1}{2m+4n+1} \sum_{l=1}^{\mathrm{N}} \mathscr{Im}\, ({}_l A_{mn}\, {}_l \tilde{a}_n{}^m + {}_l B_{mn}\, {}_l \tilde{b}_n{}^m) \tag{61}$$

$$= \int_0^{2\pi} d\varphi \int_0^{\pi/2} P(\theta, \varphi) \sin\theta\, d\theta \;. \tag{62}$$

Transmission coefficient of the whole holes:

$$t \equiv \frac{W}{\mathrm{N} W_0} = \frac{2}{\mathrm{N} ka} \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \frac{1}{(2)_m} \frac{1}{2m+4n+1} \sum_{l=1}^{\mathrm{N}} \mathscr{Im}\, ({}_l A_{mn}\, {}_l \tilde{a}_n{}^m + {}_l B_{mn}\, {}_l \tilde{b}_n{}^m) \;, \tag{63}$$

where

$$W_0 = \frac{1}{2} \pi a^2 \omega\sigma k |C|^2$$

is the normal incident energy flow on each hole.

§ 8. Case of Normal Incidence and Large Wave Length

In the case of normal incidence $\alpha=0$, and for large wave length $\gamma = 2\beta < 1$, we obtain

$$
\begin{aligned}
{}_{\iota}A_{00}&={}_{\iota}A_{00}^{(0)}+{}_{\iota}A_{00}^{(1)}+{}_{\iota}A_{00}^{(2)}+{}_{\iota}A_{00}^{(3)}+O(\beta^4)\\
&=\sqrt{\frac{2}{\pi}}\,X_{00}^{0}\Big\{1-2X_{00}^{0}\sum_{\iota'}{}'G_{00}^{00}(q_{\iota'\iota})+(2X_{00}^{0})^2\sum_{\iota'}{}'G_{00}^{00}(q_{\iota'\iota})\\
&\quad\times\sum_{\iota''}{}'G_{00}^{00}(q_{\iota''\iota'})-(2X_{00}^{0})^3\sum_{\iota'}{}'G_{00}^{00}(q_{\iota'\iota})\sum_{\iota''}{}'G_{00}^{00}(q_{\iota''\iota'})\sum_{\iota'''}{}'G_{00}^{00}(q_{\iota'''\iota''})\Big\}+O(\beta^4)\,,\\
{}_{\iota}A_{01}&={}_{\iota}A_{01}^{(0)}+{}_{\iota}A_{01}^{(1)}+{}_{\iota}A_{01}^{(2)}+O(\beta^4)\\
&=\sqrt{\frac{2}{\pi}}\Big[X_{10}^{0}-2X_{00}^{0}\Big\{X_{10}^{0}\sum_{\iota'}{}'G_{00}^{00}(q_{\iota'\iota})+X_{11}^{0}\sum_{\iota'}{}'G_{01}^{00}(q_{\iota'\iota})\Big\}\Big]+O(\beta^4)\,,\\
\begin{matrix}{}_{\iota}A_{10}\\ {}_{\iota}B_{10}\end{matrix}&=\begin{matrix}{}_{\iota}A_{10}^{(1)}+{}_{\iota}A_{10}^{(2)}\\ {}_{\iota}B_{10}^{(l)}+{}_{\iota}B_{10}^{(2)}\end{matrix}+O(\beta^4)=-\sqrt{\frac{2}{\pi}}\,X_{00}^{0}X_{00}^{1}\sum_{\iota'}{}'\begin{matrix}\cos\psi_{\iota'\iota}\\ \sin\psi_{\iota'\iota}\end{matrix}\\
&\quad\times\Big\{G_{00}^{10}(q_{\iota'\iota})-G_{00}^{-10}(q_{\iota'\iota})\Big\}\Big\{1-2X_{00}^{0}\sum_{\iota''}{}'G_{00}^{00}(q_{\iota''\iota'})\Big\}+O(\beta^4)\,,\\
{}_{\iota}A_{20}&={}_{\iota}A_{20}^{(1)}+O(\beta^4)=-\sqrt{\frac{2}{\pi}}\,X_{00}^{0}X_{00}^{2}\sum_{\iota'}{}'\cos 2\psi_{\iota'\iota}\Big\{G_{00}^{20}(q_{\iota'\iota})+G_{00}^{-20}(q_{\iota'\iota})\Big\}+O(\beta^4)\,,
\end{aligned}
\tag{64}
$$

all the other ${}_{\iota}A_{mn}$, ${}_{\iota}B_{mn}$ being of the order β^4 at most. And, putting

$$\gamma q_{\iota'\iota}=\zeta_{\iota'\iota}\,, \tag{65}$$

we get

$$G_{00}^{00}(q_{\iota'\iota})=\{f(\zeta_{\iota'\iota})-ig(\zeta_{\iota'\iota})\}\beta+\{f_1(\zeta_{\iota'\iota})+ig_1(\zeta_{\iota'\iota})\}\beta^3+O(\beta^5)\,, \tag{66}$$

where

$$
\left.
\begin{aligned}
f(\zeta)&=\sqrt{\frac{2}{\pi}}\frac{1}{\sqrt{\zeta}}J_{-(1/2)}(\zeta)=\frac{2}{\pi}\frac{\cos\zeta}{\zeta}\,,\\
g(\zeta)&=\sqrt{\frac{2}{\pi}}\frac{1}{\sqrt{\zeta}}J_{1/2}(\zeta)=\frac{2}{\pi}\frac{\sin\zeta}{\zeta}\,,
\end{aligned}
\right\}
\tag{67}
$$

$$
\left.
\begin{aligned}
f_1(\zeta)&=-\frac{4}{3}\sqrt{\frac{2}{\pi}}\frac{1}{\sqrt{\zeta}}\Big\{J_{-(1/2)}(\zeta)+\frac{1}{\zeta}J_{-(3/2)}(\zeta)\Big\}=-\frac{4}{3}\frac{2}{\pi}\frac{1}{\zeta}\Big\{\cos\zeta-\frac{1}{\zeta}\Big(\frac{\cos\zeta}{\zeta}+\sin\zeta\Big)\Big\}\,,\\
g_1(\zeta)&=\frac{4}{3}\sqrt{\frac{2}{\pi}}\frac{1}{\sqrt{\zeta}}\Big\{J_{1/2}(\zeta)-\frac{1}{\zeta}J_{3/2}(\zeta)\Big\}=\frac{4}{3}\frac{2}{\pi}\frac{1}{\zeta}\Big\{\sin\zeta-\frac{1}{\zeta}\Big(\frac{\sin\zeta}{\zeta}-\cos\zeta\Big)\Big\}\,.
\end{aligned}
\right\}
\tag{68}
$$

Hence,

$${}_{\iota}A_{00}=\sqrt{\frac{2}{\pi}}\{1+{}_{\iota}\lambda_1\beta+{}_{\iota}\lambda_2\beta^2+{}_{\iota}\lambda_3\beta^3+i({}_{\iota}\mu_1\beta+{}_{\iota}\mu_2\beta^2+{}_{\iota}\mu_3\beta^3)\}+O(\beta^4)\,, \tag{69}$$

where

$${}_{\iota}\lambda_1=-2\sum_{\iota'=1}^{N}{}'f(\zeta_{\iota'\iota})\,, \tag{70}$$

$${}_{\iota}\lambda_2=-\frac{16}{\pi}\sum_{\iota'=1}^{N}{}'g(\zeta_{\iota'\iota})+4\sum_{\iota'=1}^{N}{}'\sum_{\iota''=1}^{N}{}'\{f(\zeta_{\iota'\iota})f(\zeta_{\iota''\iota'})-g(\zeta_{\iota'\iota})g(\zeta_{\iota''\iota'})\}-\Big(\frac{16}{\pi^2}-\frac{4}{3}\Big)\,, \tag{71}$$

$$
\begin{aligned}
{}_{\iota}\lambda_3&=-2\sum_{\iota'=1}^{N}{}'f_1(\zeta_{\iota'\iota})+16\Big(\frac{6}{\pi^2}-\frac{1}{3}\Big)\sum_{\iota'=1}^{N}{}'f(\zeta_{\iota'\iota})+\frac{48}{\pi}\sum_{\iota'=1}^{N}{}'\sum_{\iota''=1}^{N}{}'\{f(\zeta_{\iota'\iota})g(\zeta_{\iota''\iota'})+g(\zeta_{\iota'\iota})f(\zeta_{\iota''\iota'})\}\\
&\quad-8\sum_{\iota'}{}'\sum_{\iota''}{}'\sum_{\iota'''}{}'f(\zeta_{\iota'\iota})f(\zeta_{\iota''\iota'})f(\zeta_{\iota'''\iota''})\\
&\quad+8\sum_{\iota'}{}'\sum_{\iota''}{}'\sum_{\iota'''}{}'\{f(\zeta_{\iota'\iota})g(\zeta_{\iota''\iota'})g(\zeta_{\iota'''\iota''})+g(\zeta_{\iota'\iota})f(\zeta_{\iota''\iota'})g(\zeta_{\iota'''\iota''})+g(\zeta_{\iota'\iota})g(\zeta_{\iota''\iota})f(\zeta_{\iota'''\iota''})\}\,,
\end{aligned}
\tag{72}
$$

$$ {}_{l}\mu_1=\frac{4}{\pi}+2\sum_{l'=1}^{N}{}' g(\zeta_{l'l}) \,, \tag{73}$$

$$ {}_{l}\mu_2=-\frac{16}{\pi}\sum_{l'=1}^{N}{}' f(\zeta_{l'l})-4\sum_{l'=1}^{N}{}'\sum_{l''=1}^{N}\{f(\zeta_{l'l})g(\zeta_{l''l'})+g(\zeta_{l'l})f(\zeta_{l''l'})\} \,, \tag{74}$$

$$\begin{aligned} {}_{l}\mu_3=&-2\sum_{l'=1}^{N}{}' g_1(\zeta_{l'l})-16\left(\frac{6}{\pi^2}-\frac{1}{3}\right)\sum_{l'=1}^{N}{}' g(\zeta_{l'l})+\frac{48}{\pi}\sum_{l'=1}^{N}{}'\sum_{l''=1}^{N}{}'\{f(\zeta_{l'l})f(\zeta_{l''l'})-g(\zeta_{l'l})g(\zeta_{l''l'})\} \\ &+\frac{64}{\pi}\left(\frac{1}{9}-\frac{1}{\pi^2}\right)-8\sum_{l'}{}'\sum_{l''}{}'\sum_{l'''}{}' g(\zeta_{l'l})g(\zeta_{l''l'})g(\zeta_{l'''l''}) \\ &+8\sum_{l'}{}'\sum_{l''}{}'\sum_{l'''}{}'\{f(\zeta_{l'l})f(\zeta_{l''l'})g(\zeta_{l'''l''})+f(\zeta_{l'l})g(_{l''l'})f(_{l'''l''})+g(\zeta_{l'l})f(\zeta_{l''l'})f(\zeta_{l'''l''})\} \,. \end{aligned} \tag{75}$$

The acoustic resistance and reactance becomes respectively,

$$\begin{aligned} (R_{ac})_l&=-\frac{\pi\omega\sigma a}{8}\frac{\Gamma(1/2)}{\Gamma(3/2)}\sqrt{\frac{2}{\pi}}\,\mathscr{Im}\frac{1}{{}_{l}A_{00}} \\ &=\frac{\pi\sigma c}{2}\beta^2\{{}_{l}\mu_1+({}_{l}\mu_2-2{}_{l}\lambda_1\,{}_{l}\mu_1)\beta+({}_{l}\mu_3-2{}_{l}\lambda_1\,{}_{l}\mu_2-2{}_{l}\lambda_2\,{}_{l}\mu_1-{}_{l}\mu_1{}^3+3{}_{l}\lambda_1{}^2{}_{l}\mu_1)\beta^2+O(\beta^3)\} \,, \end{aligned} \tag{76}$$

$$\begin{aligned} (X_{ac})_l&=\frac{\pi\omega\sigma a}{8}\frac{\Gamma(1/2)}{\Gamma(3/2)}\sqrt{\frac{2}{\pi}}\,\mathscr{Re}\frac{1}{{}_{l}A_{00}} \\ &=\frac{\pi\sigma c}{2}\beta\{1-{}_{l}\lambda_1\beta-({}_{l}\lambda_2-{}_{l}\lambda_1{}^2+{}_{l}\mu_1{}^2)\beta^2-({}_{l}\lambda_3-2{}_{l}\lambda_1\,{}_{l}\lambda_2+2{}_{l}\mu_1\,{}_{l}\mu_2+{}_{l}\lambda_1{}^3-3{}_{l}\lambda_1\,{}_{l}\mu_1{}^2)\beta^3+O(\beta^4)\} \,. \end{aligned} \tag{77}$$

And, the total energy flow from the whole holes is

$$\begin{aligned} W&=\omega\sigma a|C|^2\pi\sqrt{\frac{2}{\pi}}\sum_{l=1}^{N}\mathscr{Im}\,{}_{l}A_{00} \\ &=2\omega\sigma a|C|^2\sum_{l=1}^{N}\{{}_{l}\mu_1\beta+{}_{l}\mu_2\beta^2+{}_{l}\mu_3\beta^3+O(\beta^4)\} \\ &=4\sigma c|C|^2\beta^2\sum_{l=1}^{N}\{{}_{l}\mu_1+{}_{l}\mu_2\beta+{}_{l}\mu_3\beta^2+O(\beta^3)\} \,. \end{aligned} \tag{78}$$

Using the formula (55)

$$(v_m)_l=\frac{2C}{a}\sqrt{\frac{2}{\pi}}\,{}_{l}A_{00} \,,$$

we can easily show that

$$\frac{1}{2}\sum_{l=1}^{N}\pi a^2(R_{ac})_l|(v_m)_l|^2=W \,. \tag{79}$$

Transmission coefficient of the whole holes is

$$t=\frac{W}{NW_0}=\frac{1}{N}\frac{2}{\pi}\sum_{l=1}^{N}({}_{l}\mu_1+{}_{l}\mu_2\beta+{}_{l}\mu_3\beta^2)+O(\beta^3) \,. \tag{80}$$

§ 9. Numerical Examples

We notice that the approximation of the previous section gives fairly correct value when $\gamma=2\beta$ is small. For example, we give here the transmission coefficient t for normal incidence computed by the formula (80).

When N=2, the results are as shown in Fig. 3. The abscissa q represents the distance between the centres of the two holes, and the ordinate shows the value of t. Each curve corresponds to $\gamma=0.05$, 0.10, 0.15, 0.20, 0.25.

When $q\to\infty$, t should take the value in the case of single hole

$$t_{\text{single}}=\frac{8}{\pi^2}\left\{1+4\left(\frac{1}{9}-\frac{1}{\pi^2}\right)\gamma^2+O(\gamma^4)\right\}.$$

In fact, continuing the computation for larger q, we see that each curve in Fig. 3 tends to t_{single}, oscillating about the limiting value. The greater the value of γ is, the smaller the oscillation amplitude and the shorter the oscillation peroid is.

As q increases starting from $q=2$, each curve attains to the first maximum point (q_1, t_1), the greatest value t_1 being fairly greater than 1, which fact is worth noticing.

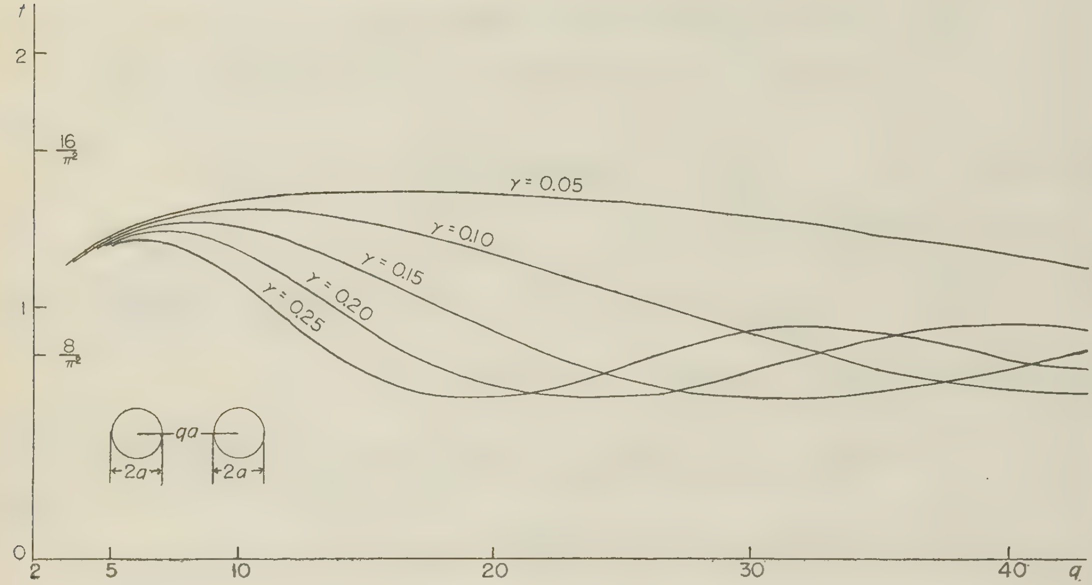

Fig. 3. Transmission coefficient t of two equal circular holes. (γ=circumference of the circle divided by the wave length.)

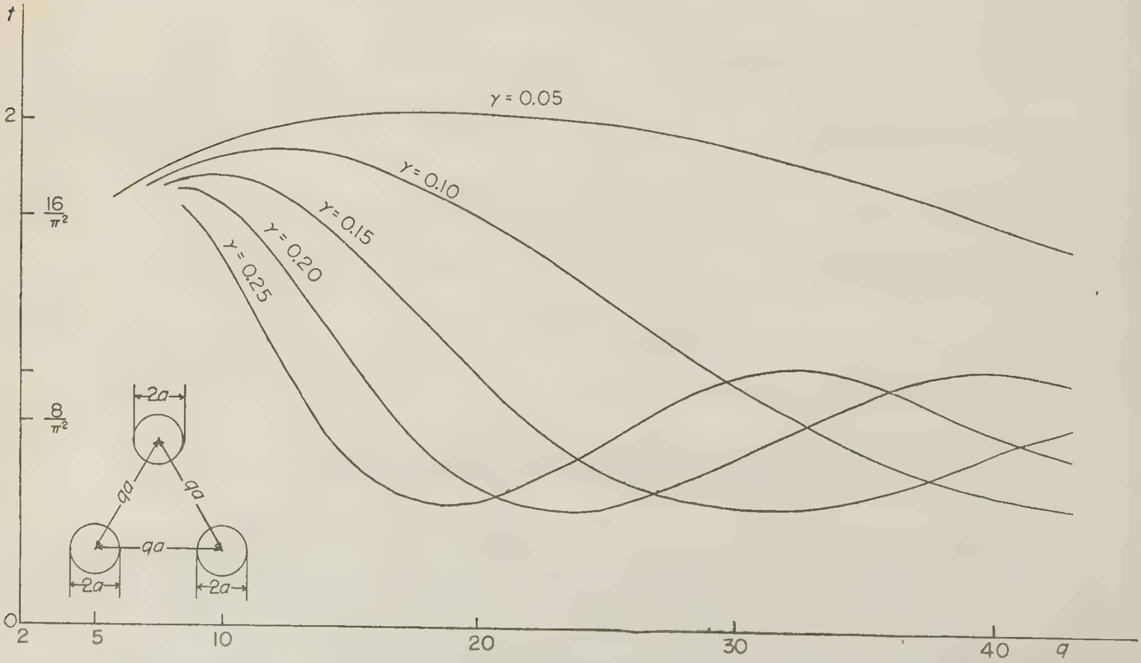

Fig. 4. Transmission coefficient t of three equal circular holes, the centres making a regular triangle. (γ=circumference of the circle divided by the wave length.)

The smaller the value of γ is, the greater the q_1 becomes; $q_1 \to \infty$, $t_1 \to (16/\pi^2) = 1.621$, when $\gamma \to 0$.

When N=3, we calculated two simple cases. Fig. 4 shows the results of the case when the three centres of three equal circular holes make a regular triangle with the lateral sides of length qa. The behaviour of each curve is similar to that in Fig. 3, but the greatest value t_1 becomes greater, and the smallest value smaller.

Fig. 5 shows the results of the case when the three centres of three equal circles are situated on a straight line, the distances from the middle one to the other ones being to qa. The curious curvatures in the descending parts of each curve suggest the appearance of sub-maximums due to the factors $f(2q\gamma)$, $g(2q\gamma)$ and $g_1(2q\gamma)$, when γ is larger.

In both cases, we can show that $t \to t_{\text{single}}$ when $q \to \infty$, and that $q_1 \to \infty$, $t_1 \to (24/\pi^2) = 2.432$, when $\gamma \to 0$.

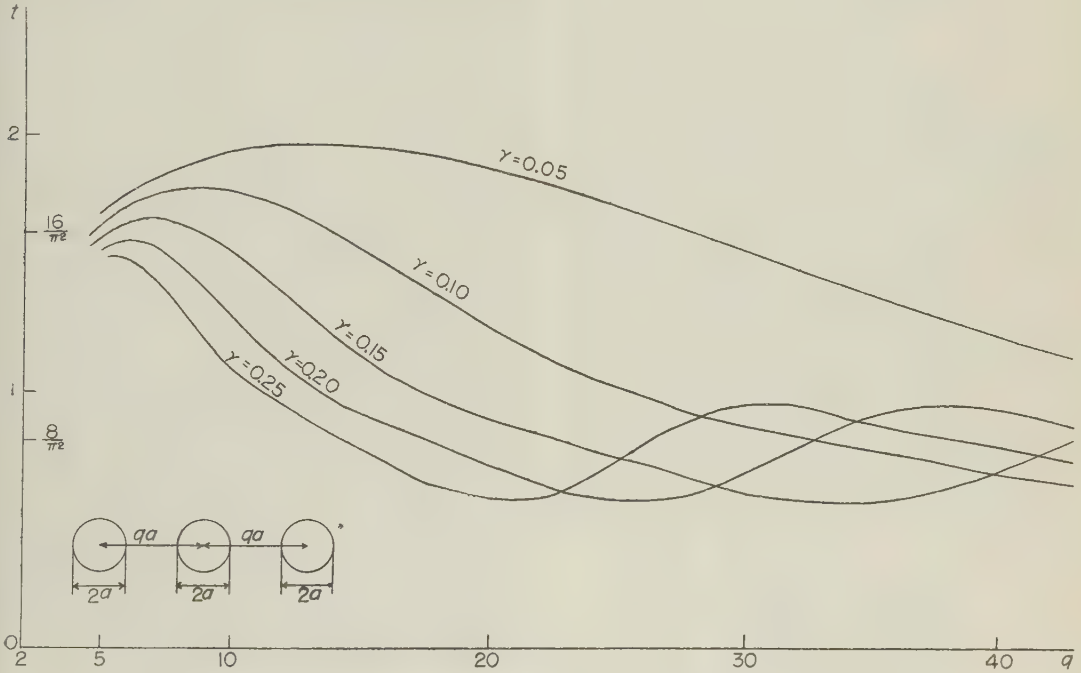

Fig. 5. Transmission coefficient t of three equal circular holes, the centres lying on a straight line. (γ=circumference of the circle divided by the wave length.)

In the above three Figs., the first maximum point (q_1, t_1) and the first minimum point (q_2, t_2) for $\gamma = 0.15$ are read as follows:

	q_1	t_1	q_2	t_2
Fig. 3	8.3	1.33	31.0	0.64
Fig. 4	9.8	1.78	30.6	0.46
Fig. 5	7.1	1.68	34.0	0.57

In the case of $\gamma > 0.25$, we have to compute t by (63). It is necessary to compute ${}_iA_{mn}^{(s)}$, ${}_iB_{mn}^{(s)}$ by (34), (35) and (36), (37) successively taking $s = 1, 2, 3, \cdots$. However, the preparation of the numerical tables of these values for various γ and $q_i\gamma_i$ should be left for electronic computer. If we have such tables, we can compute any physical quantity directly by its formula.

Effects of Vacancies on Pulse Photoconductions in CdS Single Crystals

By Junji Shirafuji and Yoshio Inuishi
College of Engineering, Osaka University
Osaka, Japan

(Received January 23, 1961)

The temperature dependence of pulse photocurrent and decay time constant in comparatively pure CdS single crystals have been reported in our previous paper[1]. Here the effect of stoichiometric defect introduction on the pulse photoconduction of the same samples (M-1, M-2) will be mentioned with notations quite similar to the previous report. To introduce the stoichiometric defects, the melt grown CdS crystals were sealed into a silica tube with suitable amount of Cd (denoted "Cd doped") or S ("S doped") in vacuum and heated at 850°C for 1 hour. Thus S or Cd vacancies seem to be introduced, judging from thermally stimulated current data taken by Prof. Tanaka[2]. Fig. 1 shows the temperature dependence of the shortest decay time constant τ_1 of photocurrent excited with 0.5 *μsec* light pulse. τ_1 was found to be shortened very effectively at lower temperatures by S doping having a maximum at about 200°K, while in "Cd doped" crystal τ_1 was rather similar to "pure" crystal. The next shortest decay time constant τ_2 which had been observed in pure crystals did not appear in doped crystals. The peak photocurrent I_1 in this case is shown in Fig. 2, where the introduction of Cd vacancies ("S doped") reduces the current remarkably at lower temperatures and S vacancies ("Cd doped") result in enhancement. As seen in Fig. 3, the longer decay time constant τ_3 when crystals were illuminated with 5 *msec* light pulse is shortened remarkably by Cd vacancy introduction. On the contrary, the crystal with S vacancies shows similar behavior to pure crystals being rather insensitive to temperature. The photocurrent I_3 (dotted lines in Fig. 3) in this case has similar behavior to τ_3, where S vacancies result in the very remarkable enhancement. Transition in photocurrent from the linear to the sublinear relation at high light intensity was seen in "Cd doped" sample. In resume, introduction of Cd vacancies (acceptor) shortens the electron lifetimes, τ_1 and τ_3, very remarkably at lower temperatures. S vacancies (donor) enhance the quantum efficiency enormously, increase the electron lifetime τ_3 and improve the temperature dependency of photoresponse especially at lower temperatures. The experiments on spectral response and surface effects are being continued to clarify the detailed mechanism.

Conductivity of Grain Boundaries in Ge

Yasuo Matukura and Shigezo Tanaka
Semiconductor Division, Nippon Electric Company, Ltd. Kawasaki, Japan

(Received January 12, 1961)

It has been known[1),2)] that grain boundaries in Ge have a p-type character due to the acceptor action of dangling bonds. Conduction in these grain boundaries of Ge was studied by A. G. Tweet[3)] and B. Reed[4)] using measurements of Hall effect and conductance, respectively. As dislocation line has a cylindrical space charge[2)], it is expected that the carrier mobility in small angle grain boundaries may depend upon the direction of the current flow in this sheet.

This work is performed on carefully oriented bicrystals grown by the vertical pulling technique with [100] seeds symmetrically tilted about the [010] axis at angles of 2.5-40°. The intrinsic starting material is doped with Sb and the bulk resistivities are 7 to 20Ω cm. Samples approximately $1.5\times1.5\times10$ mm are cut parallel (A) or perpendicular (B) to the [010] tilt axis, as shown in Fig. 1. In order to minimize the parallel current flow in the bulk material, it is necessary to use contacts which are ohmic on the grain boundary and rectifying on the bulk. Indium alloyed contacts[3)] are used for current electrodes, resistivity and Hall effect probes after electrolytically etching.

Measurements are performed on the resistivity and Hall coefficient at the temperature range of 80 to 300°K. Voltages are checked for linearity as a function of current and magnetic field magnitude and these directions. In the case of the grain boundary space-charge layer conduction, the thickness of the conducting layer can only be estimated and the density of carriers is a function of the perpendicular distance from the grain boundary. Consequently, the reduced Hall coefficient[3)], as $R^*=R/t$, and the reduced resistivity, as $\rho^*=\rho/t$, are measurable.

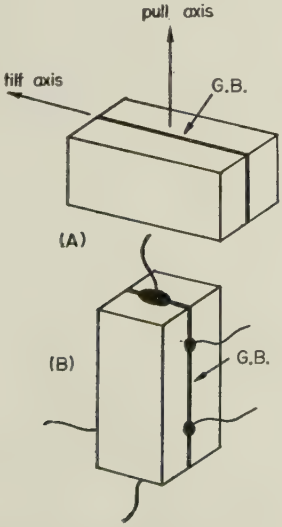

Fig. 1. Schematic drawing of Hall sample containing a grain boundary.

ρ^* on all samples of the various misorientation decreases gradually with the decreasing temperatures, has a minimum value of several kiloohm at about 120°K, and then increases gradually with the decreasing temperatures. However, ρ^* on B samples of the misorientation 2.5° increases with a slope of about 0.1 eV at the temperatures below 120°K. On the other hand, the sign of R^* shows that the current carriers in the grain boundary layer are holes in all samples. R^* on all samples except misorientation 2.5° is nearly constant at the measured temperature range and the values are about 10^6 cm²/coulomb. On the samples of 2.5°, R^* increases with a similar slope to ρ^* of 2.5°B with the decreasing temperatures below 150°K.

If the Hall mobility of holes in the grain boundary is given by $\mu=R^*/\rho^*=R/\rho$, the Hall mobility is not implyed the thickness of the grain boundary layer. Fig. 2 shows Hall mobilities for three samples. There is a high temperature range in which the mobility increases with the decreasing temperatures

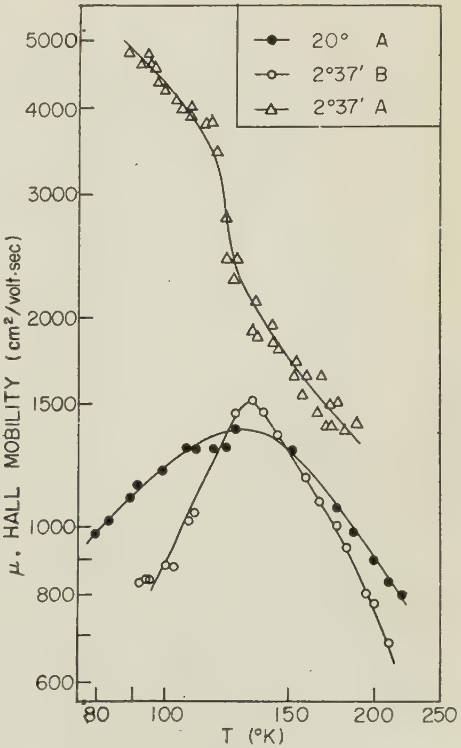

Fig. 2. Temperature variation of Hall mobility.

as does that of the bulk Ge. There is a low temperature range in which the mobility decreases with the decreasing temperatures except the case of 2.5°A.

It seems that the mobility in the high temperature range is determined by a scattering as lattice scattering and in the low temperature range by a scattering as the charged dangling bond scattering. If it is assumed that the hole moving along through the cylindrical space charge is more weakly scattered by the charged dangling bond than the hole moving perpendicular to that, it seems to be reasonable that the mobility of 2.5°A in Fig. 2 is larger than B of the same orientation and does not decrease with the decreasing temperatures. As the misorientation increases, thc feature of the cylindrical space charge in the grain boundary will diminish. In middle-angle grain boundaries, therefore, it seems that the anisotropy of the grain boundary mobility by the direction of current flow will not be observed.

The authors are indebted to Mr. J. Oda in Electrotechnical Laboratory for bicrystal pullings.

Direct Observation of the Lattice Imperfections in Pearlites by Electron Microscopy

By Zenji NISHIYAMA and Atsuo KORE'EDA
Institute of Scientific and Industrial Research, Osaka University, Japan

Isamu EGUCHI and Koshi KATO
Research Laboratory, Daido Steel Co., Nagoya, Japan

Nishiyama, Kore'eda and Shimizu formerly reported about the morphology of the pearlite observed in specimens of thin foil. The present writers have made further detailed observations by an electron microscope of HU-11 type (100 kV) which is more improved than that formely used.

Specimens were prepared from a sheet of 0.7% carbon steel. It was originally cold-rolled to the thickness of 0.35 mm, and annealed for 1/2 hr at 950°C, followed by slow cooling at the rate of 2°C/min. It was then electropolished with a mixture of phosphoric acid and chromic acid to make thin foils for transmission electron microscopy.

Observations of this specimen have confirmed the results formerly obtained and given finer patterns showing the lattice imperfections. Figs. 1 and 2 are two examples. The bands (θ) appearing in these figures are sections of cementite plates in pearlite. In these bands are seen complex figures probably due to Moiré pattern affected by lattice imperfections which seem to have some relation to the dislocations appearing in the neighbouring ferrite (α). At the boundary between the cementite plate and the ferrited plate a featherlike structure of a certain width is seen although it is diffused in Fig. 1. This boundary structure suggests us that there are parallel arrays of defects due to lattice coherency between cementite and ferrite.

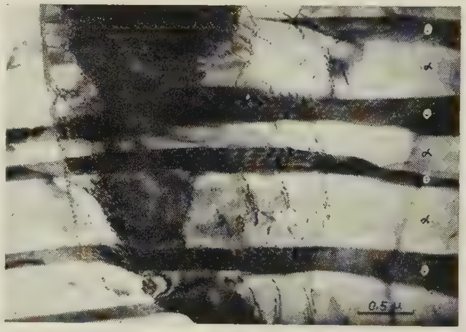

Fig. 1.

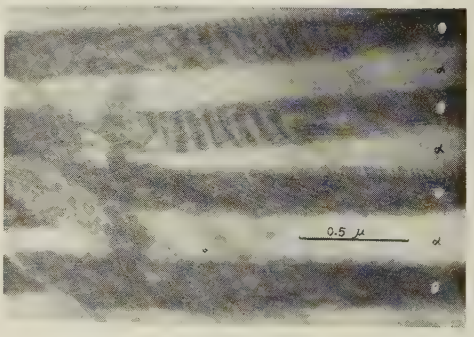

Fig. 2.

Many other photographs showing various aspects of pearlite have been taken, which will be described in "Denki-Seiko" (Electric Furnace Steel).

Proton Magnetic Resonance in Ferroelectric (CH_3NH_3) $AlSO_4 \cdot 12H_2O$

By Ryosuke Hoshino

Department of Physics, Faculty of Science, Hokkaido University, Sapporo, Japan

(Received February 5, 1961)

Measurements have been made of the proton magnetic resonance absorption in $(CH_3NH_3)AlSO_4 \cdot 12H_2O$, methyl-ammonium aluminum sulfate dodecahydrate (MASD) in the temperature range from 90°K to room temperature.

Fig. 1 (a) shows the observed derivative of the absorption curve for the powdered MASD at room temperature. It showed a rather complicated line shape with a central peak of a width about 4 gauss. On the other hand the absorption of $KAlSO_4 \cdot 12H_2O$, which is an isomorphous compound of MASD, showed only a broad line with flat top as given in Fig. 1 (b). In this case all the nuclei which contribute to the resonance, are the protons in water molecules. And, moreover, the line width 12.8 gauss is of the same order with that of the two-proton system in rigid lattice.[1] Comparing the line shape of $KAlSO_4 \cdot 12H_2O$ with that of MASD, it is resonable to assume that the observed absorption in MASD is the superposition of the two lines: a narrow central line and a broad one indicated by dashed line in Fig. 1 (a). The broad line arises from the effectively fixed protons in water molecules and the narrow line from a rapidly rotating (CH_3NH_3) group.[2] The rotation will bigin at lower temperatures owing to the roughly spherical shape of methyl-ammonium group.[3] The observed absorption derivatives and their second moments as a function of temperature are given in Fig. 2 and Fig. 3, respectively. These results were obtained for rising temperature. Above about 160°K, the sharp line located at the central portion of the line begins to appear and becomes more pronounced as the temperature is raised. The variation of the second moments is rather small owing to the fact that the broad line in water molecules remains constant up to room temperature, but it is evident that the rotation of (CH_3NH_3) group occurs at about 160°K, i.e. about 16° below the Curie temperature, 176°K.[4] The temperature dependence of the ferroelectric behavior, measured by Pepinsky et. al.,[4] shows the same variation as the NMR observation, i.e. the anomaries begin at about 20° below the Curie point. From the above data one may conclude that the rotation of (CH_3NH_3) group is closely related to the disappearance of ferroelectricity in MASD. The measurements in single crystal will be reported later.

Temperature Dependence of ESR Line-Width in $K_2CuCl_4 \cdot 2H_2O$

By Hidetaro Abe

The Institute for Solid State Physics,
University of Tokyo, Azabu, Minato-Ku,
Tokyo, Japan

(Received February 2, 1961)

In the former report,[1] electron spin resonance (ESR) of $K_2CuCl_4 \cdot 2H_2O$ was studied, using seven frequencies, in its single crystals and at room temperature, which gave us some knowledge on the exchange interaction between the copper ions in the crystal. Some preliminary results will be given in the present report about the temperature dependence of the line-width observed at about 24 Gc.

The unit cell of this crystal contains two inequivalent Cu^{++} ions, at (0, 0, 0) and (1/2, 1/2, 1/2). Both ions have the identical g-tensor with rhombic symmetry except that the directions of their principal axes are different, g-tensor of one ion can be obtained from the other by a rotation through 90° about their common principal axis, [0,0,1].

When the static magnetic field H is applied at the [1,1,0] direction, the difference between their Zeeman energies, $\Delta g\beta H$, becomes maximum, whereas it vanishes when H is applied at the [0,0,1] direction, the similar direction.

(a) In case of $H//[1,1,0]$, two separated peaks were observed only at higher frequencies, giving the exchange energy, $2J$, between dissimilar copper ions as

$$2J \gtrsim 0.1\,\mathrm{cm}^{-1} \qquad (1)$$

at room temperature. At 24 Gc, one single lines was observed, the width of which was measured at room temperature to be about 800 oer. This value is mainly ascribed to the difference in the Zeeman energy between the dissimilar ions.[1] At reduced temperature, it becomes narrower as in Fig. 1 (a).

(b) On the other hand, the line-width for $H//$ [0,0,1] observed at the higher most frequency was about 40 oer at room temperature,[1] which can be well described by a relation,[2]

$$\Delta H \simeq (\Delta H_{dip})^2/H_{ex} \qquad (2)$$

where ΔH_{dip} is the dipolar width and H_{ex} the exchange energy between the copper ions expressed in unit of magnetic field. The width observed in our present study, 65 oer., is somewhat larger than that mentioned above, because of the "10/3 effect". Within the experimental errors, it remains constant over the present temperature range as shown in Fig. 1 (b).

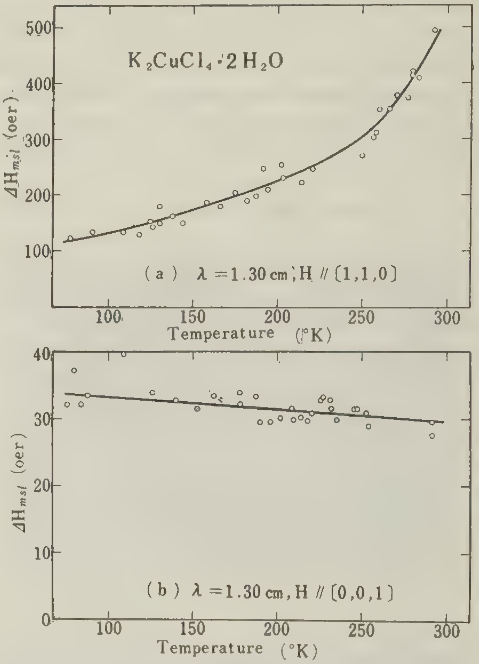

Fig. 1. Temperature dependence of line-width of $K_2CuCl_4 \cdot 2H_2O$.

In both cases of (a) and (b), the line shape fits well the Lorentzian curve at every temperature of measurement from 80°K to 300°K. The origin of this temperature dependence is not yet clear. Some possible models were examined, e.g., the situation that the rhombicity of g tensor of the individual ion decreases in decreasing temperature which can not be expected in the normal case, or that the exchange energy is temperature dependent, such as only that between dissimilar ions increases for decreasing temperature.

In order to make clear the origin, detailed measurements at different frequencies and at lower temperature are now in progress which will be reported in this Journal. A curious behaviour[3] in ESR of this crystal at helium temperature is found at Osaka University.

E.S.R. of Irradiated DPPH Protected by Polystyrene

By Kohzoh MASUDA
Department of Electronic Engineering
and Tokuo SUITA
Department of Nuclear Engineering College of Engineering, Osaka University, Osaka

(Received February 10, 1961)

The number of the unpaired electrons in DPPH with polystyrene under γ-ray irradiation was studied.

The number of the unpaired electrons in DPPH increased with increasing γ-ray dosage and passing through a maximum point it gradually decreased with increasing of total dosage. Total dose was changed from 10^4 to 10^6 röntgens.

In the experiments the maximum number of unpaired electrons appeared at higher radiation dosage by addition of polystyrene. This phenomena cannot be explained only by the shielding effect of polystyrene but to introduce another mechanism such as the interaction of electrons and polystyrene is necessary.

The number of the unpaired electrons in DPPH was observed by ESR (Electron Spin Resonance) of 10 Gc.[1)]

The number of the electrons produced in DPPH by irradiation of γ-ray is estimated by the equation,

$$n_p/n_{p0}=1-\exp(-k_p t)\,,$$

where n_p is the number of electrons and t is total dose. The number of the electrons remains from annihilation in ESR is estimated at

$$n_a/n_{a0}=\exp(-k_a t)\,.$$

The total number of unpaired electrons is then

$$n/n_0=\exp(-k_a t)+K[1-\exp(-k_p t)]\,,$$

where K is the constant which is determined by the ratio of the number of the unpaired electrons presented in case of non irradiation to the number of atoms which can be ionized by radiation and can produce free radicals.

k_a and k_p are the coefficients of annihilation and production of unpaired electrons. The coefficients k_a and k_p can be introduced by following theoretical assumptions.

1) The chemically stable unpair electrons are annihilated by the recombination of disintegrated molecules.

2) DPPH molecules coagulate in polystyrene and critical concentration for the coagulation R_c can be determined. For concentrations below R_c the hindered rotation of molecules is the dominant term of annihilation mechanisms, while over R_c the recombination of unpaired electrons is suppressed by the polystyrene barriers.

3) Molecules are in some cases ionized by γ-ray and compton electrons termed direct process and in other cases ionized by coagulation of exited states of molecules termed indirect process.

4) In the indirect process there are excited states of electrons which must be transport and are suppresed.

In Fig. 1. and Fig. 2. the heavy lines show the

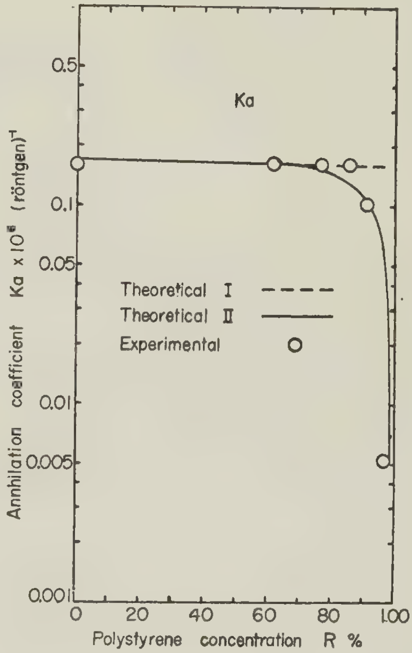

Fig. 1. The annihilation coefficient vs polystyren concentration.

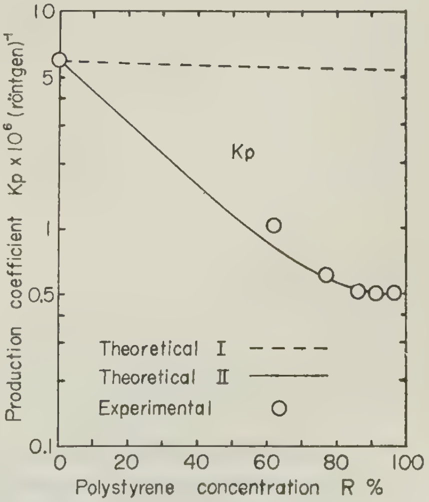

Fig. 2. The production coefficient vs polystyren concentration.

annihilation coefficient k_a and production coefficient k_p versus polystyrene concentration. The dotted lines show the coefficients k_a and k_p including only shielding effect of polystyrene. The points indicate the experimental data.

From the comparison of experimental data and the considerations described above we can conclude that there is not only shielding effect of polystyrene but protection mechanism in DPPH with polystyrene under γ-rays irradiation.

The authors thank to Prof. J. Yamaguchi for his valuable discussions.

Spin Wave Resonance in Pd-Ni Alloy Films

By Hiroshi NOSÉ

Department of Physics, Faculty of Science
Tokyo Metropolitan University

(Received February 7, 1961)

The spin wave resonance in Pd-Ni alloy films was observed in the same manner as in the case of Cu-Ni alloy films[1].

Since the vapour pressures of Ni and Pd resemble each other, it may not be surprising that the concentrations of evaporated films were confirmed to be nearly equal to those of original alloys by means of colorimetric analysis.

On the other hand, since there is a wide difference of lattice constants between Ni and Pd, it is anticipated that the line width of electron diffraction pattern on the evaporated film would be broad, provided that its alloying are imperfect. In practice their lines on the present films, however, were comparably as narrow as those of pure Ni films and furthermore their lattice constants were in good agreement with the results of X-ray diffraction measured on a bulk specimen by Hultgren and Zapffe[2], as shown in Fig. 1. Thus the nearly perfect alloying in present films was confirmed, and this may be perhaps due to the rapid rate of evaporation.

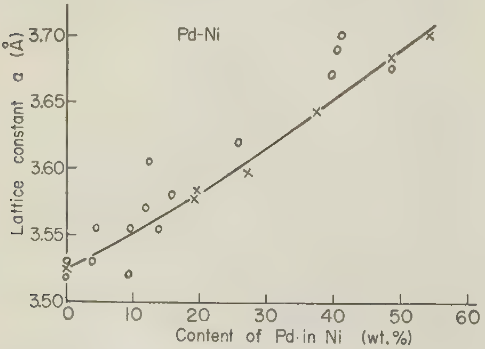

Fig. 1. Concentration dependence of lattice constants of Pd-Ni alloy films; ○: present value by E. D., ×: X-ray value for bulk alloys by Hultgren and Zapffe[2].

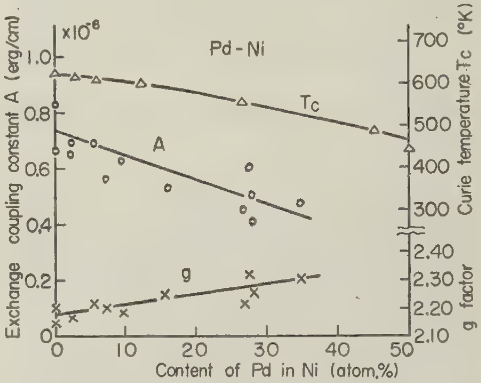

Fig. 2. Concentration dependence of exchange coupling constants and g-factors of Pd-Ni alloy films; ○: present value of A, ×: present value of g, △: T_c by Marian[3].

The exchange coupling constants A of these alloy films were determined from the spin wave resonace at 9300 Mc/sec in a magnetic field being perpendicular to the film plane. These values of A decreased monotonously with increasing concentration of Pd, as shown in Fig. 2. The g-factor was estimated from the main resonances in both perpendicular and parallel field to the plane of each film and plotted also on this figure. For reference, the Curie temperature T_c measured for a bulk specimen by Marian[3] is plotted too. Similarly to the case of Cu-Ni alloy films, it seems that the variation of A in the present case behaves in the similar way to that of T_c and it may be pronounced that the present values of A are the same as those of bulk materials with which there are no data to be compared.

The author wishes to express his thanks to Prof. R. Kimura for his continued encouragement and to Mr. M. Ichikuni for his colorimetric analysis.

The O-H···O Bond in Orthoboric Acid

James A. IBERS and C. H. HOLM
Sheel Development Company, Emeryville, California, U.S.A.

(Received October 28, 1960)

Recently Kume and Kakiuchi[1)] (hereafter designated KK) concluded that their measured second moment of the proton magnetic resonance absorption spectrum of polycrystalline orthoboric acid (H_3BO_3) was incompatible with the presence of linear or nearly linear O-H···O bonds in the structure. The purpose of this note is to show that their experimental second moment of 10.6±0.9 gauss²* *is* compatible with the presence of linear O-H···O bonds, in support of Zachariasen's[2)] conclusions from his precise X-ray determination of the structure.

The appropriate expression for the second moment $M_2(H_n)$ of a given type of stationary hydrogen nucleus, say H_1, in polycrystalline orthoboric acid is

$$M_2(H_1)=357.97\sum_{H\neq H_1} r_{H_1-H}{}^{-6}+72.12\sum_{B} r_{H_1-B}{}^{-6}$$

The first sum takes into account the interaction of nucleus H_1 with the hydrogen nuclei and the second sum the interaction of nucleus H_1 with the boron nuclei in the structure. The H_1-X distance is r_{H_1-X}. The coefficients are derived from the usual expressions which involve spins, relative isotope abundances, and magnetogyric ratios of the nuclei. The values of $M_2(H_n)$ for each of the six non-equivalent hydrogen nuclei in the unit cell of H_3BO_3 are computed and the results averaged to obtain the total moment M_2. Using the X-ray data of Zachariasen and a Datatron 205 electronic computer we have evaluted the contributions of the nuclei to the total second moment. Contributions from nuclei more distant than 5A were assumed to be the same for each type of hydrogen nucleus and were estimated by integration. (KK also computed directly from the X-ray structure the contributions out to 5A and then applied an integration correction for more distant nuclei.) Table I lists the total second moment, together with the contributions to it of the boron and hydrogen interactions. It is interesting to note that KK obtain for their total second moment a value of 7.7 gauss², just the value we would have obtained had we omitted the boron contributions.

Zachariasen's X-ray data lead to a separation of the maximum oxygen electron density from the maximum hydrogen electron density of 0.88A, and the results in Table I are based on the assumption, known to be erroneous[3)], that the hydrogen electron density coincides with the position of the hydrogen nucleus. However, if we assume the heavy-atom positions of the X-ray study, but take a more reasonable value for the O-H internuclear distance in a linear O-H···O bond, then the hydrogen contributions to the second moment are increased slightly and the boron contributions decreased slightly over those presented in Table I. The overall result is the increase of the calculated second moment by only 0.2 to 0.4 gauss², depending upon the O-H distance assumed. The effect of zero-point motion of the nuclei, particularly the hydrogens, on the second moment is more difficult to calculate, owing to a lack of knowledge of the nuclear motions. However, past experience[4,5)] suggests that the effect will be to increase the calculated second moment by at most 10%. Hence the corrected value of the calculated second moment is about 10 to 11 gauss². It is clear then that the experimental second moment of 10.6±0.9 gauss² is compatible with one calculated from a structure based on the X-ray results. The O-H···O bond in orthoboric acid is thus linear or nearly linear, as suggested by the X-ray results, and the magnetic resonance results do little more than confirm this fact.

Table I Contributions to the Second Moment M_2

Proton No.*	Contributions to M_2 (in gauss²)	
	Hydrogen	Boron
I	7.34	1.69
II	8.29	1.88
III	5.62	1.83
IV	6.95	1.86
V	6.54	1.93
VI	8.13	2.58
Average	7.15	1.96
Integration correction	0.53	0.04
Total contribution	7.68	2.00
Total moment	9.7	

* These correspond to Zachariasen's numbering system.

Volume Magnetostriction in Nickel-Iron Alloys

By Yoji Nakamura, Tetsuo Nakajima
and Hideo Takaki
Faculty of Science, Kyoto University

(Received December 27, 1960)

The study on the thermal expansion in iron nickel alloys made by Chevenard1) shows that there are an anomalous contraction in the high nickel content alloys ($>77.2\%$ Ni) and an anomalous dilatation in the low nickel content alloys ($<66.8\%$ Ni) below the Curie temperature.

According to the molecular field theory of ferromagnetism the effects mentioned above correspond to the negative and positive volume magnetostrictions, and also to the positive and negative pressure dependences of the Curie temperature respectively2),3). Theoretical analysis shows that the anomalous expansion and contraction depend on the sign of tangent in Bethe's curve4). Consequently Chevenard's results suggest that the maximum point in the Bethe's curve at which the volume dependence of the spontaneous magnetization vanishes, lies in the region from 66.8% to 77.2% Ni content. The volume magnetostriction, therefore, should change its sign at this region.

The specimens of the Fe-Ni polycrystalline alloys in γ-phase, were prepared by mixing powders of electrolytic iron and those of nickel homogeneously and then melting them at 1600°C. To measure the volume magnetostriction at room temperature, we adopted the D-C Wheatstone bridge with resistance strain gauge whose strain sensitivity was 6.3×10^{-7} per mm scale. The magnetostriction changes linearly with the increasing external magnetic field. When we assume the isotropic forced magnetostriction, we can obtain the volume magnetostriction from the slopes of these curves as shown in Fig. 1.

According to the present author's experimental results the alloy showing no volume magnetostriction is found in the region of higher nickel content side (i.e. from 85.9% Ni to 93.7% Ni) than the region expected from the Chevenard's data.

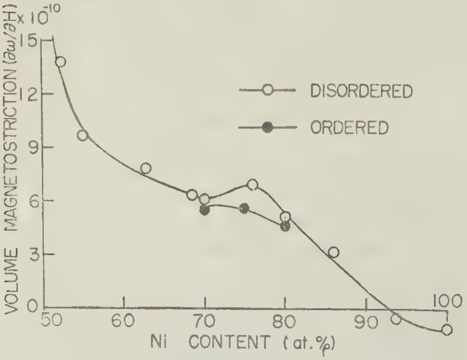

Fig. 1. Volume magnetostriction in nickel iron alloys measured at room temperature.

In recent years, the experimental verification of the following the modynamical relation has been reported for low nickel content alloys by Gugan5)

$$\left(\frac{\partial\omega}{\partial H}\right)_{T.P.}=I\left[-\frac{1}{I}\left(\frac{\partial I}{\partial P}\right)_{T.H.}+\beta\right],$$

where $\frac{\partial w}{\partial H}$ is the volume magnetostriction and β the compressibility. The term $-\frac{1}{I}\frac{\partial I}{\partial P}$ in the above equation can be replaced by $-\frac{1}{2\omega}\frac{\partial\omega}{\partial P}$ when we assume the following relation6)

$$\omega=\omega_0\left(\frac{I}{I_0}\right)^2,$$

where ω and ω_0 are the relative volume change associated with the appearance of the spontaneous magnetizations, I and I_0, at an arbitrary temperature and 0°K respectively. Since the term $-\frac{\partial\omega}{\partial P}$ is always positive, the sign of $-\frac{1}{I}\frac{\partial I}{\partial P}$ depends on the sign of ω which corresponds to the thermal expansion anomaly. In case of low nickel content alloy β is negligibly small as compared to the other terms. However, the measured volume magnetostriction in high nickel content alloys is in the order of 10^{-11} Oe^{-1}. It may, therefore, be impossible to neglect the contribution of the compressibility which is always positive. The shift of the concentration at which the sign of the volume magnetostriction changes, therefore, is due to the effect of compressibility superimposed upon purely magnetic effect, so far as the molecular field approximation is concerned.

In order to investigate the effect of ordering of the alloys upon their volume magnetostriction, we prepared ordered and disordered specimens, the former being annealed at 490°C for 168 hours and the latter quenched from above the critical temperature. As shown in Fig. 1, the volume magnetostriction in the ordered state is smaller than the one in disordered. It is known that the spontaneous magnetization of Ni_3Fe increases by 5.8%7) and the volume of the specimen decreases by 5×10^{-4} when the alloy is brought into the ordered states. Consequently a smaller volume magnetostriction can be expected in the ordered state. Thus the observed result shows a qualitative agreement with the data of the spontaneous magnetization.

Decay of Ir^{195} and Ir^{197}

By Saburo HOMMA, Tokihiro KUROYANAGI,*
Department of Physics, Tohoku University, Sendai
and Haruhiko MORINAGA
Department of Physics, University of Tokyo, Tokyo

(Received January 16, 1961)

The systematics of beta-decay energies in iridium predict a total disintegration energy of ≈1 MeV for Ir^{195} and ≈2 MeV for Ir^{197}. Christian et al.[1] reported ≈1 MeV beta ray for Ir^{195}. Butement et al.,[2] however, reported 2.1 MeV and 1.25 MeV beta ray for Ir^{195}, and also reported 1.6 MeV beta ray for Ir^{197}. Since the reported values of the beta-ray energies from Ir^{195} are various and the energy value of the beta ray from Ir^{197} is not consistent with the systematics in iridium, it is interesting to investigate the beta-ray energies of the iridium activities and to compare their values with those from the beta-decay energy systematics.

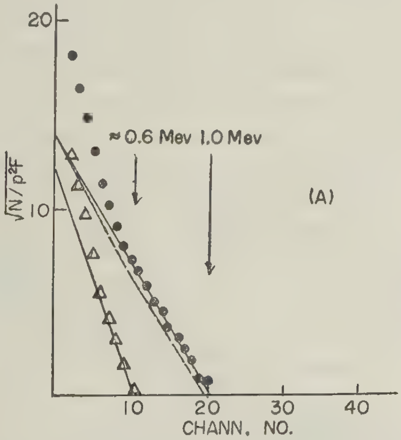

Fig. 1. (A) The Kurie plot of the beta spectrum of Ir^{195}. The contribution for the presence of the beta rays from 19 hr Ir^{194} has been subtracted. The dashed line represents the Kurie plot of Au^{198}, measured under the same conditions.

Ir^{195} was prepared by a (γ, p) reaction in natural platinium using 25 MeV bremsstrahlung from the betatron in the internal target.[3] A chemical separation was performed to get the iridium activities produced in the sample. In order to investigate the beta rays from Ir^{195}, a plastic $(2'' \times 1'')$ scintillation spectrometer, which was calibrated with Au^{198}, P^{32} and In^{114}, was used.

Fig. 1. (A) shows the Kurie plot of the beta-ray spectrum from the decay of 2.3 hr Ir^{195}. The beta rays with the energies of 1 MeV and ≈0.6 MeV were found, and no beta ray above 1 MeV with a half life of 2.3 hr was observed. (The existence of ≈0.6 MeV beta ray was confirmed from comparion with the Kurie plot of Au^{198} shown in Fig. 1. (A)). The intensity ratio of these two beta rays was about 1:0.3. The 1 MeV beta ray agrees with the systematics and the result obtained by Christian et al.

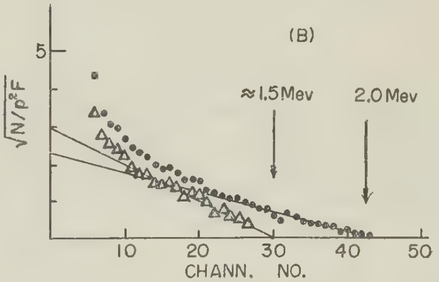

Fig. 1. (B) The Kurie plot of the beta spectrum of Ir^{197}. The contribution for the presence of the beta rays from other iridium and platinium activities has been subtracted.

In the same way the beta rays from Ir^{197} were studied. But in this case no chemistry was performed. 2.0 MeV and ≈1.5 MeV beta rays with the same intensity were found from the Kurie plot of the spectrum (Fig. 1. (B)) and assigned to 7 min. Ir^{197} from their decay curves. The 2 MeV beta ray also agrees very well with the beta-decay energy systematics, so that this beta ray is expected to be the transition to the ground state or the lower excited states in Pt^{197}.

The gamma-ray spectrum was also studied by means of conventional NaI(Tl) $(1\frac{1}{2}'' \times 1\frac{1}{2}'')$ scintillation spectrometer. In addition to the known gamma rays from Ir^{194} and Ir^{195},[2] the strong gamma rays of 100, 130, 330 and 370 KeV decaying with a half life of 2.3 hr were found and very weak gamma rays with the energy between 150 KeV and 250 KeV were also observed. The 880 KeV gamma ray[2] was beyond the limits of detection in the present work. (The gamma rays of 330 KeV and

50 keV were resolved from the corresponding gamma rays of [illegible].

For Ir¹⁸⁶, ≈300 keV gamma ray with the half life of [illegible] min. was found and 1.8 MeV gamma ray was not observed.

The energy and the relative intensity of the gamma rays following the decay of Ir¹⁸⁶ and Ir¹⁸⁸ are listed in Table 1.

Table 1. Gamma rays following the decay of Ir¹⁸⁶ and Ir¹⁸⁸

Properties of Grain Boundaries in Silicon

By [illegible]

[illegible]

Japan

(Received January [illegible], 1961)

The non-ohmic character for current flow perpendicular to grain boundaries is frequently experienced in p-type Si. The properties of grain boundaries in Ge were studied by many investigators¹⁻³ and it has been known that this boundary layer has a p-type character due to the acceptor action of dangling bonds⁴. In Si, however, the properties of grain boundaries have not yet been reported. Contrary to Ge, an n-type character has been observed at the grain boundary layer in p-Si.

P-type Si bicrystals are grown by the vertical pulling technique with dual seeds symmetrically tilted about the [110] axis at angles of 10° and 5°. The bulk resistivities are 200 to 400 Ω cm. Photovoltages are measured on the rectangular specimens by scanning a [illegible] perpendicular to the grain boundary. The sign of the photovoltage shows for the grain boundary to be n-type [illegible] crossed the grain boundary.

The resistance of the boundary is non-linear, increasing with increasing voltage, and is [illegible] regardless the current direction. The curve for both directions of current flow resembles the ordinary rectifier characteristics in the blocking direction. In order to measure the voltage drop across the boundary, Au-Sb alloyed contact is used for the boundary and Al-Si contacts for the bulk, as shown in Fig. 1. For the current flow in this figure, the voltage drops V_1 and V_2 are shown with the correction of IR drop. It is seen that V_1 and V_2 resemble the forward and reverse characteristics of p-n junction, respectively. Taking into consideration of the polarities, it may be concluded

Linear Potential Barrier Model for Nuclear Surface

By Tutomu INOUE

Nagoya Technical College, Nagoya

(Received February 5, 1961)

Sugiyama[1] developed the theory of surface of Fermi gas on the basis of the charge neutrality condition, and gave the method of correcting a potential barrier which does not satisfy the charge neutrality. He derived expressions for the surface energy σ and the correcting displacement b in terms of a phase shift produced by the barrier. His Eqs. (4.8) and (4.7) can be proved to be equivalent to Swiatecki's formula[2] for surface energy and to the definition of the effective surface, respectively. And they are applicable to the nuclear matter.

Sugiyama applied the expressions to the calculation of the surface energy of linear potential barrier $V(x)=-(\hbar^2k_F{}^2/2M)\cdot(x/x_0)$ for $x\leq 0$. His calculation, however, was limited only to a sharp barrier, i.e., that with smaller slope parameter k_Fx_0, and was not compared with Swiatecki's results[3]. Here, the calculation is made for larger range of k_Fx_0. For a diffused barrier, we can calculate an approximate phase shift by the W-K-B method on one hand; and, on the other hand, the surface energy and the position of the effective surface by the Thomas-Fermi approximation. Thus it is interesting to examine, in the case of this simple barrier, whether his expressions in the W-K-B approximation are reduced to the Thomas-Fermi approximation.

The phase shift $\eta(k_x)$ for this barrier is given by

$$\eta(k_x)=F(\omega)=\tan^{-1}[\{J_{1/3}(\omega)+J_{-1/3}(\omega)\}/\{J_{-2/3}(\omega)-J_{2/3}(\omega)\}]\ ,$$

where J_ν is Bessel function of order ν and $\omega=(2k_Fx_0/3)\cdot(k_x/k_F)^3$. The numerical calculations for $\beta=\sigma/\sigma_s$ and b/b_∞, where σ_s and b are those for the infinite wall, are carried out easily by use of tables of the Bessel function[4] and the results are shown in Table I as a function of k_Fx_0. Taking the same Fermi energy $\hbar^2k_F{}^2/2M=22$ Mev as used by Swiatecki, we obtain the surface coefficient in the mass formula, $a_s=4\pi r_0{}^2\beta\sigma_s$ (r_0 is the radius of the nucleon) as a function of x_0, and it is shown in the curve 1 in Fig. 1. This curve is a quantitative presentation for the qualititative estimation by Swiatecki[3]. The straight line 2 shows the limiting behaviour for $k_Fx_0\ll 1$, given by Sugiyama's Eq. (4.12′).

Table I. The values of β and b/b_∞ as functions of the slope parameter k_Fx_0

k_Fx_0	β	b/b_∞
0.00	1.0000	1.0000
0.15	1.0131	0.3702
0.30	1.0274	0.1976
0.45	1.0426	0.0724
0.60	1.0589	−0.0302
0.90	1.0943	−0.1995
1.2	1.1338	−0.3419
1.5	1.1776	−0.4688
1.8	1.2260	−0.5858
2.1	1.2795	−0.6964
2.4	1.3383	−0.8026
2.7	1.4029	−0.9061
3.0	1.4736	−1.0078
4.5	1.9206	−1.5132
6.0	2.4704	−2.0281
7.5	3.0284	−2.5407
9.0	3.5835	−3.0492
10.5	4.1547	−3.5598
12.0	4.7293	−4.0705
13.5	5.3003	−4.5795
15.0	5.8765	−5.0893

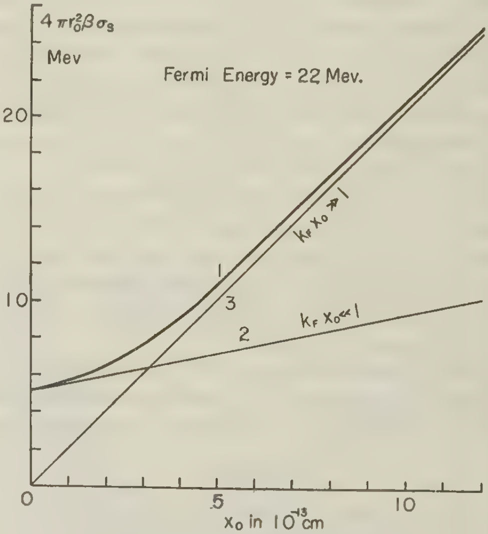

Fig. 1. The surface coefficient in the mass formula as function of the width of surface x_0.

For larger k_Fx_0, the use of the asymptotic expansion of the Bessel functions gives the simple expression

$$F(\omega)\sim\omega+\frac{\pi}{4}\left(+\frac{1}{72\omega}(1+6\cdot\sin 2\omega)\right),$$

which can be obtained also from the W-K-B method. This reduces Sugiyama's Eqs. (4.11) and (4.12) to those of the Thomas-Fermi approximation

$$b/b_\infty=-(15/16\pi)k_Fx_0 \quad \text{and} \quad \beta=(128/105\pi)k_Fx_0,$$

respectively, and the latter is shown as the straight line 3 in Fig. 1.

Fig. 1 shows that the coefficient corresponding to an experimentally reasonable value[5] $x_0\sim2\times10^{-13}$ cm is about 1/3 of the empirical value 17 Mev. This may be due to the defects common to the one-particle treatment and reveal the importance of the contribution of the correlation energy.

The reduction of Sugiyama's expressions to the Thomas-Fermi approximation is practicable not only in the case of the diffused linear barrier but also in that of any diffused barrier, if the phase shift can be calculated by the W-K-B method. The verification will be given in future with that of the equivalency of Sugiyama's expressions to the Swiatecki's.

The author wishes to express his thanks to Dr. Sugiyama for the suggestion of this analysis.

Lateral Density Distribution of Charged Particles in the Central Region of Extensive Air Shower

Saburo MIYAKE, Kensaku HINOTANI, Itsuo KATSUMATA,
Tatsunosuke KANEKO and Nobuo ITO

Department of Physics, Osaka City University

(Received November 14, 1960)

The lateral density distribution of the ionizing particles around the core of the extensive air shower has been observed with ten plastic scintillation counters at mountain altitude (2775 meters above sea level). The lateral density distribution, which has seemed so far to be expressed by the unique function of the distance from the central axis of extensive air showers, has been clearized as that it could be expressed by $1/r^n$ approximately is a range of 20 meters from the axis and n varies from 0.8 to 2.0 by the character of each shower. The result seems to have a relation to the fluctuation which has been presented in the previous paper or to the fluctuation of nuclear cascade in the development of extensive air showers.

The density spectrum at single counter has been also analysed and the result supports above conclusion.

§ 1. Introduction

It is well known at the present time that the study of an extensive air shower is the only way to get information of nuclear interaction and of primary cosmic radiation at very high energy region (10^{15}–10^{18} ev). The general aspects of the extensive air shower has been also clear at least for the average character of the event. The next steps in the air shower experiment are, then, (1) to analyse the character of individual event, and (2) to study nuclear interactions in very high energy. Only a brief summary of the problems is given here, since a detailed description is available in the previous paper[1].

The lateral density distribution of the charged particles in the extensive air shower has been studied by many authors[2] at various altitude and it has been also estimated by the theoretical calculation of various authors[3]. Most of the results so far obtained were average lateral distribution of all detected showers, or, in some cases, of the shower classified into small groups of fixed range of shower size (total number of shower particles). Their conclusive distribution functions were consistent with estimated distributions of shower particles at age 1.2–1.4, calculated by Nishimura and Kamata[4], at least in altitude lower than mountain altitude and they were not sensitive for any classification. Recent studies on the distribution for individual extensive air shower by the use of large span density detectors array have also shown that the distribution for individual large showers at sea level was approximately consistent with that of age 1.4[5]. Nevertheless, the arrangement of counters in above experiments seems to be too far from the axis of shower to detect the fluctuation because the electromagnetic cascade theory does not show so much sensitivity for the age of showers in such distant region, and statistical error of the observed density, population of μ-meson etc. were not favorable to this item. Then, it can be said that no experiments have yet been made which allow one to evaluate the possibility that each extensive air shower has specific character (individuality) and we have as yet very little information as to what is involved in the fluctuation.

One of the authors has suggested that there may be large fluctuations caused by the fluctuations of the starting altitude of the extensive air showers (level fluctuation) and the characteristic fluctuations of elementary process in the development of nuclear cascade, and their effect should appear especially in the central region of the extensive air shower as the variety of the lateral distribution of density of charged particles. An attempt is made in this paper to determine between the possibilities of above suggestion and further object of the work is to study the characters of primary particles and nuclear interactions in very high energy region. The results obtained here show the existence of large fluctuation and it suggest that we must change the image of the extensive air shower which was considered as the averaged scheme so far.

§ 2. Experimental Method

a) *Experimental arrangement and apparatus*

Fig. 1 shows the arrangement of the apparatus; in this figure, S_1–S_{10} are square plastic scintillation counters of $50\times50\times5\,\mathrm{cm}^3$ large, **C.C.** is a multiplate cloud chamber of $2.0\times1.3\times0.9\,\mathrm{m}^3$ large which containes 21 lead sheets of 1.0 cm thickness[6], and **N.M.** is a neutron monitor of standard type[7]. A thickness of the roof of the laboratory is about 1–3 g/cm² for the scintillation counters.

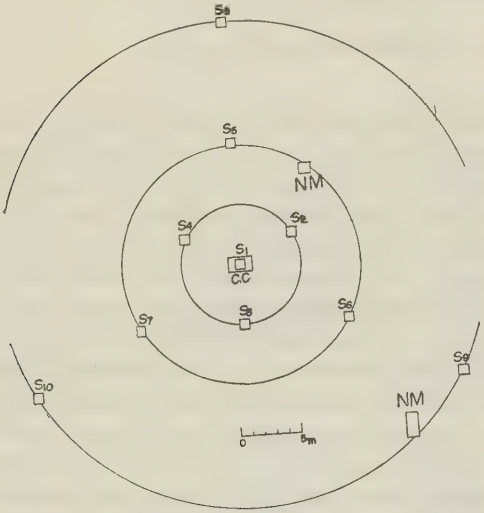

Fig. 1. The arrangement of air shower detectors. $S_1, \cdots S_{10}$ are density detectors which size are $50\times50\,\mathrm{cm}^2$ in area and 5 cm in thickness. **C.C.** is a large multiplate cloud chamber which size is 200 cm wide and 130 cm high and 90 cm deep. **N.M.** is a neutron monitor of standard type which is made for purpose of continual observation of neutron in cosmic ray.

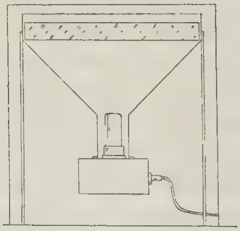

Fig. 2. Crossectional diagram of the plastic scintillator. Photo tube is Du mont 6292 type.

In this report, only the results by the counters are described and the other data concerned to nucleon component will be reported near future.

The detail of the scintillation counter is shown in Fig. 2. The signals from the preamplifier are fed to logarithmic amplifier and amplified. Their logarithmic out put signals are recorded by the method of photographing of the cathode-ray tube. The possible range of pulse height to record is corresponding to the particle density from 4 to 10^6 particles per square meter with the estimated error of about 10%. Starting point of the recorded picture was based on the maximum point of the pulse height distribution curve of the single particle counting by pulse height analyser and the observed pulse height is converted to time interverval as logarithmic scale which is defined as its $6.0\,\mu$sec is twice in this case. The calibration of logarithmic scale has been done by the use of hydrogen discharge tube and romble slit which can vary photo-intensity in the range of six order for the relation of photo-input to recorded output. The frequency of " ghost image " by accidental particles is about one percent of the records, and they can be excluded in the stage of the reading or treatment of observed data. The chance of accidental coincidence between two different extensive air showers can be neglected. These electronic technics employed in this experiment were due to Air Shower Group at Institute for Nuclear Study of Tokyo University[8].

b) *Triggering method*

Three series of observation has been done; These triggering method are as follows;

1. When every pulse from S_1, S_2. S_3, and S_4 exceed 200 particles per square meter.
2. When S_1 exceeds 300 particles/m² and S_2, S_3 and S_4 are more than single particle.
3. When only S_1 exceeds 300 particles/²m.

In these series, average time interval was about 8–13 minutes and the pulse heights from ten scintillation counters and the time when the event occurs are recorded simulteneously.

c) *Treatment of the observed data*

To determine the position of axis and total number of charged particles of the air shower from the recorded particle densities, a simple mechanical analogue computer was used. Nevertheless, since the lateral distribution function is not unique for all showers, the practical method of analysis is as follows; firstly, the position of the axis is searched in the way that the observed data become to show a smooth lateral distribution in axial symmetry, secondly, the exponent of the distribution function, which is expressed approximately the power fuction of the distance from the axis, is given by the comparison of obtained distribution with the already provided curves for the various exponent, and lastly the conventional size is given by the comparison of the density at 10 meters from the axis with the density of standard distribution function which was taken as $r^{-n}\exp-r/r_0$ in this case, where r_0 is taken as 100 meters.

In above treatment, the position of axis is defined with the error of about 1 meter in the central region of experimental arrangement. The exponent n has a error of about 10%, but there is noticeable discrepancy between the showers of low and high value of n and the discrepancy is not artificial.

Since an experiment to determine the relation between the exponent n and r_0 has not yet been made and our counter arrangement is not so wide as to determine r_0 for every shower, the conventional size is not changeable at once to the true size. But it becomes approximated size by multiplying $1/2^{n-1}$, if the lateral distribution function is a standard type mentioned above far from 20 m that is a radius of our counter arrangement.

The pulse height from scintillation counter is not always depend on the particle numbers, and the use of many unshielded G.M. counters are thought to be more available to detect it. Though, the recorded data were calibrated by comparing with track density in the picture of cloud chamber, so as it is mentioned in later section.

The zenith angle of the shower is obtained from the stereoscopic analysis of cloud chamber photographs.

§ 3. Experimental Results

a) *Density distribution in single counter*

The present study was designed to secure the general information about the experimental method and possible significance of the results. Obtained data for S_1 are summarized in Fig. 3 in which low density part is obtained by pulse height analyser and scaling circuits, and the data contributed by air shower are obtained by the coincidence with the signals of other nine counters substituting the probability of accidental coincidence, and high density part is evaluated from all data through the experiment because the frequency is very small and the difference of triggering condition is thought to do not affect to the data in this very high density region.

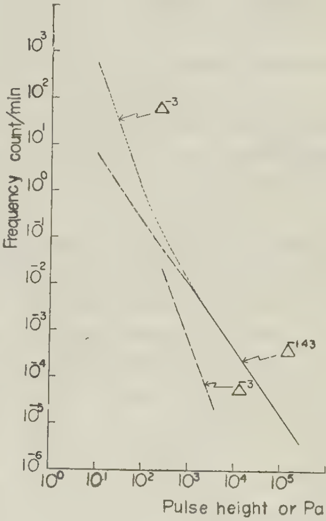

Fig. 3. Density distribution obtained by the density detector S_1. Real line shows that the distribution larger than 10^3 particles per meter square is almost identical to the density distribution obtained by air shower triggering. Dashed line shows density distribution by the event not associated to air shower.

In low density part, the distribution is expressed as the power function of the density with the exponent of -3.0. To analyze what contribute to this density region, the experiment has been done by the cloud chamber under the scintillation counter. The phenomena are divided into following three groups;

1. No significant phenomena are observed.
2. Low energy electron component distributes sparsely.
3. Local high energy electron component are observed only.
4. The others are extensive air showers clearly shown by the signals from other nine counters.

The events belong to group 1) are seemed to be nuclear disintegrations in plastic scintillator and their pulse height distribution is expressed as $\exp(-E/300\,Mev)$ where E is a dissipation energy in the scintillator. Then this events are rapidly decreased according to the output signal is increased and they cannot contribute to high density part.

The events belong to group 2) are seemed to be the core of small size air showers which seemed to be a group of gamma ray distributed mainly in about a few meters.

The events belong to group 3) are young high energy electron cascade and secondaries of high energy nuclear event in the air above the laboratory. The events 2) and 3) are thought to be smaller events, though their age is somewhat different, and their primary energies will be corresponded to larger than 10^{12} ev.

The density distribution by air shower has been seemed so far to be corresponded to the size distribution under the hypothesis that air showers have a unique lateral distribution function for the particle density independent their sizes, and then the exponent of density distribution has to be agreed with the exponent of size distribution, namely, 10 particles/m² and 10^3 particles/m² correspond to sizes of about 10^5 and 10^7 respectively. But in the high density part there exist clear discrepancy. One of the reasons to explain it is the variation of average lateral density distribution function with the size, and the other is variety of the function even in the same size showers, as that described in later section.

In Fig. 4, the rate of contribution from every shower size group has been plotted against the density. It should be noticed that the fixed density is related to very wide range of shower size. The tendency will be more emphasized if the true shower size was used, because the conventional shower size mentioned already have an inclination to strengthen the correspondency of the observed density and shower size.

b) *The distribution and size dependence of the exponent n*

As shown in Fig. 5 the exponent, n, distributes in very wide range, namely, from 0.6 to 2.2. The exponent α of 0.8 and 2.0 is equivalent to the age parameter of about 0.6 and 1.8 in the electromagnetic cascade theory when the culculation by Nishimura and Kamata[4] was applied. Although the relationship between this fluctuation and other character of air shower has never been clear, it seems to us that there are various age of air showers, from young to old, at least in the central region of the showers.

Fig. 6 shows the variation of the mean value of the exponent n for divided shower

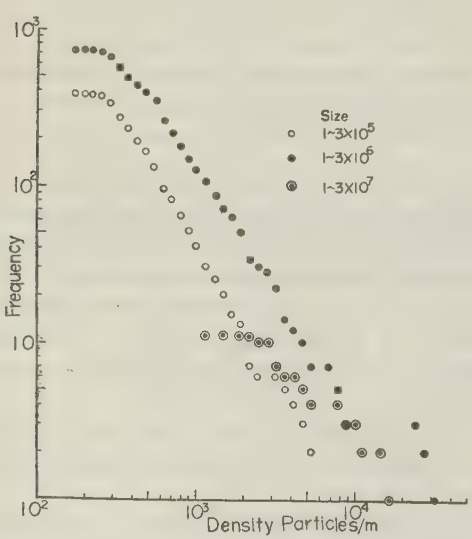

Fig. 4. Three groups of plots show the density distributions of S_1, which are caused by the air showers of size $1-3\times10^5$, $1-10^6$, and $1-10^7$ particles respectively.

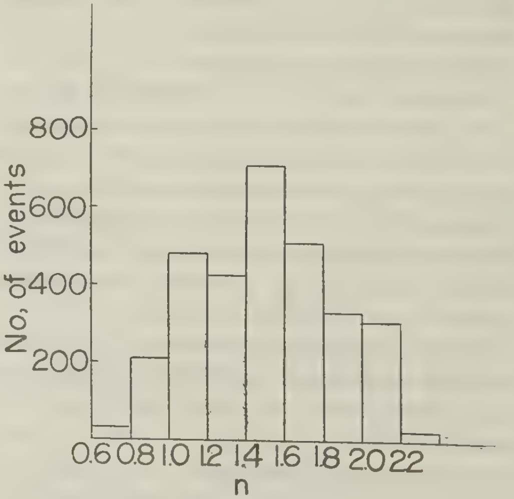

Fig. 5. This histogram shows the distribution of the exponent, n, of lateral density distribution function. We can see from this figure that the exponent fluctuate very wide range.

size groups. In this figure, the value of the exponent at low size must be corrected to smaller one because the showers which have small exponent are missed by the bias of air shower triggering at such small size. Then, it can be said that the mean value of the exponent is increased with the shower size.

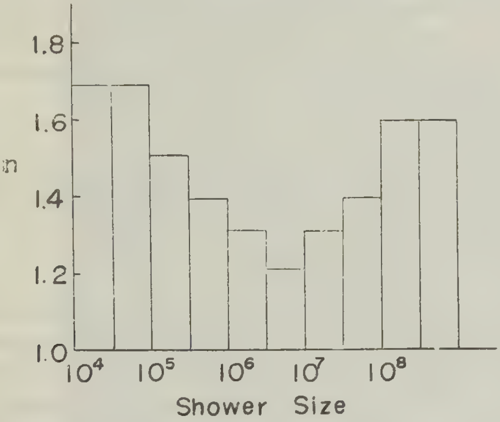

Fig. 6. This histogram shows size dependence of mean value of the exponent, n, of lateral distribution function.

It may be seemed to be natural that the results are, as predicted by electromagnetic cascade theory, understood as larger showers have their maximum at lower atmosphere. But it should be noticed that the exponent is not sensitive to zenith angle of air showers. The difference of the exponent for divided zenith angle group is almost in their error. Then the fluctuation is seen mainly dependent on the character of the showers discussed in later section.

c) *Relation of density distribution to size spectrum*

Fig. 7 shows size spectrum obtained in this experiment. Comparing this size spectrum with density distribution shown in Fig. 3, one can easily find out that the exponent is not identical to each other in larger density and size region. This discrepancy is explained by using the gradual changing of lateral distribution function with the size.

The integral size spectrum $F(N)$ can be represented approximately, in some range of size N, by the following form,

$$F(N) \propto N^{-(\gamma_0 + c \log N')} \tag{1}$$

where N' is the logarithmic mean size of the range. And the size dependent lateral distribution function is assumed as follows,

$$\begin{aligned} \Delta(N, r) &= k(N) N r^{-(a+b \log N)} e^{-r} \\ &= k(N) N^{1-b \log r} r^{-a} e^{-r} \end{aligned} \tag{2}$$

where $k(N)$ is the normalization factor which can be seemed to be constant in some range of size N, in first approximation. The value of γ_0, C, N', a and b will be given in later part of this section. The observed lateral distribution at central region within a few meters from cores shows rather larger fluctuation and there have been few data about the fluctuation. Present data are also not enough to evaluate the fluctuation with some accuracy. Then, the lateral distribution function written in eq. (2) loses its reality in the central region of the air shower. The forms of lateral distribution function at central region plays important role in culculating the density spectrum. By these reasons, it is seemed to be impossible to calculate the accurate density spectrum directly from eq.

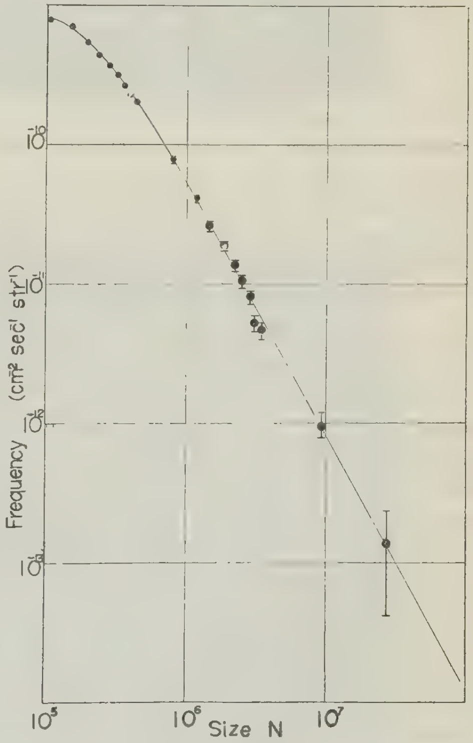

Fig. 7. Size spectrum at Mt. Norikura 2775 m altitude. The size spectrum can be expressed by the following formula;

$$R(>N) = 4.8 \times 10^{-11} \left(\frac{N}{10^6}\right)^{-1.85} \text{cm}^{-2}\,\text{sec}^{-1}\,\text{str}^{-1}$$

for range of size $10^6 - 10^6$.

(1) and (2). Accordingly, it is impossible to show directly that the difference of the exponent between the density distribution and the lateral distribution is due to the size dependency of the lateral distribution. Then, the following method, though it is not directly, is taken.

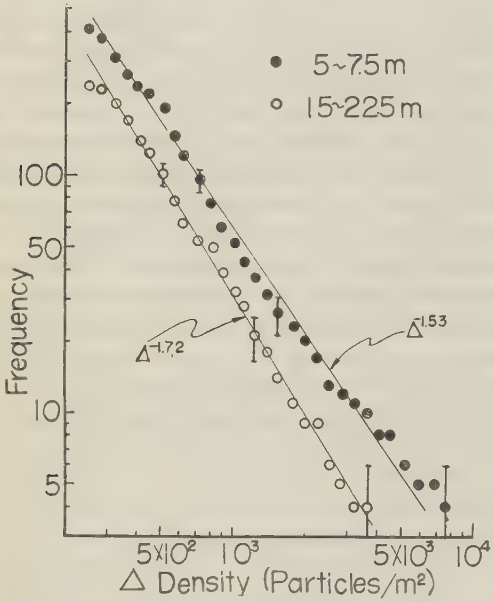

Fig. 8. Two density distributions. One of them (shown by black point) is a density distribution of air showers whose cores strike a ring shaped zone defined by two radii of 5 and 7.5 m from S_1 and the other (shown by circles) is one by two radii of 15 and 22.5 m.

In Fig. 8, two density distribution are shown. One of them (shown by black point in the figure) is a density distribution of air showers whose cores strike a ring shaped zone defined by two radii of 5 and 7.5 *m* from the density detector S_1, and the other distribution curve (shown by circles) is one by two radii of 15 and 22.5 *m*. The exponents of the curves are −1.53 for 5–7.5 *m* and −1.72 for 15–22.5 *m*, respectively, in the range of density $3\times10^2-3\times10^3$ particles per square meter.

On the other hand, the integral density spectrum, $D(\Delta, r)$ by the air shower striking at distance, r, from the density detector S_1 can be written as follows by considering eq. (2),

$$D(\Delta, r)\propto N^{-(\gamma_0+c\log N')}$$
$$=\left\{\frac{1}{k(N)}r^a e^r \Delta\right\}^{-(\gamma_0+c\log N')/(1-b\log\gamma)}$$
$$\propto \Delta^{-(\gamma_0+c\log N')/(1-b\log\gamma)}$$

In this relation, putting, $-\dfrac{\gamma_0+c\log N'}{1-b\log r}=\beta$, we can obtain the follwing relation,

$$b=\frac{\beta-(\gamma_0+c\log N')}{\beta\log r}$$

Mean shower size N' in above relation is 1.4×10^6 and this value corresponds to mean density 10^3 particles per m^2 at distance 5–7.5 *m* from S_1. For distance 15–22.5 *m*, N' is 5×10^6. From these values, we can obtained the following relation,

$$b=0.10$$

This value for b is thought to explain the present experimental results fairly well.

§ 4. Discussion

The present series of experiments shows clearly that there are large fluctuations, although the nature of the fluctuation related to the essential role in individual shower is still a matter of speculation. There appear to be two possible explanations to account for the large fluctuations, namely, (1) the fluctuations of the starting altitude of extensive air showers, as that has been described in the previous paper (level fluctuation) and (2) the characteristic fluctuations of elementary process in the development of nuclear cascade in the core of air shower. These two models, shown in Fig. 9, are different in the inelas-

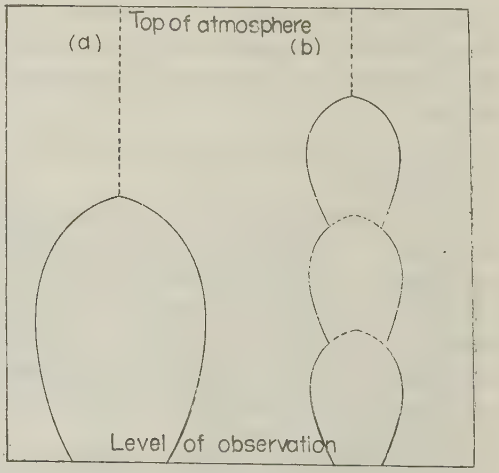

Fig. 9. A schematic figure of the development of air shower in atmosphere. (a) shows the fluctuation of the starting altitude of the air shower. (b) shows the characteristic fluctuations of elementary process in the development of nuclear cascade in the core of air shower.

ticity of high energy nuclear interactions.

Since the experiments in this report give the informations only near the core and the observed particles are small fraction of total, the discrepancy between the above models is not clear. We have not yet sufficient data on the character of individual shower to give an accurate evaluation of these two possibilities.

But if we accept these general specification: By any way the above models essentially equal

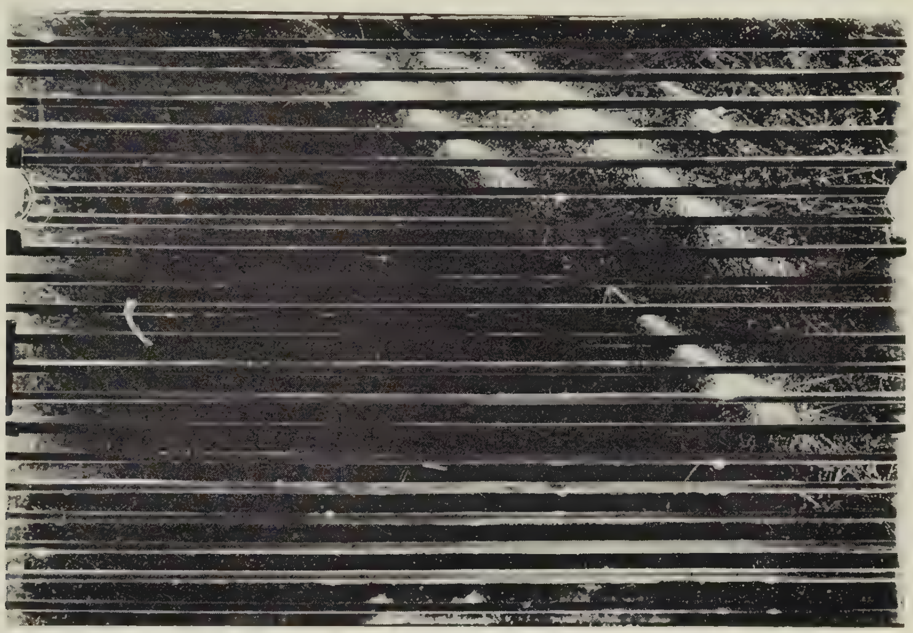

Fig. 10. This picture shows the cloud chamber photograph of the air shower which the core strikes 1.5 m distance from the cloud chamber and the size is 3×10^6 particles. This picture shows very large lateral density fluctuation.

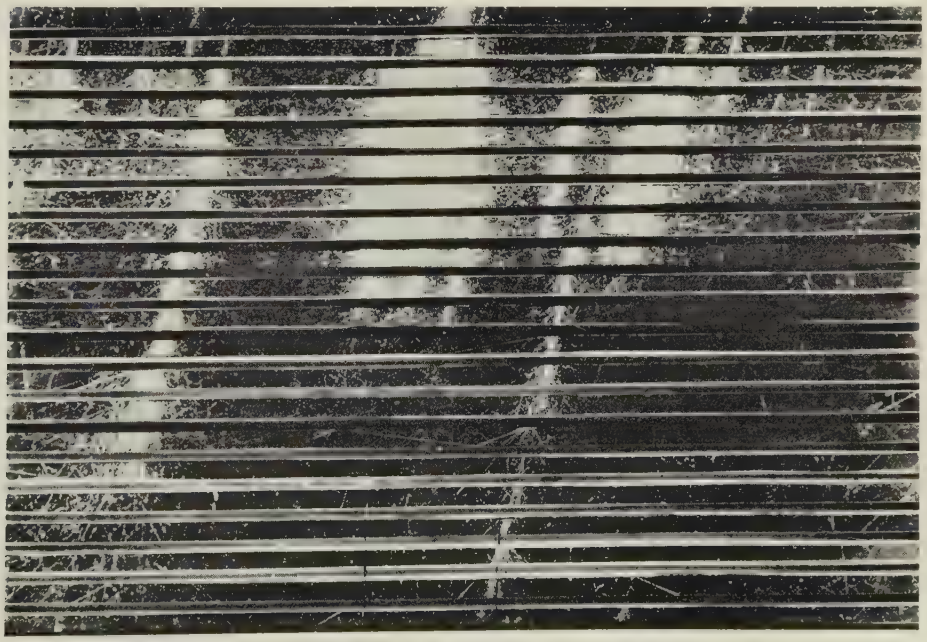

Fig. 11. An example of very young air shower (size$=5\times10^5$, distance from core$=2.5$ m). All particles in this picture are fairly high energy.

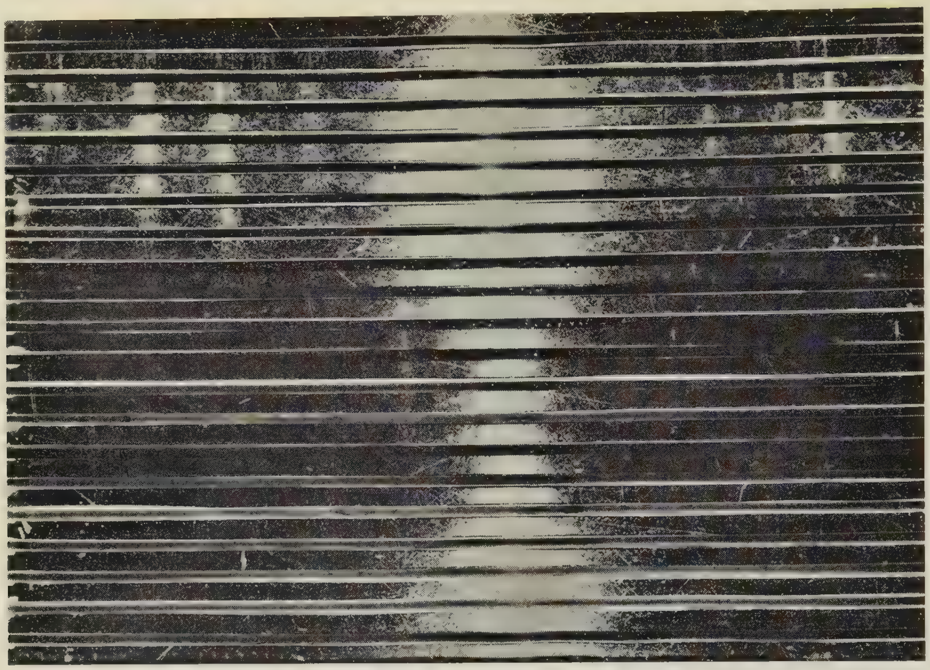

Fig. 12. This picture obtained by triggering of only S_1, so this event is not associated to air shower. It seems that the event is the very early stage of air shower which will develop to the size of about 10^4.

in the fact that core characters are determined by the nearest high energy interaction which occurs with large level fluctuation: It becomes considerable easier to understand some other characters of extensive air shower, for example, high density μ-meson shower in underground, high energy nucleon component in the core and so on which were explained already in the previous paper from the standpoint of model (1).

Several points of interest have come to clear by the use of multiplate cloud chamber, (1) lateral density fluctuation which is understood as azimuthal unisotropy that is shown in Fig. 10. (2) local high energy event as shown in Fig. 11. (3) the very early stage of air shower which will develope to the size of about 10^4. as shown in Fig. 12.

These are seemed to support above explanation. The study for these point will be continued.

Acknowledgement

The authors wish to express their thanks to Professor Y. Watase for his continual encouragements. This study has been supported in part by a Grant in Aid for Fundamental Scientific Research from the Ministry of Education and from Cosmic Ray Laboratory of Tokyo University.

Mu-Meson Component of Air Shower Below the Ground

By Kenji WATANABE

Osaka City University

(Received January 6, 1961)

Mu-meson component, observed underground, of the extensive air shower is studied, which has come from the nuclear cascade of the shower core in the ground and possibly shows high concentration of mu-mesons below the ground. The total number of them can be estimated independently of energy and multiplicity distributions of secondary particles of the elementary collision each of shower particles undergoes, and also independently of some fluctuations. It is only because they depend upon the whole feature of the nuclear cascade in the shower core.

Experimental data of the multiple penetrating particles (M.P.P.), whose feature is the high concentration of mu-mesons, could not be interpreted in terms of those mu-mesons, i.e., decay products within the nuclear cascades in the ground initiated by impinging nucleons of high energy in the air shower cores, even though the possible contribution of the K-meson and Hyperon production in the high energy collisions within nuclear cascades is taken into consideration.

§ 1. Introduction

It is well known that mu-meson component of the extensive air shower (abbreviated as EAS) penetrates deep into the ground, that has been observed by Cornell group[1], George et al.[2], Osaka group[3] and Sakvarelidze et al.[4] These experiments have revealed that the *mu*-meson component of EAS covers some extension of about 60 m and about 13 m radius at 60 mwe and 1600 mwe respectively, with low particle density of about one particle or less per square meter. These date have been used to construct a model of EAS[5,6,7] together with those obtained at sea level and at mountain altitude.

On the other hand Osaka group has observed the multiple penetrating particles, abbreviated as the M.P.P., by means of a multiplate cloud chamber at 50 mwe and 250 mwe underground[8]. The events occur too frequently with the high concentration of *mu*-mesons to be interpreted by the use of the air shower model so far deduced from previous experiments and calculations of the nuclear cascade[5,6,9]. They shows *mu*-meson concentration from several to a few tens particles per square meter.

About the same time Soviet group has reported experimental results on the nucleon component of EAS at mountain altitute[6,10]. They observed at 3600 m elevation that in the EAS of total 10^5 particles there exists a very high energy nucleon in the shower core of about one hundredth or more of energy of primary cosmic rays, a few nucleons of 10^{12} eV or more energy each being in the EAS of total size more than 10^5 particles. Hence these facts should be taken into account not only for the interpretation of ordinary EAS, but also for the M.P.P., that has firstly suggested by G. Cocconi[6]. The existence of these energetic N-component has afterwards been established extensively by S. Miyake et al.[11], Soviet group[12] and Tokyo group[13].

The *mu*-mesons, observed underground, of EAS, then, are reasonably considered as follows; i) some of them are such *mu*-mesons as to have come from *pi*-meson decays within the nuclear cascades of the shower core in the atmosphere and penetrated into the ground as *mu*-meson, ii) the others are such as to have come within the nuclear cascades below ground, which are initiated by high energy N component impinging on the ground. None has been quantitatively estimated on the latter *mu*-mesons, while about the former several calculations have been performed[5,14,15,16] under various simplifying and sometimes too simplified assumptions. Hence it seems to be worthwhile estimating the contribution of *mu*-mesons generated by the latter mechanism of generation to the air shower *mu*-mesons, observed underground. This problem is studied in this paper and the results of estimate is compared with the experimental results of the M.P.P., discussion being given on its interpretation.

On the other hand it has been also suggested that the M.P.P. comes, because of some fluctuation, from the abruptly developing showers under the mountain altitude[17,18]. This is based upon the new model of air showers presented by S. Miyake[18]. The model may be however not consistent with recent experiments by K. Greisen et al.[18]. In this paper, then, the analysis is performed from the traditional point of view of the air shower.

It needs emphasis that the estimate given in this paper is free from such ambiguities as the adaptation of the energy and multiplicity distributions of secondary particles of elementary collisions in the shower and as their fluctuations. These ambiguities have been of doubtful feature for the calculations, so far attempted, of nuclear cascades in the atomosphere.

§ 2. Inherent Property of Observation of Air Shower *Mu*-Mesons Underground

The EAS so far observed at sea level or mountain altitude gives us an information about the features at some cross sections of the nuclear and electronphoton cascades developing or diminishing in the atmosphere. Then the calculations on the nuclear cascade, to be compared with experimental data, have been required to present the estimates not about the whole cascade but about each cross section along the developing of the nuclear cascade. Hence these estimated results had inherent features directly affected by the assumption adapted for the energy and multiplicity spectra of secondary particles of the elementary collisions in the cascade, and further by their fluctuations. This feature limits the applicability and the confidence of usual EAS theories, since the elementary collision of very high energy has not yet been clarified. It is also because the complexity of EAS calculations requires the various simplifying assumptions, for example the energy equipartition of secondary particles[5,14,15], or the neglection of essential factors, for example the fluctuations. In this way the experimental data of EAS at sea level or at mountain altitudes have to be considered on taking into account various ambiguous factors, but the reason for these complexities is only that the experimental data refer to a cross section of EAS on its developing.

On the contrary, the observation of *mu*-mesons underground of EAS, for example at 250 mwe, gives the information about the whole feature of cascade showers. This is an essential feature of the underground observation, different from those at sea level or mountain altitude: Let us consider a simple example, the EAS initiated from a proton with energy of 10^{15} eV. The inelasticity is assumed to be 0.3 for the nucleon-nucleus collision. On the average exists a high energy proton of 10^{13} eV at sea level (10 mwe), and the proton penetrates into the ground with successively colliding with rock nucleus. In this way at the depth of 30 mwe from the atmosphere the maximum energy particle reaches to have an energy of 1 GeV, where the interaction mean free path is about 1 mwe in the rock. If we observe *mu*-mesons of 1 GeV or more energy by means of a cloud chamber, like the experiment of the M.P.P., the nuclear cascade of EAS of 10^{15} eV may be considered to have disappeared at 30 mwe. Hence the observation of EAS *mu*-mesons at 250 mwe may be contributed from the whole cascade showers, which have disappeared at 30 mwe, through the *mu*-mesons come from the whole developing process of EAS. This fact is the essentially different characteristic from the observation at sea level or at mountain altitudes.

The fact that the probability of *pi*–*mu* decays abruptly changes at the ground surface along the shower developing has to be taken into account, although it has been neglected in the above consideration. If an EAS developed in the atmosphere for 90 % of its age, the underground *mu*-mesons may exist much more than those of another EAS with 50 % of its age in the atmosphere. Thus this fact introduces into consideration such an ambiguous factor that in what partition of the observed *mu*-mesons comes from below the ground. As described above, therefore, only such *mu*-mesons are considered in this paper as to have come from the nuclear cascade initiated by impinging nucleons on the ground. Such *mu*-mesons may be reasonably refered to the experimental data of the

M.P.P. in the first approximation. Then the nuclear cascade under consideration is initiated from the ground surface and developing wholly in the ground, so that it is able to be considered quantitatively with few ambiguity as shown in the following sections.

§ 3. Total Track Length, E_0/E

Considering the nuclear cascades or electron-photon cascades, the physical quantities refering to the whole cascade, but not to each cross section in its developing process, are to be determined by the incident energy and the observing energy, the familiar one being the total track length of the shower particles of more than or equal to E. Let us consider the cascade process initiated from a particle of energy E_0, for convenience. The total track length, $T(E_0, E)$, of the shower particles (of energies more than E) in the whole cascades is expected to be expressed as

$$T(E_0,\ E)=\omega\frac{E_0}{E}\ , \qquad (1)$$

where ω is a constant of about 1/2, as shown in the following, and only a parameter concerning with the energy partition of elementary collisions in the cascade process.

On the basis of the expression (1), the number of *mu*-mesons observed underground is estimated in the next section. In this section it will be shown that, for a few important cases, the expression (1) is valid and independent from the energy and multiplicity distributions of elementary collisions in the cascades. Hence the independency is to be held for the result deduced from the expression (1) on the *mu*-meson numbers observed underground.

i) Electron-Photon Cascade Theory

For the electron-photon cascade theory the expression (1) is described in the radiation unit. As is well known, the total track length is expressed in the so called approximation A, following B. Rossi[20], as

$$T(E_0, E)=0.437\frac{E_0}{E}\ , \qquad (2)$$

if $E_0 \gg E$, being equal to the expression (1). This is the case for the electron-initiating showers, and also the similar expression is valid for the showers initiated by photons, only replacing the numerical factor by the value of 0.572. The elementary processes in the approximation A are the bremsstrahlung by electrons and the pair creation by photons, and the probabilities of energy transfers per radiation length are approximately expressed as

$$\varphi_{\mathrm{brem}}(E_0, E)dE=dE/E$$
$$\varphi_{\mathrm{pair}}(E_0,\ E)dE=\mu_0\frac{dE}{E_0}\ ,$$

respectively, where μ_0 is a constant. In this case, the attention is called that both components, i.e., electrons and photons, contribute to the developing of the cascade showers until each dissipating its energy practically (see the following).

ii) Nuclear Cascade Theory

For the nuclear cascade theory the expression (1) is expressed in the unit of the interaction mean free path. Several nuclear cascade theories[5,14,15,16,21,22] have, so far, been provided, but discussion is given here for the Buddini-Molière theory[22] and the Fukuda-Ogita-Ueda theory[16], the former starting from the Heisenbery theory[23] as the elementary nucleon-nucleon collision and the latter refering to the Landau theory[24]. It is because the Heisenbery theory and the Landau theory are considered as describing comparatively satisfactorily the elementary collisions at high energy though the very high energy collision have not yet been investigated conclusively.

ii-a) Buddini-Molière Nuclear Cascade Theory[22]

In this theory the integral energy spectrum of secondary particles, which contribute to the developing of the nuclear cascade, in the elementary collisions is approximately expressed by

$$F_1(\eta)=\frac{\gamma}{\alpha!}\left(\ln\frac{1}{\eta}\right)^{\alpha}\ , \qquad (3)$$

where $\eta=E/E_0$, E_0 being the energy of the incident particle and E that of the secondary particle. α and γ is constant parameters, and the variation of their values serves to widely reproduce various spectra encountered in high energy collisions. Of course, the approximation cannot be satisfactory in the wide energy range by only a value of the constant α, but the suitable dividing of energy range gives a satisfactory approximation by only one value of α for each energy division. Fig. 1 shows various energy spectra expressed by the expression (3) with corresponding values of α. The Heisenberg theory can be expressed in the satisfactory approximation, following Buddini and Molière, by the one with $\alpha=2.0$ for energy range from $\eta=0.03$ to $\eta=0.3$.

On the other hand the next formula holds,

$$\gamma=\int_0^1 d\eta\cdot\eta\left(-\frac{dF_1(\eta)}{d\eta}\right), \qquad (4)$$

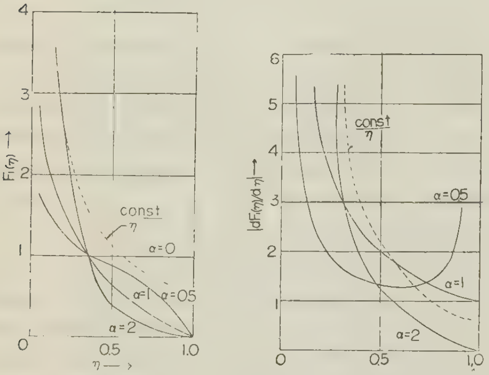

Fig. 1. Integral and differential energy spectra used in the Buddini-Molière nuclear cascade theory (after the authors[22]).

i.e., γE_0 is the energy transfered to the secondaries under consideration. From the view point of the cascade shower, the value of $(1-\gamma)$ is the portion of energies which escape from the cascade in each elementary collision and thereafter does not contribute to the developing of the cascade. When the secondaries of the elementary collision are composed of nucleons, charged *pi*-mesons and neutral *pi*-mesons, regardless of their contribution to the cascade, the energy conservation states that

$$\gamma_n+\gamma_\pi+\gamma_{\pi^0}=1\ ,$$

or more generally,

$$\sum_i \gamma i=1\ .$$

Almost all of the neutral *pi*-mesons decay into two photons, initiating the electron photon cascade showers, and do not contribute to the further developing of the nuclear cascade. In this case, the value of γ in the sense of the expression (4) is to be the value of $(1-\gamma_{\pi^0})$, being a value of about 0.9* at present. The emphasis is that the value of γ is nearly equal to unity, if the portion of the energy escaping from the cascade is small and does not extensively deform the developing of the cascade.

Following Buddini and Molière, the experimental results on the energy spectrum of secondary *pi*-mesons in high energy collisions can be approximated with a set of parameters, $\gamma=0.2$ & $\alpha=2.2$.

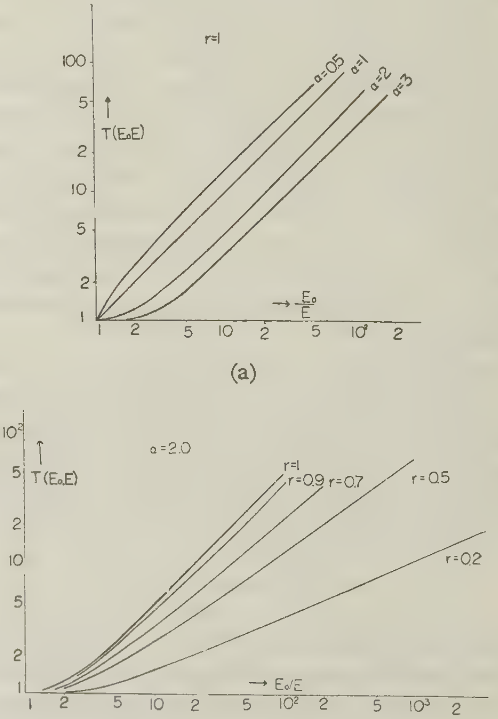
The cascade theory based on the expression (3) states that the number, $F(\eta,\ l)$, of particles of energies equal to or more than ηE_0 at the position of l nuclear m.f.p.s. from the initial point is expressed by

$$F(\eta,\ l)=e^{-l}\sum_{n=0}^{\infty}\frac{(\gamma l)^n\left(\ln\frac{1}{\eta}\right)^{n\alpha}}{n!\ (n\alpha)!}\ .$$

Hence the total track length $T(E_0,\ E)$ is obtained as follows,

$$T(E_0,\ E)=\int_0^\infty F(\eta,\ l)dl$$
$$=\sum_{n=0}^{\infty}\frac{\left[\gamma\left(\ln\frac{1}{\eta}\right)^\alpha\right]^n}{(n\alpha)!}\ .$$

The curves representing the expression (5) are shown in Figs. 2a and 2b for various values of α and γ. From these figures it is



(a)

(b)

Fig. 2. Total track length, $T(E_0,\ E)$, for various pairs of parameters, α and γ.

---

* The value of γ, 0.9, here presented is based on the value of the inelasticity, 0.3, of high energy nuclear collisions in the cascade.

emphasized that the expression (1) can approximately reproduce the expression (5) independently of the values of α, $\alpha=0.5$, 1, 2, 3, i.e., the wide variation of energy and multiplicity spectra if the value of γ is unity. The approximation is satisfactory for the region of E/E_0 smaller than 0.3. The value of ω in the expression is changed from 0.3 to 1.

Even when the spectrum of the elementary collision is changed along the developing of the shower, the expression (1) can be adapted throughout in good approximation. The adaptation of different values of α in different energy regions is also not affect the applicability of the expression (1). These facts may be easily seen from curves of Fig. 2.

In the case of the value of γ smaller than unity, the total track length is reexpressed by the expression (1) in replacing E_0/E by $(E_0/E)^\beta$ with the value of β smaller than unity. For example, the curve with $\gamma=0.5$ and $\alpha=2.0$ is approximated by

$$T(E_0, E)=\text{const.}\,(E_0/E)^{0.71}\,. \qquad (6)$$

Heretofore, the "secondary" particles in this subsection mean those contributing to the further shower developing, regardless of species of particles. But the secondary particles are really considered to be composed of *pi*-mesons and nucleons in the high energy collisions. Both particles contribute concurrently to the developing of the shower. *Pi*-meson induced collisions may be, as usual, considered here to have a same feature as nucleon induced collisions. But energy spectrum of secondary *pi*-mesons may be expected as different from that of secondary nucleons, in which there contains the outgoing of the incident nucleon. Since the secondary particles, both *pi*-mesons and nucleons, undergo further nuclear interactions of the same feature as described above, the secondary energy spectrum may be composed of *pi*-meson spectrum and nucleon spectrum, i.e.,

$$f(\eta)=f_\pi(\eta)+f_n(\eta)\,.$$

In this case, also, the resultant spectrum, $f(\eta)$, may not deviate from the expression (3) with $\alpha=0.5-3$*, and considering that $\gamma=\gamma_\pi+\gamma_n\approx 1$, the expression (1) may be accepted. Also, considering the existence of secondary neutral *pi*-mesons, the curve of $\alpha=2.0$ and $\gamma=0.9$ is approximately proportional to $(E_0/E)^{0.90}$.

ii-b) Fukuda-Ogita-Ueda Theory of Nuclear Cascade[16]

A nuclear cascade theory has been presented, by Fukuda, Ogita and Ueda[16], with reference to the Landau theory of nucleon-nucleon collisions.

The following expression (7) gives the number, dn, of secondary nuclear active particles of energy $(E, E+dE)$, which are produced in the elementary nucleon-nuecleus collision, after Amai et al.[25],

$$dn=\left(\frac{E_0}{E_M}\right)^{1-\delta}\frac{1-\delta}{\delta}\,d\left(\frac{E_0}{E}\right)^{\delta} \qquad (7)$$

where E_0 is the energy of the incident nucleon, δ a constant of about 0.52, and E_M is the energy of the most energetic particle among secondary particles and may be approximately equal to E_0. This expression represents the number of only such secondary particles as to be ejected forward in the center of mass system, but is enough to be used, according to the authors[16], for the calculation of high energy nuclear cascades with the interest in high energy shower particles. The familiar diffusion equations for the nuclear cascade have been formulated on the basis of the expression (7) and have analytically been solved. Suppose that a nucleon of energy E_0 initiates a nuclear cascade at $x=0$, and the number of nuclear particles of energy $(E, E+dE)$ at $x=x$ is expressed[16] by

$$N(E, x)dE=\frac{dE}{E_0}\left(\frac{E_0}{E}\right)^{1+\delta}\left(\frac{Ax}{y}\right)^{1/2}\cdot e^{-x} \cdot I_1(\sqrt{4Axy}\,)\,, \qquad (8)$$

where $y=ln(E_0/E)$, $A=\Delta\left(\frac{E_M}{E_0}\right)^{\delta-1}\cdot(1-\delta)$, and Δ the ratio of the number of charged *pi*-mesons to that of total *pi*-mesons. $I_1(z)$ is the usual imaginary Bessel function of the first order.

The total track length is obtained, using the expression (8), as follows,

$$T(E_0, E)=\int_0^\infty dx\int_E^{E_M} N(E, x)dE$$
$$=\frac{A}{\delta+A}\left[\left(\frac{E_0}{E}\right)^{\delta+A}-\left(\frac{E_0}{E_M}\right)^{\delta+A}\right].$$

When $E_0 \gg E$, it turns out, using $\delta=0.52$ and $\Delta=2/3$,

---

* It is noted that the expression (3) with $\alpha=0.5$ represents such a spectrum as to show the existence of high energy outgoing of the incident particle.

$$T(E_0, E)=0.4\cdot\left(\frac{E_0}{E}\right)^{0.85}.$$

The fact that the power value of 0.85 differs from unity may be attributed to the neglection of the secondary particles ejected backward in the center of mass system. Without the neglection it is expected that the power is unity.

In this way, if the interaction is of the bremsstrahlung type, the expression (1) is valid, for the electromagnetic cascade theory and for the nuclear cascade theory currently accepted, independently of plausible energy and multiplicity spectra of secondary particles.

The problem of fluctuation is essential and can not be neglected for the energy region of $E/E_0>1/10$, but it is apparent that the consideration presented above may be fluctuation-free, because of the statistical averaging, over the energy rigion of $E/E_0<1/50$, which is mainly interest in the cascade theory.

§4. Energy Spectrum of *Mu*-mesons From The Cascade

The energy spectrum of *mu*-mesons come from the nuclear cascades is obtained on the basis of the expression (1). The *pi–mu* decays may affect the nuclear cascades, but is negligible for the case, considered here, in the ground. Each nuclear active particle in the cascade undergoes the next nuclear interaction, upon travelling one mean free path on the average. Hence the total track length, $T(E_0, E)$, can be reinterpreted as intergral energy spectrum, $N(E_0, E)$, contained in the nuclear cascade inititated by a particle of energy E_0, i.e.,

$$N(E_0, E)=T(E_0, E)=\omega\frac{E_0}{E}, \tag{9}$$

since the expression (1) is expressed in the interaction mean free path. Then differential energy spectrum, $n(E_0, E)dE$, of particles contained in the wholly cascades is given by

$$\begin{aligned} n(E_0, E)dE &= \left|\frac{dN}{dE}\right|dE \\ &= \omega\frac{E_0}{E^2}dE\,. \end{aligned} \tag{10}$$

As the nuclear active particles in the nuclear cascades are usually considered to be *pi*-mesons*, the *mu*-meson spectrum from the cascade is the expression (10) multiplied by the decay probability. The decay probability, P, is somewhat different from the usual meaning. In this case, only the interest is in whether the *pi*-meson has ceased its travelling with the interaction or with the decay into the *mu*-meson. On the average, the *pi*-meson is considered to die on travelling one interaction mean free path. Hence the followings are obtained, i.e.,

$$P_{\text{int}}=\frac{dx}{\lambda} \text{ and } P_{\text{decay}}=\frac{dx/\rho}{c\beta}\cdot\frac{1}{\gamma\tau_0},$$

and if $E\simeq pc$,

$$P=\frac{P_{\text{decay}}}{P_{\text{int}}+P_{\text{decay}}}=\frac{B}{E+B}, \tag{11}$$

with

$$B\equiv\frac{mc^2\cdot\lambda}{\rho\cdot c\tau_0}, \tag{12}$$

m being the mass of *pi*-mesons, λ the interaction mean free path, ρ the density of rock in the ground, c the light speed, and τ_0 the mean life time of *pi*-mesons. For the *pi*-mesons in the ground, it turns out, using $\rho=2.6\text{ g/cm}^3$ and $\lambda=100\text{ g/cm}^2$,

$$B_\pi=6.5\text{ MeV}.$$

As the interest at present is in the energy region of more than a few GeV, the developing of nuclear cascades is not affected by the *pi-mu* decays.

Under the assumption of $B\ll E$, the differential energy spectrum of *mu*-mesons is obtained, using (10) and (11), as

$$n_\mu(E_0, E)dE=\omega_\mu\frac{BE_0}{E^3}dE, \tag{13}$$

where

$$\omega_\mu=\frac{\omega}{(m_\pi/m_\mu)^2}=\frac{\omega}{1.72}, \tag{14}$$

this being resulted from the average energy missing in the *pi–mu* transmutation. By the use of the expression (13), the intergral energy spectrum of *mu*-mesons is obtained, under the assumption of $E\ll E_0$, as

$$\begin{aligned} N_\mu(E_0, E) &= \int_E^{E_0} n_\mu(E_0,E)dE \\ &\simeq \frac{\omega_\mu}{2}\cdot\frac{BE_0}{E^2}\,. \end{aligned} \tag{15}$$

---

* For $E>10^{12}$ eV, the K-mesons probably contribute in the cascade, the effect being considered in the next section.

Heretofore the nuclear cascade initiated by a nucleon of energy E_0 has conveniently considered. A glance of the expression (15) gives the estimate for the nuclear cascade initiated by a group of nuclear active particles.

§ 5. Frequency of Observing EAS *Mu*-mensons Underground

In order to compare the estimate, the expression (15), with the experimental results of the M.P.P., we must obtain the frequency of bundles of EAS *mu*-mesons observed below the ground.

As the nuclear active particles in the core of EAS have not yet been investigated thoroughly, the integral frequency of EAS, in which the nuclear active particles carry the energies more than E_s in all, is assumed to be expressed as

$$F(>E_s)=\text{const.}\ E_s^{-\xi}\ . \qquad (16)$$

The nuclear active particles of total energy E_s impinge on the ground, initiate the nuclear cascades in the ground and produce a number of *mu*-mesons of energy more than E, the number of which is given by the expression (15) with E_s replacing E_0. When impinging many particles of total energy more than E_s, *mu*-mesons are to be produced in number of more than N_μ, which is expressed by (15) with E_s replacing E_0. Therefore the frequency, $\mathfrak{F}(\geq n, \geq E)$, of being produced a group of *mu*-mesons (its number is more than n) of energy more than E each in the EAS core in the ground, not from the ground surface, is given, from (15) and (16), by

$$\mathfrak{F}(\geq n, \geq E)=\text{const.}\left(\frac{\omega_\mu}{2}\right)^{\xi}\frac{B^{\xi}}{n^{\xi}E^{2\xi}}$$

$$\propto n^{-\xi}E^{-2\xi}\ .$$

In the above estimate, an assumption is made that each of nuclear active components initiating nuclear cascades in the ground has an energy more than E, the sum ming up of energies of all these nuclear particles being E_s. But it is not the actual case, since the nuclear particles in each EAS are to be in an energy spectrum: Suppose the energy spectrum, $h(E_s, E)dE$, be proportional to dE/E^{φ}, φ is a constant of a value more than two, for the total energy not to diverge. Then it turns out to be

$$\int_{E}^{E_{\max}} E\cdot h(E_s, E)dE=E_s\left(\frac{E_{\min}}{E}\right)^{\varphi-2}\ ,$$

where $E_{\max}$ is assumed to be very large compared to E. The integration with the lower limit of $E_{\min}$ lead to E_s, $E_{\min}$ being determined by the experimental condition. In this case the expression (15) must be changed, on taking into account the energy spectrum of nuclear active particles, as

$$N_\mu(E_0, E)=\frac{\omega_\mu}{2}\cdot\frac{BE_sE_{\min}{}^{\varphi-2}}{E^{\varphi}}\ , \qquad (15')$$

and the frequency, $\mathfrak{F}(\geq n, \geq E)$, leads to be

$$\mathfrak{F}(\geq n, \geq E)=\text{const.}\left(\frac{\omega_\mu}{2}\right)^{\xi}\frac{B^{\xi}E_{\min}{}^{\xi(\varphi-2)}}{n^{\xi}E^{\varphi\xi}}$$

$$\propto n^{-\xi}E^{-\varphi\xi}\ , \qquad (17)$$

where $\varphi>2$.

§ 6. Comparison With the M. P. P. Experiment and Discussion

The energetic nuclear active particles in the core of EAS impinge on the ground, and develop the nuclear cascade in the ground, from which the *mu*-mesons are produced through the *pi*-*mu* decay process. The number of *mu*-mesons produced by this mechanism is estimated almost without ambiguity, as described in the preceding sections. Using the estimate obtained above, the experimental results of the M.P.P. are discussed here from the view point of whether this mechanism being possibly responsible or not.

First of all, the experimental data of M.P.P. so far obtained are summarized in Table I[26]. Underground *mu*-mesons, which are simultaneously falling onto a cloud chamber, with multiple lead plates, of area of about 0.4 m², have been observed in numbers of *mu*-mesons

Table I. Summary of experimental results of the M.P.P.

Depth	Obs. Frequency of M.P.P. of more than 4 P.P.	Integral Number Distribution ($N\geq 4$)	Integral Zenith Angle Distribution	Lateral Spread
50 mwe	$(1.5\pm 0.5)\cdot 10^{-2}$ hr^{-1}	$\sim N^{-1}$	$\sim\cos^{9}\theta$	
250 mwe	$(1.2\pm 0.5)\cdot 10^{-3}$ hr^{-1}	$\sim N^{-1}$	$\sim\cos^{7}\theta$	$\gtrsim$a few meters

in each event up to about thirty. The lateral spread were obtained by means of a few trays of counters aside the chamber, and is likely to be more than a few meters at 250 mwe. Here discussion is given about the absolute frequencies and the number distributions of observed *mu*-mesons of the M.P.P.

In the first place, let us consider, as usual, all of the secondary particles of the elementary collision to be *pi*-meson. Even when the survival of the parent nucleon is taken into account, the results may remain to be unchanged.

Since the nuclear cascades in the EAS is to have vanished in the ground of, at most, 20 mwe from the ground surface, *mu*-mesons observed at 250 mwe could be considered in good approximation to be produced at the ground surface. The energy of a *mu*-meson having the range of 240 mwe is about 60 *GeV*. E in the expression (17) can be replaced by the depth of observation. Further, n in the expression is conveniently replaced by the observing density of particles, Δ. This is because in the cascade the produced *pi*-mesons can reasonably be assumed to have about constant transverse momentum p_t, independently of its energy[27,28], so that the lateral spread of the nuclear cascade remains unchanged along its developing, which implies that the total number, n, is proportional to the particle density, Δ. Therefore the expression (17) may be rewritten as

$$\mathfrak{F}(\geq d,\ \geq\Delta)\propto\Delta^{-\xi}d^{-\varphi\xi}\,. \qquad (\varphi>2) \qquad (18)$$

This relation can directly be compared with the experimental data. The experimental results on the particle density spectrum is $\Delta^{-\xi'}$ with $\xi'\simeq1$ at 50 mwe and at 250 mwe both. Then the expression (18) predicts the depth dependence of the frequencies of the events having the same density to be d^{-2} or more steep with respect to the depths. Contrary to the prediction, the experimental result is expressed as $d^{-1.3}$ or flatter, shown in Fig. 3, where rather large error of 50 mwe point resulted from the producing point of *mu*-mesons along the longitudinal extension of the nuclear cascades. Therefore this mechanism of producing the underground *mu*-mesons in the EAS could not interpret consistently both the data of the M.P.P. at 50 mwe and at 250 mwe.

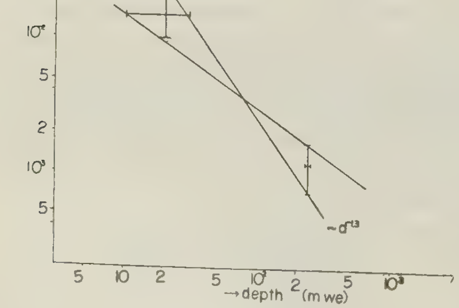


Fig. 3. Depth dependence of the frequency of M.P.P.s. See the text about the comparison with this theory.

Thus the possibility of interpretation by this mechanism leaves only on the data at 50 mwe. The possibility is examined here by the comparison between the spectrum of primary cosmic rays, which refered to the frequency of EAS, and the relation of estimated frequency *vs* E_s, which is obtained from the data of the M.P.P. at 50 mwe. As the lateral spread of the M. P. P. is not well known, let us represent by S the area covered by the events of the M.P.P., S remaining to be a parameter throughout. The absolute frequency, I_v, of the M.P.P. with more than four particles is refered to the observed frequency, I_{obs}, as usual, to be approximately

$$I_{\text{obs}}=\int_0^{\pi/2}I_v\cos^{m-1}\theta d\Omega\cdot T.S=\frac{2\pi}{m}I_v\cdot T.S\,,$$

then it turns out, using the experimental values,

$$I_v\simeq\frac{(6\pm2)\cdot10^{-10}}{S}\,\text{cm}^{-2}\,\text{sec}^{-1}\,\text{sterad}^{-1}\,.$$

On the other hand, if the expression (15) is employed for the estimate of E_s, replacing E_0, then it is obtaind as

$$E_s=(2.7\sim6.8)\cdot10^5\cdot S\ \text{GeV}\,,$$

for which have been used the values, $N_\mu=\dfrac{4}{0.4}\cdot S$, $E=5\sim8$ GeV and $\omega\simeq0.5$. This value of E_s is the lower limit, since the expression (15) is the special case of the expression (15′) with $\varphi=2$, and in general the value of E_s is to be much larger. The pair of values of I_v and E_s is plotted on the energy spectrum of primary cosmic rays, shown in Fig. 4, S being remained as parameter. It is of no doubt experimentally that S is more than some ten m^2, though not yet determined precisely. Hence the plot for E_s

shows unreasonable representation compared with the E_0 spectrum, since the curve, E_s, is necessary to be under the one of E_0 in the Fig. 4. If the expression (15′) is adapted for the estimate of E_s, the impossibility of interpretation by this mechanism increases in much more degree. In conclusion it is confirmed that this mechanism can not interpret even the data of M.P.P. at 50 mwe, too.

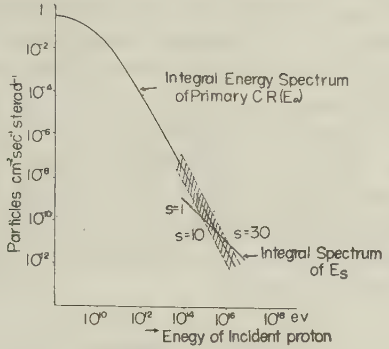

Fig. 4. Intergal energy spectrum, E_0, of primary cosmic rays (after Barrett et al[1)]) and integral energy spectrum, E_s, of the impinging N-component of EAS on the ground, where S is the area covered by the M.P.P.

The contribution of K-mesons and hyperons, though neglected heretofore, must be taken into account in this consideration. It is suggested by the experiment of Bristol group[28)], which shows the existence of X-particles, and also by the experiments of accelerators.

The K_{μ_2}-meson and the $\sum_\mu{}^{\pm}$-particle are mainly found out among so called new particles as to decay into *mu*-mesons[29)], being considered and discussed in the following. It is interesting here that in what partition *pi*-mesons and these heavy particles are produced in the very high energy interactions. So far, only the Bristol group have observed in reference with these problems, showing that X-particles, besides the *pi*-mesons, are produced about 25 % as much as *pi*-mesons in the jet showers produced by about 10^{13} eV particles[27)]. In the more energetic interactions they may be produced more frequently than just described, but have not yet been investigated. In order to investigate the produced *mu*-mesons of energy of a few tens GeV, the production ratio of K-mesons or $\sum$-particles to *pi*-mesons in the interaction of about 100∼1000 GeV must be known, since *mu*-mesons of the lowest energy are to be dominantly observed, as seen from the expression (15). Then the ratio of 25 % is tentatively used here for the K-meson or $\sum$-particle production to *pi*-meson production ratio, as given by Bristol group.

The decay constant B for $K_{\mu 2}$-mesons and $\sum_\mu{}^{\pm}$-particles is given, using $\lambda_k \simeq 3\lambda_\pi$ and $\lambda_\Sigma \simeq \lambda_\pi$[29)], as

$$B_k = 70\,\text{MeV} \text{ and } B_\Sigma = 15\,\text{GeV}\ .$$

Hence the existence of $K_{\mu 2}$-mesons does not deform, as the case of *pi–mu* decays, the nuclear cascade under consideration. The $\sum_\mu{}^{\pm}$-particle is also the case in spite of the large value of B_Σ, since the $\sum_\mu{}^{\pm}$-particle is produced with a branching ration, b, of less than 3 % within the $\sum$-particles.

Then the contribution of $K_{\mu 2}$-mesons and $\sum_\mu{}^{\pm}$-particles is taken into account as follows. The nuclear cascades in the ground are considered unchanged by the existence of the $K_{\mu 2}$-mesons and the $\sum_\mu{}^{\pm}$-particles, as described above, the expression (10) being valid unchanged. Corresponding to the expression (13), the following holds, on taking into account the different decay probability for various components,

$$\begin{aligned} &n_\mu(E_0, E)dE \\ &= \omega \frac{E_0 dE}{E^3} \left\{ \frac{f_\pi B_\pi}{(m_\pi/m_\mu)^2} + \frac{f_k B_k}{(m_k/m_\mu)^2} \right. \\ &\qquad \left. + \frac{f_\Sigma}{m_\Sigma/m_\mu} \cdot \frac{(B_\Sigma/(m_\Sigma/m_\mu)) \cdot E}{(B_\Sigma/(m_\Sigma/m_\mu)) + E} \right\} . \end{aligned}$$

In this expression f_π, f_k and f_Σ is the production ratio of charged *pi*-mesons, $K_{\mu 2}$-mesons and $\sum_\mu{}^{\pm}$-particles in the elementary collisions in the cascades under consideration. It is noticed that the production ratio of *pi*-meson component, K-meson component and $\sum$-particle component is expressed, by notations here used, as $f_\pi/b_\pi : f_k/b_k : f_\Sigma/b_\Sigma$, where b_π is the branching ratio of charged *pi*-mesons in the produced *pi*-meson component, and so on. Charged *pi*-mesons and K-mesons undergo both two body decays into *mu*-mesons, the average energy missing during the transmutation being expressed in the similar expression (see the expression (14)). The $\sum_\mu{}^{\pm}$-prticle undergoes so called the three body decay but in the crude approximation the similar expression being used as the *pi*-mesons, on the average, only considering the mass ratio. Each terms in the curled parenthesis represent the contribution of *pi*-mesons,

$K_{\mu 2}$-mesons and $\Sigma_\mu{}^\pm$-particles, the ratio of which is estimated as follows. It turns out, using $f_\pi \sim (1-0.25)\times\frac{2}{3}$,

$$\frac{f_\pi B_\pi}{(m_\mu/m_\mu)^2}\simeq 1.1\ \mathrm{MeV}\ .$$

It holds experimentally that $\frac{f_k}{b_k}+\frac{f_\Sigma}{b_\Sigma}=0.25$. Assuming that $\frac{f_k}{b_k}\simeq\frac{f_\Sigma}{b_\Sigma}$, it is given, for $K_{\mu 2}$-mesons,

$$\frac{f_k B_k}{(m_k/m_\mu)^2}\simeq 0.23\ \mathrm{MeV}\ .$$

With regard to $\Sigma_\mu{}^\pm$-particles, it holds that

$$\frac{f_\Sigma B_\Sigma}{(m_\Sigma/m_\mu)^2}\simeq 0.45\ \mathrm{MeV}\ .$$

Thus, over the energy range under consideration, the contribution of these particles to the *mu*-meson production is made in the ratio of

$$\pi^\pm : K_{\mu 2} : \Sigma_\mu{}^\pm = 1:0.2:0.5\ .$$

Therefore the contribution of the $K_{\mu 2}$-mesons and the $\Sigma_\mu{}^\pm$-particles could not largely affect the number of *mu*-mesons, $N_\mu(E_0, E)$, obtained when impling only the contribution of *pi*-mesons, and could not accordingly interpret the experimental data of M.P.P. at 50 mwe*. As is also shown in the expression (15), the contribution of the $\Sigma_\mu{}^\pm$-particles could not make flatten the depth dependence of the events under consideration, since the $\Sigma_\mu{}^\pm$-particles of energy more than 100 GeV may mainly contribute because of the energy missing of the $\Sigma_\mu{}^\pm$–*mu* decays.

§ 7. Conclusion

The nuclear active component of EAS impinges onto the ground surface and produces the nuclear cascade showers in the ground, a number of *mu*-mesons being produced in the cascades through the *pi–mu* decay process. The number of the *mu*-mesons underground thus produced has been estimated, given by the expression (15), independently of the energy and multiplicity spectra of secondary particles of the elementary (nucleon-) nucleus collisions in the EAS and further independently of some fluctuations. On the basis of the expression (15) it has been examined whether or not the *mu*-mesons produced by the mechanism just described can interpret the experimental results of so called M.P.P. underground. However no success of interpretation has been obtained, even though the contribution of the $K_{\mu 2}$-meson or the $\Sigma_\mu{}^\pm$-particle production in the very high energy collisions is taken into account.

Acknowledgement

The author wishes to express his sincere thanks to Prof. Y. Watase for his interest and kind encouragement. Thank are due to the underground C. R. group, especially to Prof. S. Ozaki and Dr. S. Miyamoto for helpful discussion and criticism during the course of the work. He is also indebted to Professors J. Nishimura and K. Suga of Tokyo University for valuable advice.

* If the interaction mean free path of *K*-mesons is about three times larger than that of *pi*-mesons, the nuclear cascades might be expected to prolong its range in the ground. Accordingly the nuclear cascades cited for the example in § 2 would penetrate to the deeper depth than 20 mwe, and the observed *mu*-mesons at 50 mwe might have energies less than 5 GeV at their production point, and hence the mechanism just described might be enough to interpret the data of the M.P.P. at 50 mwe. But the estimate in § 2 is based on the experimental data of the inelasticity of 0.3, which must imply the contribution of these heavy particles in high energy collision, if exist.

A Study on High-Energy Nuclear-Active Particles in Extensive Air Showers

By Yasuo TANAKA

Institute for Nuclear Study, University of Tokyo

(Received January 21, 1960)

A new type of detector called transition chamber was used to study high-energy nuclear-active particles (N-particles) above 10^{11} ev in extensive air showers (EAS) of size above 10^3. The differential energy spectrum of N-particles is shown to be represented by $E_N^{-2.0\pm0.1}dE_N$ up to 3.10^{13} ev irrespective of shower size. The lateral distribution of nuclear-active particles is obtained within 10 m from the axis. This distribution is tentatively explained by a phenomenological model assuming the Maxwell-Boltzmann distribution for the transverse momentum of N-particles. Total number of N-particles of energy $E_N \geqq 10^{11}$ ev, N_N, in an extensive air shower is expressed as a function of size N_e by $N_N=(50\pm5)(N_e/10^5)^{1.1\pm0.1}$, for N_e ranging from 10^3 to more than 10^6. Then the total energy carried by all N-particles of $E_N \geqq 10^{11}$ ev is estimated to be as much as that of the electron component in an EAS. On the basis of the observed general relationship between the electron component and N-particles for a wide range of sizes, a model of the development of EAS is suggested. The energy spectrum of N-particles is discussed in relation to that of high-energy γ-rays. In particular the existence of very high-energy N-particles implies that the average inelasticity in high energy interactions $\eta=0.4\sim 0.5$, if they are assumed to be survivors of primary particles. Also the possibilities are discussed for the occurrence of N-particles with energies as much as 10% or more of primary particles.

§ 1. Introduction

It is well known that the nuclear cascade in an extensive air shower (EAS) plays a fundamental and basic role in its development in the atmosphere. Therefore, the information on the high-energy nuclear-active particles (N-particles) which are responsible for the development of nuclear cascade is very important for the study of very high-energy nuclear interactions and the development and structure of EAS. However, because of the low frequency of N-particles and the difficulty in detecting them and measuring their energy, the data available on the N-component are much less than those on other components of EAS.

Recently, detectors using ionization chambers which are efficient for detecting high-energy N-particles have been developed mainly by Russian workers. By means of these detectors it has also been possible to estimate the energies of N-particles. These experiments have led to the remarkable result that N-particles in an EAS carry as much total energy as the electron component, and sometimes as much energy could be concentrated in a single N-particle.[1)-4)] Thus the importance of N-particles as the source of energy supply of EAS has been recognized.

In order to arrive at a quantitative description of phenomena from the qualitative understanding we have so far, it is necessary to improve the accuracy of energy measurement of N-particles and also determine the character of associated EAS by fixing the position of shower axis, its incident direction, the total number of particles or the size and other parameters as accurately as possible. The purpose of the present experiment is to study EAS through investigation of the high-energy N-particles as described above. Characteristic features of very high-energy phenomena will be reflected the better in the higher energy N-particles. Therefore, it would be worth while to observe such N-particles for a wide range of sizes of EAS. In fact, this is equivalent to covering a wide range of energy of the primary particles producing EAS, so that one may hope to get possible clues regarding the characteristics of very high-energy phenomena, as well as gain a better understanding of the role of nuclear cascade in EAS.

§ 2. Experimental Arrangement

It has been shown already that the "transition chamber" is quite useful for the detection and energy measurement of high-energy N-particles.[5),6)] The schematic diagram of the transition chamber is shown in Fig. 1. This detector consists of thick material in which five layers of scintillation counters are inserted as illustrated in the figure. The top layer of 5 cm lead absorbs the electron component of EAS efficiently. The total thickness of iron is 320 gcm^{-2} which corresponds to about 3 nuclear mean free paths so that almost all the N-particles which hit the detector will cause nuclear interactions.

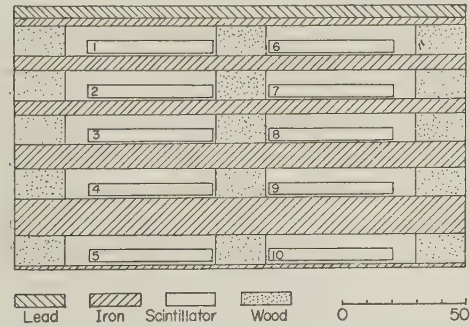

Fig. 1. Schematic diagram of the transition chamber.

In order to measure the energy of N-particles, the so-called "total absorption spectrometer" is perphaps the best detector. It has enough thicknesss of material to absorb the entire nuclear cascade initiated by a N-particle and measures the total energy dissipated by all particles within the detector.

The transition chamber does not have sufficient thickness of material for this purpose, but it can be used to measure the energy of neutral pions produced by nuclear interactions fairly accurately. These neutral pions, each immediately decaying into two γ-rays, initiate electromagnetic cascade showers. As is well known, the number of electrons at shower maximum is almost proportional to the energy of incident γ-rays, and this relation still holds approximately for the superposition of several showers of different energies. In other words the number of electrons at the maximum of the composite shower is proportional to the total energy of the incident γ-rays. On the other hand, the number of electrons varies very slowly, say by less than 20%, within several radiation lengths arround the shower maximum, if the incident γ-ray energy is more than several Bev. Therefore, the particle number at the shower maximum can be obtained with fair accuracy by scintillation counters separated by less than several radiation lengths from each other. Thus, the transition chamber can give the total energy transferred to neutral pions and hence one can estimate the energy of N-particles as explained later.

For the detection of N-particles among the many background electrons of EAS, one should examine the transition curve for a second hump following the rapid absorption, characteristic of pure electromagnetic cascade.

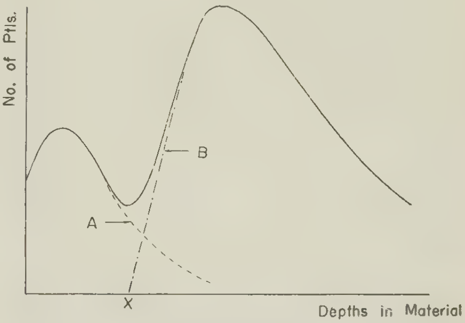

Fig. 2. Shematic figures of transition curves.
A: The transition curve of the electron component.
B: The transition curve of the shower initiated by a high-energy N-particle at X.

This second hump should be obviously due to nuclear interaction which initiates cascade showers through the production of neutral pions. This situation is illustrated schematically in Fig. 2. Since pure electron component is absorbed quite rapidly, almost all N-particles that give rise to neutral pions of more than 10 Bev can be certainly distinguished from the dense background of electrons and photons, unless the nuclear interaction takes place within the lead layer such that the cascade develops too fast to be observed at shower maximum. Thus, the detection efficiency of the transition chamber for high-energy N-particles is considered to be about 70%.

As N-particle detectors, cloud chambers, counter piles, and neutron counters have been used so far. These detectors, however, are not suitable for quantitative measurements on high-energy N-particles. The transition chamber, though it is inferior in accuracy to the method of energy measurement by total absorption, gives the energies of N-particles with a constant degree of accuracy upto very high energies.

Since each layer of transition chamber consists of two scintillation counters each of area 0.25 m^2, it can be used as two independent N-particle detectors. The output signal of each scintillation counter is displayed on the screen of an oscilloscope through a special device by which the pulse height is converted into a signal proportional to the logarithm of the number of particles.[7)]

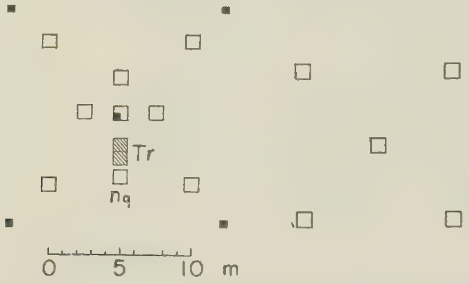

Fig. 3. Arrangement of the detectors. Open squares 1 m^2 each, are n-detectors. Filled squares 0.25 m^2 each, are fast detectors. The detector denoted as Tr is the transition chamber.

An EAS array consisting of 14 scintillation counters was operated in conjunction with the transition chamber. These counters, called n-detectors are each of area 1 m^2. The arrangement of the n-detectors as well as the transition chamber is shown in Fig. 3. One can determine the position of the axis and the size of EAS from the observed density of particles at each n-detector. The output of each n-detector was also represented logarithmically on oscilloscope screen and photographed. Sensitivities of all scintillation counters—counters of the transition chamber as well as the n-detectors—were continuously recorded on a chart of self-recording monitor. They were usually maintained within 10% variation. Besides these counters, a timing network of five 0.25 m^2 scintillation counters was also operated, to obtain information on the incident direction of EAS of more than 10^4 in size. The accuracy was within about 5° near the vertical. These counters are called fast detectors.

The following triggering condition was imposed for efficient selection of N-particles: at least 10 particles in each of any two counters among scintillators No. 1 to No. 5 or No. 6 to No. 10 in the transition chamber, in addition to at least one particle in n-detector n_9 (see Fig. 3). Whenever this condition was satisfied, the recording system was triggered and all the information of the event was recorded. The rate of such events was about 15 per hour. The experiment was carried out at sea level in December 1959. The total working time was about 290 hrs.

§ 3. Identification and Energy Estimation of N-Particles

From the data so obtained, only those events which showed a clear hump of more than 50 particles on the observed transition curve were selected as due to nuclear interactions of N-particles. However, this condition may possibly be satisfied also by the following phenomena: (i) EAS incident at large zenith angle, (ii) nuclear disintegrations occurring within the scintillators, and (iii) radiation burst caused by muons.

When an EAS hits the detector with zenith angle more than 30°, the electron component, without traversal in lead layer, might cause a hump similar to that observed in nuclear interaction. Naturally, such types of events are more likely to occur in inclined EAS. However, the zenith angle distribution obtained for above selected events associated with EAS agrees with that of ordinary EAS well within the limits of experimental errors. Therefore, the contribution of events from (i) should be less than several % if it exists.

Events of type (ii) are caused by relatively low energy N-particles, say more than a few Bev. These N-particles may produce nuclear disintegrations within the scintillation material with some probability, and give rise to a pulse equivalent to that corresponding to more than 50 particles. However, the scintillation efficiency of organic scintillators for heavily ionizing particles is very low. Moreover, the number of such fragments emitted in ordinary nuclear disintegrations is small because the target consists of only light elements. Therefore, a simple estimate shows that this effect is negligible. This type of events can also be picked out and rejected by inspecting the observed transition curves, because only one scintillation counter can show a large pulse height in these cases.

It is possible that the radiation bursts caused by muons satisfy the triggering condition, if muons are coming from directions such that they can penetrate n-detector n_9, or the particles of radiation bursts can hit this n-detector. Since cascade showers of bursts do not develop in the vertical direction for these events, the number of counters which show high density of particles is limited to only one or two from geometrical considerations. Then, the transition curves show an apparent rapid absorption compared to ordinary cascade curves. In fact, a few tens of such events were observed which could be obviously distinguished by inspecting the transition curves.

The rate of radiation bursts of more than 50 particles at shower maximum within the transition chamber caused by muons is about 5 per hour. However, since at least one particle should hit the n-detector n_9 according to the triggering requirement, only those muon-bursts which are associated with EAS could be effectively recorded. Simple estimation shows that such cases could not be more than 10 during the whole period of observation. Moreover, because the energy spectrum of muons is much steeper than that of N-particles, as will be shown later, this effect of muon-bursts on the data of N-particles must be limited to only the low energy regions.

Therefore, the 495 events selected are believed to be due to high-energy N-particles.

As a further confirmation, the distribution in the depths of the points of interactions was checked. The collision mean free path calculated from this distribution turned out to be about 100 gcm^{-2}. Therefore, it is reasonable to suppose that all the selected events are due to N-particles.

The energy of N particles can be estimated as follows. As already mentioned, the total energy of neutral pions is first determined from the number of particles at shower maximum. The number of electrons, $\pi_{\max}$, at shower maximum as a function of primary γ-ray energy $E_0^{(\gamma)}$ is given by Eq. (1) for a single cascade under "Approximation B",

$$\pi_{\max}(E_0^{(\gamma)}) = \frac{0.3}{\sqrt{\ln(E_0^{(\gamma)}/\mathcal{E})}} \frac{E_0^{(\gamma)}}{\mathcal{E}}, \qquad (1)$$

where $\mathcal{E}$ represents the critical energy and is 21 Mev for iron. The cascade shower actually observed is not neccessarily a single cascade but rather a superposition of several showers. However, Eq. (1) can still be applied to the composite cascade showers for obtaining the total energy of neutral pions. The accuracy of the energy determined by the above method can be considered to be of the order of 30%. The event with 50 particles for $\pi_{\max}$ corresponds to about 10 Bev for $E_0^{(\gamma)}$ or the total energy of neutral pions.

In order to estimate the energy of N-particles from the total energy of neutral pions, two quantities should be known. One is the fraction of N-particle energy transferred to secondary particles, or the inelasticity, η, and the other is the ratio of neutral pions to all secondary particles, R. Although either of these might fluctuate from case to case, many experiments on jets by nuclear emulsions allow one to take about 1/3 for the average value of R at high energy. There is much ambiguity in the values of η obtained so far, because they are not of sufficient statistical accuracy and also the accuracy of η in individual events is not good enough. However, one can use a value 0.3 as the average η tentatively for the energy estimation of N-particles. Then the energy of N-particle, E_N, can be estimated as $E_N = 10E_0^{(\gamma)}$. Therefore, the selected events correspond to N-particles of energy $E_N \geqq 10^{11}$ ev. It is difficult to assign the error to the value of E_N thus obtained. However, an uncertainty of factor of 2 may be considered reasonable, because of the above mentioned assumptions.

§ 4. Associated Air Showers

The procedure used to obtain the position of the axis, the lateral distribution and the size of EAS is the same as that described in Ref. 6. That is, the position of the axis is regarded as the point arround which the observed densities at various n-detectors best approach to a certain smoothly decreasing function of radius, r. Then a Nishimura-Kamata (N-K) function[8] which is the best fit to this lateral distribution can be chosen.

The size of EAS, N_e, is assumed to be the area integral of this N-K function.

For the EAS array shown in Fig. 3, the position of the axis can be determined uniquely with the accuracy of usually less than a few metres for EAS which hit the region within 10 m from the centre of the array. Particularly, if EAS of $N_e \geqq 10^4$ hit near the centre, the accuracy in determining the position of the axis can be as good as 1 m (see § 5. (C)). On the other hand, the accuracy becomes worse rather rapidly when the axis is farther than 10 m from the centre. However, these cases do not occur so frequently, because a large majority of N-particles is concentrated within 10 m from the axis as will be shown later.

The accuracy of the size as determined by the above mentioned method is somewhat different from shower to shower, but in general for EAS within 10 m from the centre the statistical accuracy is about 20% for sizes $N_e > 10^4$, and becomes worse for smaller sizes. For a size of 10^3, the error becomes a factor of 2.*

The observed integral size spectrum of EAS for the selected events is shown in Fig. 4. This spectrum can be approximated by $N_e^{-0.4}$ for the region of $N_e <$ several 10^5 whereas it rather fits $N_e^{-0.8}$ for $N_e \geqq 10^6$. These would indicate that the variation of exponent occurs between the sizes 10^5 and 10^6. This fact might be very interesting if it is compared with similar variation of exponent which appears in the same range for the ordinary size spectrum of EAS irrespective of N-particles.[5)]

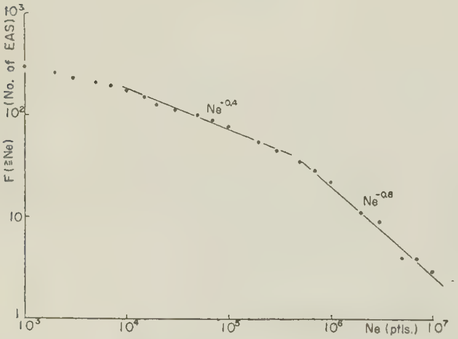

Fig. 4. Observed size spectrum of EAS in which at least one N-particle is detected in transition chamber.

§ 5. Experimental Results

(A) *Energy spectrum of N-particles*

The differential energy spectrum of all observed N-particles is shown in Fig. 5. This spectrum can be fitted very well by a power law $E_N^{-2.0 \pm 0.1} dE_N$ at least for the energy range, 10^{11} ev $\leqq E_N < 10^{12}$ ev. This law can be reasonably extrapolated upto $3 \cdot 10^{13}$ ev though the statistics are poor above 10^{12} ev. Therefore, one could consider that there is no remarkable change in the energy spectrum of N-particles for the energy range 10^{11} ev $\leqq E_N < 3 \cdot 10^{13}$ ev.

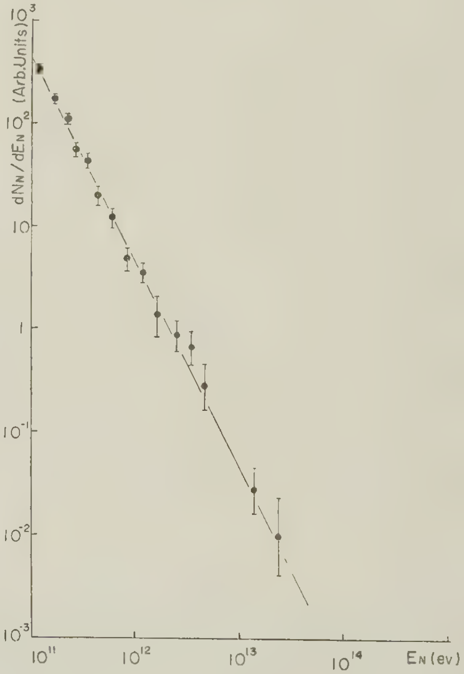

Fig. 5. Differential energy spectrum for all N-particles observed. The straight line represents the spectrum $E_N^{-2.0} dE_N$.

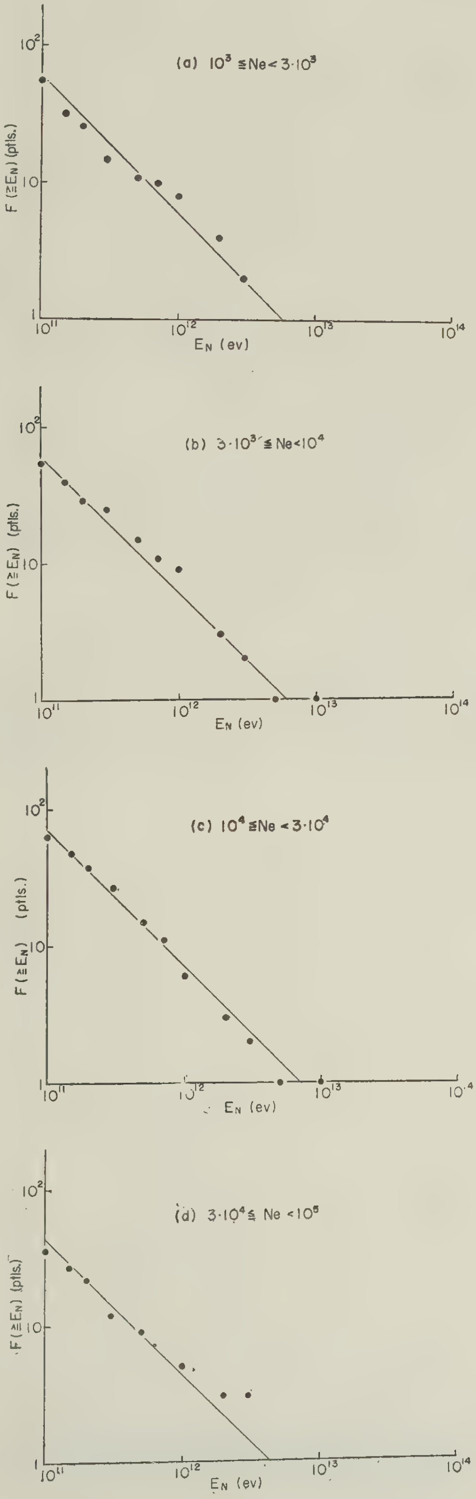
The energy spectra of N-particles have also been obtained for the following intervals of sizes N_e: (i) $10^3 \leqq N_e < 3 \cdot 10^3$, (ii) $3 \cdot 10^3 \leqq N_e < 10^4$, (iii) $10^4 \leqq N_e < 3 \cdot 10^4$, (iv) $3 \cdot 10^4 \leqq N_e < 10^5$ and (v) $N_e \geqq 10^5$. Fig. 6. a) to e) show the integral spectra for different size intervals. It is a remarkable feature that there seems to be no significant dependence of the energy spectrum of N-particles on the size N_e for a wide range of sizes from 10^3 to more than 10^5. It is also to be noted that the energy spectrum is still extending beyond 10^{12} ev even for EAS with $N_e \sim 10^3$. This fact will be discussed later.

---

* Preliminary results of detailed study of lateral distribution of particles from the axis to 200 m show an obvious deviation from the N-K function. Then, the size obtained from the N-K function turns out to be a lower estimation and should be increased by 50%.



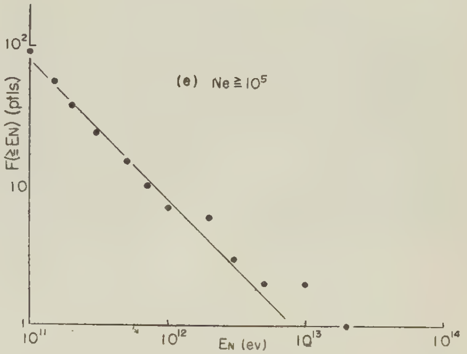


Fig. 6. Integral energy spectra of N-particles for various size ranges.

(B) *Lateral Distribution of N-particles*

As already mentioned, the transition chamber was used as two separate units of N-particle detectors. The frequency of EAS of size (N_e, N_e+dN_e) which hit at a distance $(r, r+dr)$ from either unit detecting an N-particle is given by the following equation.

$$F(N_e, r)dN_edr$$
$$= f(N_e)\Delta_N(N_e, r)2S\,W(N_e, r)dN_e2\pi rdr\,, \quad (2)$$

where $f(N_e)dN_e$ is the size spectrum of EAS, Δ_N is the density of N-particles, S is the area of each unit of transition chamber (0.25 m²) and $W(N_e, r)$ is the detection probability of EAS. (Note that Eq. (2) holds strictly for $S\Delta_N \ll 1$.) Therefore, if $F(N_e, r)$ is known for a fixed size N_e and within the region where $W(N_e, r)$ is almost unity, the lateral distribution of N-particles $\Delta_N(N_e, r)$ can be obtained.

As mentioned in § 4. the accuracy in determining the position of the axis is not very good farther than 10 m, moreover $W(N_e, r)$ is not neccessarily unity for EAS of $N_e < 10^4$ even within 10 m from the transition chamber. Therefore, the lateral distribution of N-particles is studied here only within 10 m from the axis of EAS of $N_e \geqq 10^4$.

The lateral distribution of N-particles of $E_N \geqq 10^{11}$ ev is obtained as shown in Fig. 7. Since the accuracy of r is as good as 1 m, it may be significant that the distribution becomes flatter within 2 m from the axis. If this distribution is approximated by a power low between 2 to 10 m, it can be represented by $r^{-2.5\pm0.5}$. If one assumes tentatively an empirical expression $[1+(r/a)^{2.5}]^{-1}$ for the lateral distribution of N-particles, a value 1.5 m for a can fit this formula to experimental points in the whole range within 10 m. If one supposes that this formula can be applied farther than 10 m upto 30 m as a reasonable cut off point, the fraction of N-particles existing within 10 m corresponds to about 80% and that within 5 m accounts for about 65% of the total.

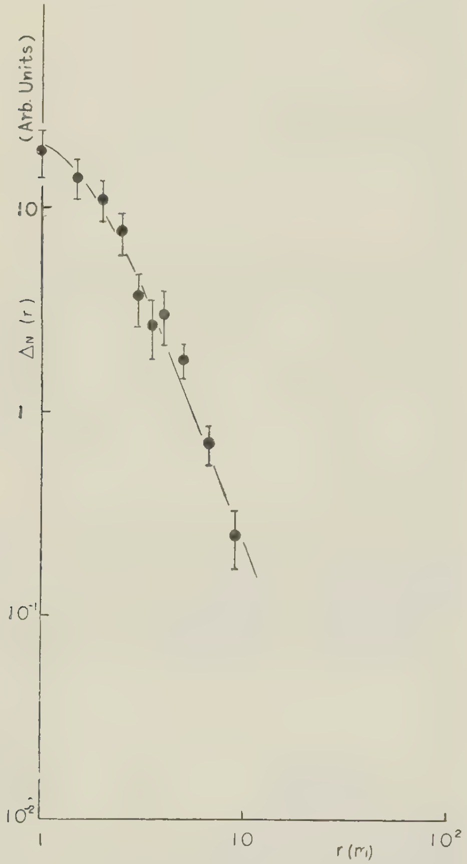

Fig. 7. Lateral distribution of N-particles with $E_N \geqq 10^{11}$ ev in EAS of $N_e \geqq 10^4$. Curve of $1/[1+(r/a)^{2.5}]$ is shown in the figure for $a=1.5$ m.

(C) *An interpretation of the lateral distribution of N-particles*

The lateral distribution of N-particles of certain energy E_N at sea level can be considered as determined by the contributions of N-particles from different altitudes and their angular distribution. Assuming that the number of N-particles of energy E_N produced within the layer $(x, x+dx)$ from the top of the atmosphere is proportional to $\exp(-x/\Lambda_N)dx$, the contribution of these N-particles at sea level, $x=X_0$, without suffering nuclear interaction between x and X_0 is as follows. Since the probability with which a N-particle can arrive at X_0 without nuclear interaction is $\exp[-(X_0-x)/L]$ where L represents the nuclear mean free path, the contribution of N-particles of energy E_N from the layer $(x, x+dx)$ to those at sea level is proportional to $\exp[(1/L-1/\Lambda_N)x]dx$ provided that the effect of decay is negligible.

If the distribution of emitted angles of N-particles is assumed to be proportional to $\exp(-\theta^2/2\theta_0^2)\,2\pi\sin\theta d\theta$ for a certain energy E_N, this corresponds equivalently to the assumption of Maxwell-Boltzmann distribution for the transverse momentum p_T, $\exp(-p_T^2/2p_0^2)\,2\pi p_T dp_T$ where p_0 is the rms average of p_T and is related to θ_0 by the equation $\theta_0 \cong p_0/p$, p being the momentum of N-particle ($cp=E_N$).

For the sake of simplicity, nuclear interaction is supposed to occur once every one mean free path. Then, the lateral distribution at sea level, of N-particles produced n mfps above is expressed by

$$\frac{1}{2\pi(nr_0)^2}\exp\left(-\frac{r^2}{2(nr_0)^2}\right)2\pi r dr\ ,$$

where r_0 is rms radius of those N-particles after traversal of 1 mfp and given by $r_0=(p_0/p)(L/\rho)$, ρ being the average density of air.

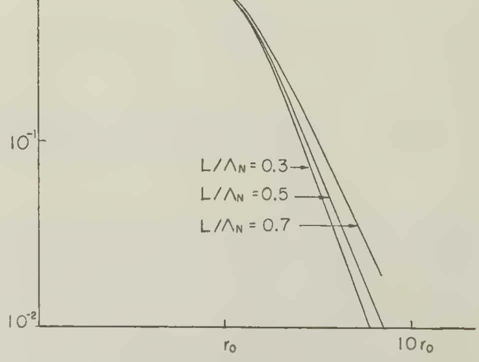

Fig. 8. Lateral distributions of N-particles calculated for different values of L/Λ_N according to Eq. (4), § 5. (C).

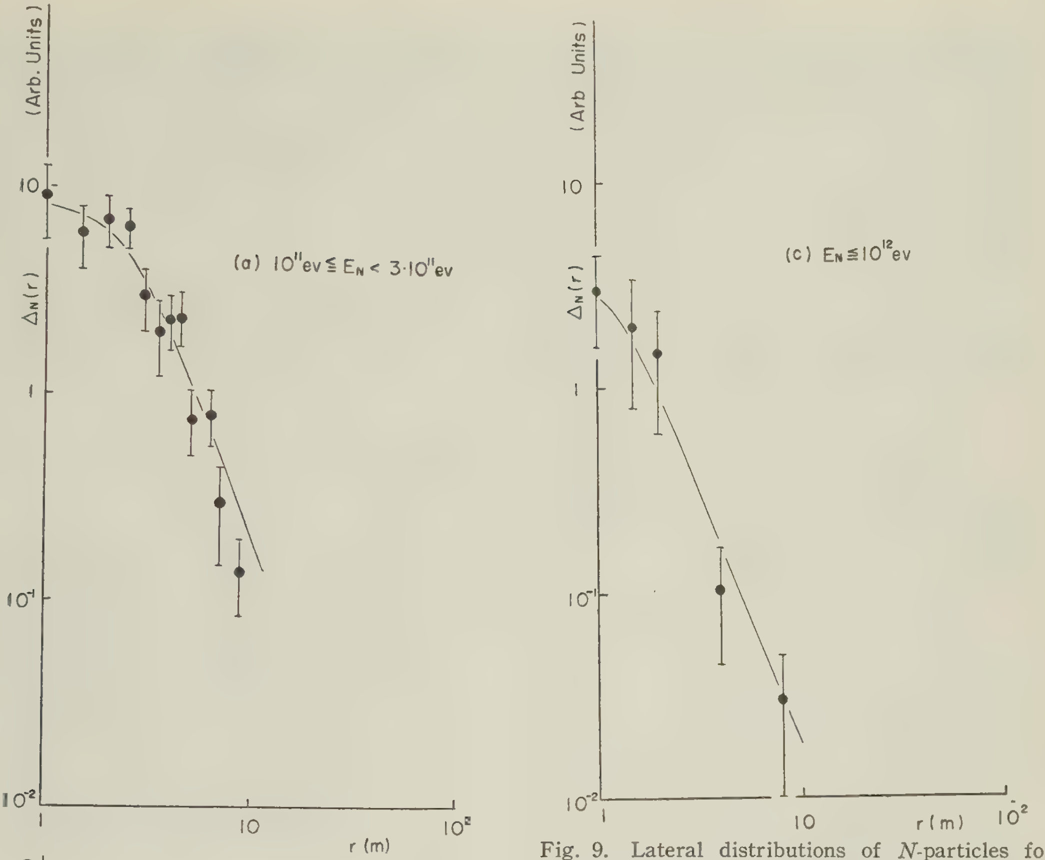

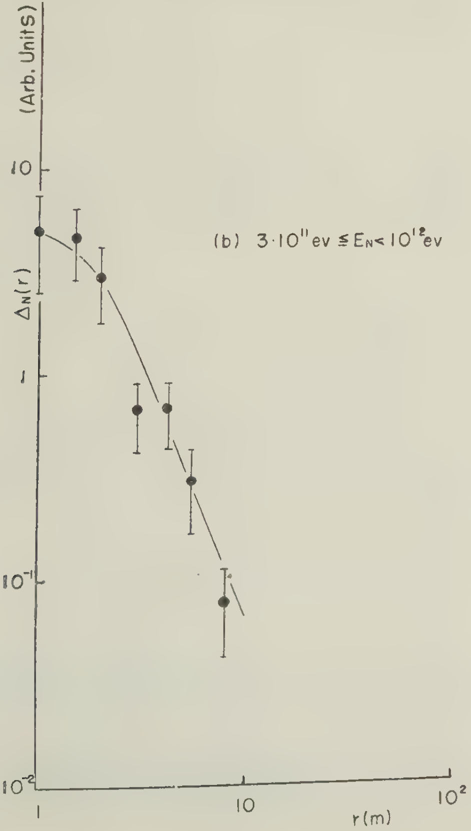

Fig. 9. Lateral distributions of N-particles for different energy ranges. Each of them is compared with calculated curve for $L/\Lambda_N=0.5$ as shown in Fig. 8.

Since the contribution of such N-particles to sea level is proportional to

$$\exp\left[\left(\frac{1}{L}-\frac{1}{\Lambda_N}\right)(X_0-nL)\right]$$

or

$$\exp\left(\frac{L}{\Lambda_N}-1\right)n$$

as given above, the lateral distribution of N-particles of energy E_N can be obtained by the superposition of contributions from various generations using the following expression

$$\Delta_N(r)\propto\sum_{n=1}\frac{1}{2\pi(nr_0)^2}\exp\left[\left(\frac{L}{\Lambda_N}-1\right)n-\frac{1}{2(nr_0)^2}\right]. \tag{4}$$

The results of calculations for three cases, $L/\Lambda_N=0.3$, 0.5 and 0.7 are shown respectively in Fig. 8. These figures illustrate that the above model can account for the part of the distribution expressible by a power function. They are approximated by $r^{-2.8}$, $r^{-2.5}$ and $r^{-2.1}$, respectively.

Fig. 9 (a), (b) and (c) show the experimental lateral distributions of N-particles for different energy intervals: (a) $10^{11}\,\text{ev} \leqq E_N < 3\cdot 10^{11}\,\text{ev}$ ($\langle E_N\rangle_{\text{AV}} = 1.7\cdot 10^{11}\,\text{ev}$), (b) $3\cdot 10^{11}\,\text{ev} \leqq E_N < 10^{12}\,\text{ev}$ ($\langle E_N\rangle_{\text{AV}} = 5\cdot 10^{11}\,\text{ev}$) and (c) $E_N \geqq 10^{12}\,\text{ev}$, respectively, for EAS of $N_e \geqq 10^4$. Curves of Fig. 8, can be fitted to the experimental points in Fig. 9, if we suppose $r_0 = 2.0 \pm 0.2\,\text{m}$ for (a), $r_0 = 1.5 \pm 0.4\,\text{m}$ for (b) and $r_0 = 1.0\,\text{m}$ for (c), respectively. Since the uncertainty in the determination of position of the axis is included in the above values of r_0, the value of r_0 for (c) ($=1\,\text{m}$) would indicate that the accuracy is about 1 m or better. Assuming 1 m for this uncertainty, the spreads of physical significance are (a) $r_0 = 1.8\,\text{m}$ and (b) $r_0 = 1.1\,\text{m}$. These spreads can be attributed to N-particles of the last generation.

Before these are related to the rms values of p_0, one should take into account the angular distribution of primary particles producing N-particles of energy E_N which has been neglected so far. This effect can be estimated by the following simple consideration. Suppose the energy of a secondary particles is $1/k$ of the primary energy on the average. Since the interactions of different generations are independent of each other, it follows that if the angular distribution in each interaction is represented by Gaussian distribution, then the multiplication of effects of successive generations in angular distribution, and hence the spatial distribution again obeys Gaussian distribution. Then the mean square radius $\langle r^2\rangle_{\text{AV}}$ of N-particles with energy $E_N = cp$ is given by

$$\langle r^2\rangle_{\text{AV}} = \left(\frac{p_0}{p}\frac{L}{\rho}\right)^2 + \left(\frac{p_0}{kp}\frac{2L}{\rho}\right)^2 + \left(\frac{p_0}{k^2p}\frac{3L}{\rho}\right)^2 + \cdots$$
$$= r_0^2 \sum_{l=1} \frac{l^2}{k^{2(l-1)}} .$$

Therefore, r_0 seems to be apparently larger by a factor

$$\left[\sum \frac{l^2}{k^{2(l-1)}}\right]^{1/2} .$$

This factor accounts for 1.7, 1.3 and 1.1 for the values of $k=2$, 3 and 5, respectively. Though information on k is still lacking, it can be assumed tentatively as follows: for instance, the ratio of the numbers of mesons to nucleons is $2\sim 5$ to 1, and $k \sim 2$ for nucleons whereas $k \sim 10$ for mesons. Then, the factor would be about 1.2, not very seriously dependent on the above assumptions. Therefore, the apparent values of r_0 have to be reduced by about 20%.

Table I.

	Energy interval (ev)	Average energy (ev)	Apparent r_0 (m)	$\frac{p_0 L}{p\rho}$ (m)	p_0 (Mev/c)
a	$10^{11} \leqq E_N < 3\cdot 10^{11}$	$1.7\cdot 10^{11}$	1.8 ± 0.2	1.5	260 ± 40
b	$3\cdot 10^{11} \leqq E_N < 10^{12}$	$5\cdot 10^{11}$	1.1 ± 0.4	0.9	450 ± 200

The values of p_0 which are shown in Table I, assuming that one nuclear mfp is $100\,\text{gcm}^{-2}$.

These values of p_0, though they are indirect and poor in accuracy, are yet generally in agreement with those obtained for high-energy neutral pions.[9] These results are consistent with the hypothesis that all secondary particles, charged pions and others as well as neutral pions of more than 10^{11} ev still belong to the same class of p_T, and that the distribution of p_T is characterized by a "well-defined" one such as the Maxwell-Boltzmann distribution.

(D) *Total number of N-particles*

Integrating Eq. (2) with respect to radius from 0 to r,

$$dN_e \int_0^r F(N_e, r)dr$$
$$= 2Sf(N_e)dN_e \int_0^r \Delta_N(N_e, r)\, W(N_e, r) 2\pi r dr .$$

Therefore, for the values of r within which $W(N_e, r) = 1$,

$$\int_0^r \Delta_N(N_e, r) 2\pi r\, dr = \frac{dN_e \int_0^r F(N_e, r)dr}{2S\cdot f(N_e)dN_e} , \qquad (3)$$

where the numerator of right hand side is the total number of observed N-particles in association with EAS of size $(N_e, N_e + dN_e)$ that hit within the radius r. Information on this and the size spectrum of EAS give the total number of N-particles within the radius

r from the axis according to Eq. (3). Moreover, if the lateral distribution of N-particles is assumed to be independent of size[6)] and is expressed as already mentioned in (B) of this Section, the total number of N-particles of $E_N \geqq 10^{11}$ ev, N_N, in an EAS can be estimated on the average.

The results of Ref. 6 can be used here for the size spectrum, because the method of determining the position of the axis and the size adopted for this experiment, is the same as that in Ref. 6. Furthermore, the same detectors and almost similar arrangements were used in both the experiments. The spectrum for $N_e < 10^4$ can be inferred by extrapolating that for $N_e \geqq 10^4$ according to $N_e^{-1.4}$.

The results thus obtained are shown in Table II as well as in Fig. 10 where the results of Ref. 6 are also quoted. They seem to be in good agreement within the experimental errors. The errors assigned to the experimental points here include not only statistical error but also inaccuracies of size spectrum.

Table II.

Size interval	Average size	r (m) in Eq. (3)	No. of observed N-ptls. within $r^\dagger$	Flux of EAS ($\mathrm{m^{-2}\,sec^{-1}}$)	Total No. of N-ptls. N_N

† Total working time was 290 hrs.

In Fig. 10 the total number of N-particles more than 10^{11} ev, N_N, can be expressed by

$$N_N = (50 \pm 5)(N_e/10^5)^{1.1 \pm 0.1}\,.$$

That is, N_N is almost proportional to the size N_e within the wide range from 10^3 to more than 10^6 without evidence of any change in size dependence.

Since the total number of N-particles as well as their energy spectrum is known, the total energy carried by all N-particles in an EAS can be estimated. The total energy carried by all N-particles between 10^{11} ev and 10^{13} ev in an EAS of size N_e turns out to be about $2\cdot 10^8 N_e$ ev. According to the results of Ref. 6, this value is about the same order of magnitude as that carried by the electron component, i.e. $(1.6\sim 2.2)\cdot 10^8 \cdot N_e$ ev[6)].

§ 6. Discussions

(A) *General relationship between N-particles and electrons*

According to the results obtained so far on N-particles of more than 10^{11} ev in association with EAS, the following characteristics

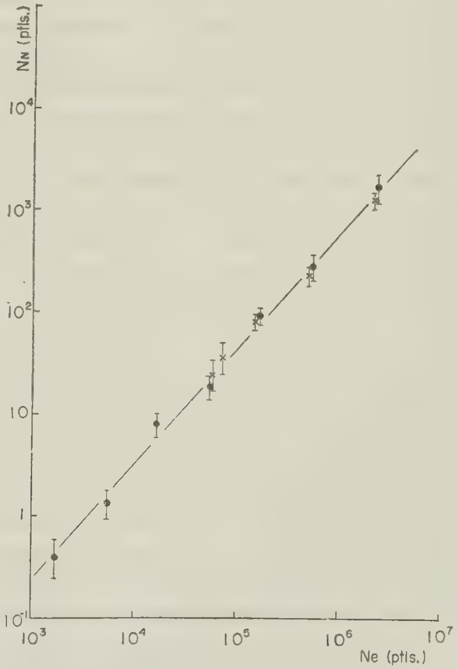

Fig. 10. Total number of N-particles N_N of $E_N \geqq 10^{11}$ ev versus size N_e of EAS. Straight line is represented by $N_N = 50(N_e/10^5)^{1.1}$. Crosses indicate the results of Ref. 6.

are to be noticed. Between a wide range of size N_e, from 10^3 to more than 10^6,

i) the energy spectrum of N-particles is independent of size,

ii) the total number of N-particles N_N is almost proportional to size N_e,

and

iii) the total energy carried by N-particles is nearly equal to that of the electron component in EAS.

Thus the fact that N-particles carry a large proportion of the total energy of EAS and that the general relation between electron component and N-particles seems to be invariant for such wide range of sizes, might suggest that the electron component is in a certain condition of equilibrium with N-particles and the latter are still playing a predominant role even at sea level. In particular, the fact that even EAS as small as 10^3 in size could have almost the same "age" with respect to N-particles as EAS of 10^4 or 10^5 might require such a kind of hypothesis as mentioned above.

In fact the results on the average energy of electrons in EAS[6),10)] as wall as the energy spectrum of high-energy γ-rays studied by emulsion technique[11),12)] would imply that neutral pions more than 10^{12} ev are rarely produced. In this case, the electron component of EAS can be considered as generated for the most part by neutral pions of energies less than 10^{12} ev. Since cascade showers initiated by such relatively low energy neutral pions will be absorbed rather rapidly, the electron component can possibly be in some state of equilibrium with N-particles if N-particles hold enough energy to supply continuously as much electrons as are absorbed[13)]*.

On the other hand, the following features are expected if the above model is supposed to hold. Then the average characters of EAS would not fluctuate very seriously, and further they would not depend on either primary energy or initial altitude of EAS, because the "age" of the EAS would be kept about constant if the electron component is in equilibrium with N-particles. In fact, preliminary results of succeeding study on the lateral structure of particles are consistent with this expectation, namely, the lateral distribution does not seem to fluctuate from case to case except in the region within several metres from the axis. Also, a unique lateral distribution of particles independent of size for almost all EAS of at least $N_e \geqq 10^4$ is not inconsistent with experimental results. Moreover, considering the correlation with the observed number of muons, there has not been found any strong evidence for the dependence of the lateral distribution on the altitude of initiation of EAS.[6)]

Another expectation on the basis of this model would be that the ratio of N_N to N_e is possibly independent of altitude; in other words the attenuation mean free path of the number of electrons is the same as that of N-particles. Although information is still lacking on this problem, the altitude dependence of N-particles could be studied by observations at different altitudes or by taking into account the correlation with the number of muons. This may give a crucial evidence for the model.

Incidentally, the lateral distribution function of N-particles has a close connection with the altitude variation of the production rate of N-particles as has been mentioned in §5 (C). Therefore, detailed study on this distribution would be useful to draw some conclusions regarding the development of EAS.

(B) *Energy spectrum of N-particles*

The energy spectrum obtained for N-particles of $E_N \geqq 10^{11}$ ev can be represented by a single power law $E_N^{-2.0}dE_N$ at least upto $3\cdot 10^{13}$ ev without any evidence of deviation. This gives an integral energy spectrum of $E_N^{-1.0}$. On the other hand, the integral spectrum of N-component not neccessarily associated with EAS has been shown to be $E_N^{-1.5}$ which is considerably different from above spectrum[14),15),16)]. Since the majority of N-particles observed in the present experiment consists of those associated with EAS of $N_e \geqq 10^3$, the difference between the two spectra should be attributed to N-particles associated with EAS of $N_e < 10^3$ as well as the leakage of primary particles to sea level without any interaction in the atmosphere.

By normalizing the spectrum $E_N^{-1.5}$ to the spectrum $E_N^{-1.0}$ of Fig. 5 at $E_N = 10^{13}$ ev, and taking the difference of the two spectra, one obtains a lower limit to the number of N-

---

* In Ref. 13 the authors investigated the transition of EAS under similar assumptions on the energies of neutral pions.

particles that are due to direct leakage of primary particles and those associated with EAS of $N_e<10^3$. If a majority of this difference is due to N-particles accompanying very small showers ($N_e<10^3$), one would expect that the energy spectrum for such N-particles would be much steeper than $E_N^{-1.0}$. However, the present experiment has shown that N-particles in EAS of size as low as 10^3 have the same spectrum $E_N^{-1.0}$ as those in higher size showers (see § 5. (A)) If we assume, therefore, that the same spectrum is likely to persist for showers of $N_e<10^3$, then it follows that the direct leakage of primary particles without any interaction in the atmosphere is appreciable. Even if we consider that 10% of the N-particles which account for the difference of the two spectra are due to such leakage, one obtains a lower limit to the collision mean free path L as 100 gcm^{-2}. It therefore follows that L cannot be much less than 100 gcm^{-2} for high-energy nuclear interactions.

It may be noted here that a comparison of the flux of high-energy N-particles observed at see level and mountain altitude with the primary flux of particles of same energy gives an absorption mean free path of 120~140 gcm^{-2}.15),16) Therefore, the lower and upper limits for L are considered to be fairly well fixed as 100 and 140 gcm^{-2}, respectively.

The energy spectrum of N-particles in Fig. 5 can be compared also with that of high-energy γ-rays, E_γ, observed in nuclear emulsions. Fujimoto et al.11) obtained the integral energy spectrum which is expressed as $E_\gamma^{-1.8\pm0.2}$ for $E_\gamma<10^{12}$ ev and as $E_\gamma^{-2.8\pm0.2}$ for $E_\gamma>10^{12}$ ev. Bristol group12) also had a similar result, that is $E_\gamma^{-3.3\pm0.2}$ for $E_\gamma>10^{12}$ ev. These results may be interpreted as indicating scarcity of production of neutral pions of more than 10^{12} ev. On the other hand, the integral energy spectrum of N-particles can be considered to be still $E_N^{-1.0}$ even in the region of more than 10^{12} ev. Now the question arises what this difference means. Here N-particles would possibly consist of charged pions, nucleons and other strongly interacting particles if they exist. If charge independence hypothesis can still hold at high energy region, charged pions would be expected to be produced as scarcely as neutral pions above 10^{12} ev. Therefore, if the energy spectrum of charged pions above 10^{12} ev is assumed to be the same as that obtained for neutral pions, then it would follow that at least 2/3 of N-particles of more than 10^{12} ev are due to particles different from pions. Of course, possible survivors of primary protons may account for some part of them. However, it is very interesting to investigate whether K-mesons or anti-nucleons exist among observed N-particles, since the composition of high-energy N-particles might give a clue to the development of EAS. The statistical accuracy above 10^{12} ev is not good enough for such analysis in this experiment, and an improved study on this feature is desirable.

(C) *Possible survival of primary particle*

Since it is shown that the integral energy spectrum of N-particles can be represented by E_N^{-1}, in the entire range of shower size and N-particle energy investigated in the present experiment, the total number of N-particles with energy more than E_N may be expressed as $(5\cdot10^{12}\,\text{ev}/E_N)\cdot(N_e/10^5)^{1.1}$. (see § 5. (D)) If the value of E_N is chosen such that the above expression becomes unity for a given size, this would mean that there exists on the average one N-particle of more than that energy in each EAS of that size. The expected values of E_N are $3\cdot10^{10}$ ev, $4\cdot10^{11}$ ev and $5\cdot10^{12}$ ev for EAS of sizes 10^3, 10^4 and 10^5, respectively. Though it is not yet assured that there is always one and only one such high energy N-particle in each EAS, those particles of more than E_N could be tentatively assumed to be surviors of primary particles. Assuming that the average primary energy is approximately given by $10^{10}\,N_e$ ev at sea level, the above values of E_N would indicate that primary particles still hold on the average more than 0.3~0.5% of their initial energies at sea level. If the collision mean free path is equal to 100 gcm^{-2}, it follows that the geometric mean of inelasticity η is approximately 0.4~0.5. This value of η is not very sensitive to the assumptions made above.

Thus, it is found that N-particles carrying about 1% of primary energies normally exist in EAS. Moreover, the existence of N-particles carrying more than several percent to several tens of percent of primary energies may be noticed. Examples of events are listed in Table III in which N-paticles are estimated to carry at least 5% of assumed primary energies, $10^{10}\,N_e$ ev.

The frequency of N-particles carrying more than 10% of primary energies is estimated to be once per 20~30 EASs according to the present energy spectrum. Events listed in Table III show 6 cases for $10^3 \leqq N_e < 3\cdot10^3$ and one case for $3\cdot10^3 \leqq N_e < 10^4$ in which N-particles are estimated to carry more than 10% of primary energies. These frequencies are consistent with those expected above.

Table III.

Size N_e	E_N (ev)	Fraction of primary energy (%)
$1\cdot10^3$	$1.1\cdot10^{12}$	11
$1\cdot10^3$	$1.1\cdot10^{12}$	11
$1.5\cdot10^3$	$1.4\cdot10^{12}$	9
$2\cdot10^3$	$1.4\cdot10^{12}$	7
$4\cdot10^3$	$2.0.10^{12}$	5
1.10^3	$2.1\cdot10^{12}$	21
$2.5\cdot10^3$	$2.1\cdot10^{12}$	8
$1\cdot10^3$	$2.3.10^{12}$	23
$4\cdot10^3$	$2.5\cdot10^{12}$	6
$1.5\cdot10^3$	$3.0\cdot10^{12}$	20
$2\cdot10^3$	$3.9\cdot10^{12}$	20
$3\cdot10^3$	$1.2\cdot10^{13}$	40

Following possibilities can be considered as reasons for such high residual fraction of primary energies; (i) fluctuation in the level of initiation of EAS, (ii) fluctuation in the number of nuclear interactions, and (iii) fluctuation of the inelasticity η.

In the first place, the possibility (i) will be examined. Suppose the EAS is initiated at x gcm^{-2} from the top of the atmosphere. If exponential attenuation is assumed for the total number of particles of EAS, the size $N_e(x)$ at sea level is proportional to $\exp(x/\Lambda_e)$, Λ_e being the attenuation mean free path. Assuming primary energy E_0 is equal to $10^{10}\cdot N_e(0)$ for an EAS started at the top, $x=0$, the relation of N_e vs x is

$$N_e(x)=\left(\frac{E_0}{10^{10}}\right)\exp\left(\frac{x}{\Lambda_e}\right). \qquad (1)$$

Suppose the interaction mean free path of primary particles is L gcm^{-2} and the inelasticity η is constant. Since the average number of interactions from x to sea level, X_0, is $(X_0-x)/L$, the residual energy of primary particle E_N will be

$$\left.\begin{aligned} &E_N=E_0(1-\eta)^{(X_0-x)/L}, \\ \text{or}\quad &E_N=E_0\exp\left[-\frac{K}{L}(X_0-x)\right]. \end{aligned}\right\} \qquad (2)$$

where $K=-\log(1-\eta)$. Therefore, apparent residual fraction of primary energy at sea level, $E_N/10^{10}\cdot N_e$, is

$$\frac{E_N}{10^{10}N_e}=\exp\left[-\frac{K}{L}X_0+\left(\frac{K}{L}-\frac{1}{\Lambda_e}\right)x\right], \qquad (3)$$

Eq. (3) means that an EAS started at lower level gives apparently higher residual fraction if

$$\frac{K}{L}-\frac{1}{\Lambda_e}>0\,.$$

Besides, the fact that $E_N/10^{10}N_e$ is at least 0.3~0.5% for each EAS would imply the following condition, putting $x=0$ in Eq. (3)

$$\exp\left(-\frac{K}{L}X_0\right)=(3\sim5)\cdot10^{-3}\,.$$

Assuming $L=100$ gcm^{-2}, $K=0.53\sim0.58$ or $\eta=0.41\sim0.45$ is obtained. On the other hand, in order to obtain a value $E_N/10^{10}N_e$ of more than 10% by means of variation of x,

$$\exp\left[(K/L-1/\Lambda_e)x\right],$$

should be able to exceed 20~30 for $0<x<X_0$. This requires the condition $\Lambda_e>500$ gcm^{-2}. Therefore, this condition may not be satisfied if the observed EAS are at a stage considerably later than the shower maximum. Rather those events with high residual fractions of primary energies may be interpreted as evidence for EAS near or even before the shower maximum.

The possibility (ii) can be considered as follows. Since the average number of inter-

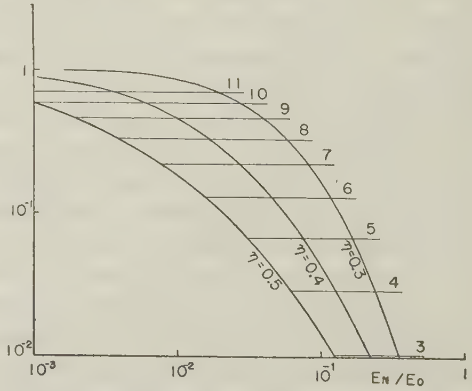

Fig. 11. Integral spectrum of fractional residual energy E_N/E_0 of primary particles for different values of η. Corresponding numbers of nuclear interactions are also shown on the curves.

actions is X_0/L, the probability with which n interactions take place is given by Poissonian distribution $P(X_0/L, \mathrm{n})$. Therefore, the probability of a N-particle having residual energy E_N at sea level greater than or equal to $E_0(1-\eta)^{\mathrm{n}}$, is represented by a partial summation of the Poissonian distribution,

$$\sum_0^{\mathrm{n}} P\left(\frac{X_0}{L}, \mathrm{n}\right).$$

This is nothing but the integral energy spectrum of survived primary particles. The energy spectra calculated for different values of η, 0.3, 0.4 and 0.5 on the assumption $L=100\,\mathrm{gcm}^{-2}$ are shown in Fig. 11. The observed frequency of events in which E_N/E_0 is estimated to be more than 10% is 3~5% of the total. This frequency in Fig. 11 corresponds to an inelasticity $\eta=0.4\sim0.5$ and the number of interactions for such events is something like 3~5. Moreover, the shape of the energy spectrum is not inconsistent with experimental results within the limits of accuracy and can be fitted smoothly with the spectrum E_N^{-1}. However, information is still lacking about EAS corresponding to such few interactions. In these cases, considerable fluctuations in longitudinal development of EAS should be expected. Then the size N_e is not necessarily a good measure of primary energy E_0. Therefore, the observed value of $E_N/10^{10}N_e$ may not be comparable with E_N/E_0 in such cases.

Besides the possibilities (i) and (ii), it can be shown that the fluctuation of inelasticity can also give rise to high residual energies. For the sake of simplicity, it is assumed that the value of inelasticity can be either η_1, or η_2 with probability of occurrence q or $(1-q)$, respectively, among the 10 interactions $(=X_0/L)$. Therefore, the number of interactions with inelasticity η_1 is $10\,q$ whereas that with η_2 is $10(1-q)$ on the average. Suppose a residual energy of 10% occurs in the events in which m interactions with η_1 and (10−m) interactions with η_2 are suffered by primary particles. Then the following equations are satisfied approximately.

$$(1-\eta_1)^{\mathrm{m}}(1-\eta_2)^{10-\mathrm{m}}=10^{-1}\,, \tag{1}$$

$$_{10}\mathrm{C}_{\mathrm{m}}\cdot q^{\mathrm{m}}(1-q)^{10-\mathrm{m}}\cong 4\cdot 10^{-2}\,, \tag{2}$$

$$(1-\eta_1)^{10q}(1-\eta_2)^{10(1-q)}\cong 4\cdot 10^{-3}\,. \tag{3}$$

Eq. (2) means the frequency of such cases as Eq. (1). Eq. (3) represents the fractional residual energy for average cases. Regarding m as a parameter, these equations can be solved. Two possible sets of solutions are shown below.

	m	η_1	q	η_2	$(1-q)$
(a)	0	0.75	0.28	0.20	0.72
(b)	1	0.70	0.40	0.12	0.60

These solutions might suggest a continuous distribution of η such that majority of interactions has η less than 0.5 but some have η values extending beyond 0.5 upto 1 instead of all interactions being necessarily limited to discrete values of η as considered above.

Although this model may only be one of the possible explanations for high residual energies of primary particles, at the same time it can account for the fact that nuclear interactions caused by primary particles studied so far almost always give rather small values of inelasticity.

In order to pursue these possibilities further, it will be inevitably necessary to specify various parameters in addition to the size so as to recognize any differences in individual characters of EAS.

On the other hand, the effect of the existence of N-particles with such high residual energies should be considered. Suppose an N-particle of energy E_N which is about 10% of E_0 interacts. It initiates another " secondary air shower " the size of which is of the order of $E_N/10^9$ at its shower maximum. This is comparable to the size of the original EAS, that is about $E_0/10^{10}$. Therefore, it is likely that such a secondary air shower will modify the structure of original EAS particularly in the vicinity of the core. A variety of effects can also be expected depending on the stage of the development of secondary air shower.

In fact, detailed investigation of cores by means of a large area of neon hodoscope detectors[6),10)] has confirmed that the structure of the core fluctuates remarkably from case to case at least within a few metres from the axis. Particularly, several examples have been found which showed steep cores with steadily increasing densities at least as close as 10 cm to the axis. These could be found in several percent of the total number of events. These events may also be interpreted as due to the superposition of young secondary air shower the energy of which is of the order of 10% of primary energy.

Experimental Studies on Electronic Trapping Processes Associated with Dislocation Lines in Alkali Halide Crystals

By Hiroshi OHKURA

Department of Applied Physics, Osaka City University, Osaka, Japan

(Received December 3, 1960)

The trapping of conduction electrons by dislocation lines in alkali halide crystals was investigated by measuring the temperature dependence of photoconductances of deformed and undeformed crystals. Furthermore, the effect was verified by observing the thermally stimulated currents. In both cases, measurements of electric currents were carried out under application of ac in order to avoid undesirable effects due to space charge formation. Special care was exerted to obtain crystals having a high degree of purity. From the first mentioned experiment, the effective width of dislocation lines for electron trapping was estimated to be 9.3×10^{-8} cm, by using dislocation densities determined from nuclear magnetic resonance studies. The thermal depth of dislocation lines was estimated to be 0.21 ev for KBr and 0.24 ev for KCl crystals. A current glow peak, which presumably may correspond to trapping by jogs, was also measured. The thermal depth of jogs may be roughly estimated to be 0.48 ev.

§ 1. Introduction

Several intensive and important research efforts to investigate the various effects of dislocation lines on electronic processes in germanium crystals were carried out during the past few years[1),2)]. However, in the case of other crystals, especially such as alkali halides, it seems that little has been done in this respect, although it was well-known that plastic deformations have considerable influence on the electrical and optical properties of alkali halides[3),4)]. Therefore, we started this investigation for the purpose to get some information of trapping effects by dislocation lines with reference to conduction electrons in alkali halides. The work here reported is mainly concerned with measurements and analysis of the decrease of photoconductances in the plastically deformed potassium bromide and potassium chloride crystals at the temperature range below about 150°K.

In order to detect the trapping effect of dislocation lines only, it is quite important to eliminate as much as possible the undesirable effects caused by impurities, vacancy clusters, etc.. Single crystals appropriate for above requirements were obtained by repetitions of Kyropoulos' method. As will be described in § 2 *b*), this method proved to be highly advantageous for potassium bromide crystals. However, as was suggested by Seitz[5)], while a crystal is deformed plastically, a number of vacancy clusters is created in the crystal by moving dislocation lines. Such vacancy clusters may act as effective electron traps and may change the photochemical properties of alkali halides considerably. In fact, as was observed by Ueta and Kaenzing[3)], the *F* band bleaching rate in the plastically deformed colored KCl and NaCl crystals under irradiation with *F*-light at room temperature is much larger than in the case of the undeformed crystals and, moreover, a number of complex color centers is created. In our preliminary tests, the photoconductances of the deformed crystals showed a marked reduction compared with that of the undeformed ones at the whole temperature region from 73°K to 273°K. This fact easily leads us to erroneous interpretations of photoconductive measuremets, if assuming that trapping effects are caused by dislocation lines exclusively. Therefore, as a first step of our experiments, it was necessary to remove such vacancy clusters and also complex color centers, if they were present. We found out that our purposes were fully achieved if the deformed crystals were subjected to a pulse annealing. That is, after the deformed crystal was kept at 400°C for about 30 sec and then it was quenched rapidly on a massive copper block to room temperature. This achievement was confirmed by observing that the optical bleaching properties in deformed crystals subjected to the pulse annealing were exactly the same as for those of undeformed ones. We were worried that the pulse annealing process might decrease a density of dislocation lines which were produced by plastic deformation. The observed increase in the *N.M.R.* signal intensity after the pulse annealing might be attributed to the decrease of dislocation density, but it was confirmed that more than one half of the *N.M.R.* signals due to dislocation lines remained in the case of above mentioned short time annealing. (§ 3 *c*)).

For all insulators, a major problem in photoconductivity measurements is the decrease of apparent conductivity over a few or less seconds after voltage application. This effect can be interpreted as the reduction of an inner field by accumulation of charged carriers near electrodes[6),7),8)]. A number of complicated techniques was tried to remove such space-charge accumulations since Glaser and Lehfeldt's investigation[9)]. In our present work, in order to reduce the space-charge effects, the applied voltage was reversed periodically by applying ac voltage. The effects of elimination of space charges were investigated in some details and the results were summarized and reported in another article[10)].

§ 2. Experimental Details

a) *Apparatus*

Both photoconductive and "current glow" measurements were made between 73°K and 220°K with the sample mounted in a vacuum cryostat of the type shown in Fig. 1. For photoconductive measurements, a sample was fastened to a copper plate connected to the bottom of the liquid oxygen reservoir in the cryostat by a phosphor bronze spring, which is insulated electrically by using a Teflon plate, and the sample was surrounded by a copper radiation shield which was kept at the temperature of the bottom plate. Two electrical leads were brought into the crystal chamber, one of them was connected to the bottom copper plate and the other to the phosphor bronze spring, respectively. Aluminium electrodes were vacuum evaporated on both flat surfaces of cleaved sample plate. Bottom copper plate, crystal, and electrode were optical flat and were in contact with each other. Plates of about 2 mm thickness with 10×10 mm rectangular flat surfaces were used. The light was forcussed on the crystal with an area of about 20 mm². For "current glow" measurements, an electrical and thermal shield was applied on input leads to a preamplifier. The input leads are doubly shielded, the inner shield being driven in phase with an input voltage so as to reduce the stray capacity between grid and cathode of preamplifier. The sample for "current glow" measurements was bar of 2×2×10 mm.

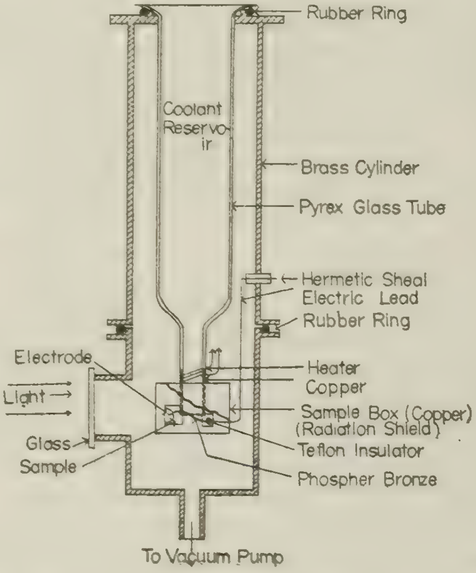

Fig. 1. Schematic block diagram of cryostat. Sample is fastened by spring of phosphor bronze, which is attached to one of electrodes vacuume-evaporated on the sample. Another electrode, the sample, and the bottom plate of the sample box are tightly contacted. Two electrical leads are connected to the phosphor bronze spring and the sample box, respectively.

Silver paint was applied on 2×2 mm faces of the bar. As for an illuminated surface, a cleaved surface was used which is the cleanest obtainable.

The temperatures were measured by a thermocouple of copper constantan attached on the bottom plate.

Block diagram for the photoconductive measurements is shown in Fig. 2. The photoconductive signal was measured by applying ac voltage of 1,000 cps to the sample and an input grid resistance of 100 kilo-ohms, which are connected in series. A rotating-sector disk, driven by a synchronous motor, chopped a light from an incandescent lamp at 30 cps. When the sample was irradiated with the chopped light, a voltage drop at the input resistance consists of 1,000 cps sinusoidal wave modulated with the photoconductive singnal of 30 cps. This modulated wave was sent to a tuned RC-amplifier of 1,000 cps and then was detected to pick up the 30 cps photocurrent signal. The faint 30 cps signal thus obtained was sent to a tuned RC-amplifier of 30 cps and then was lock-in detected. With S–1 in position M, the sensitivity of this apparatus was calibrated with a reference signal of 30 cps picked up by a PbS photo-cell from the same light source.

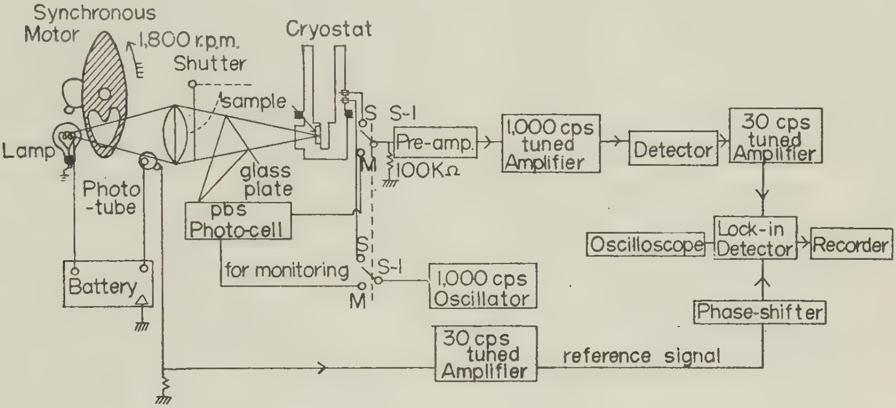

Fig. 2. Block diagram of photocurrent apparatus.

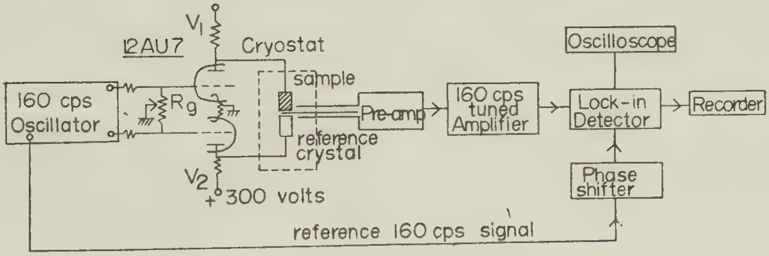

Block diagram of the current glow apparatus

Fig. 3. Block diagram of current glow apparatus. Cryostat is shown in dashed line. Sample, reference crystal, and R_g are arranged to form a balancing bridge. A dark current can be reduced to zero by adjusting R_g.

In Fig. 3, a block diagram of the "current glow" apparatus whose preamplifier consisted of Macdonald's circuit[11] is shown. At the first stage of this apparatus, a null method was used to eliminate a dark current and, furthermore, to increase a signal-noise ratio. An oscillator of 160 cps drives two triodes whose output is applied to both colored sample and control crystal (uncolored) in opposite phase. The variable grid leak resistance of two triodes and these two crystals are arranged to from four arms of a balancing bridge. The output signal due to the dark current can be reduced to zero by adjusting the grid leak resistance R_g. After the dark current has been eliminated, if the impedance of colored sample was changed thermally or by light stimulation, an unbalanced current would flow into a high input impedance in the preamplifier and result in voltage drop. This voltage signal of 160 cps was sent to a 160 cps tuned RC-amplifier and then lock-in detected. This apparatus can be used for photoconductive measurements, too. The sensitivity of this apparatus was calibrated by sending the sinusoidal signal of 160 cps having a known intensity. The input impedance of this Macdonald's preamplifier was about 600 megaohms and the noise level was 1.0×10^{-14} amp.

In a typical run of "current glow" measurements, after the crystal had been irradiated with F-light at 73°K, its temperature was raised at a rate of approximately 0.07°C per second, ac electrical field of about 100 volts per cm being applied to the crystal. The released currents were measured by means of above described apparatus as shown in Fig. 8.

A metal film interference filters were used to obtain a pure F-light irradiation from an 500 watts incandescent lamp of projector.

b) *Sample preparation*

Single crystals of alkali halides were grown from the melt in a platinum crucible by Kyropoulos' method using Yashima's analyzed grade of salt. Pure crystals were obtained by repetitions of Kyropoulos' method and by pulling up the crystal as thinly as possible. F centers were prepared by heating the crystals for about forty hours in either potassium or sodium metal vapor. The temperature of the crystals was maintained at a constant temperature within the range of 450°C and 580°C with an accuracy of ±3°C by using Chino's programmer. The crystals were sealed into an evacuated Pyrex glass tube. The alkali metal was vacuum distilled into the Pyrex tube after several preliminary vacuum distillations. The colored crystals were cleaved into several pieces of about 2 mm thickness, one of which was then plastically deformed by using the oil compressor. The remaining slices were used as reference crystals. The degree of deformation was expressed by a fractional thickness reduction.

Before describing the experimental results, it should be of interest to review the merits of the recrystallization technique which are most impressive in the case of potassium bromide crystals. Some intensitive testings were carried out and the results were summarized as follows. First, recrystallized colored crystals could not be optically bleached by F-light irradiation at room temperature, which is worthy of note. Even plastically deformed crystals, after they had been subjected to the pulse annealing described in §1, resulted in the same optical bleaching phenomena as those of the undeformed ones when they were irradiated with F-light at room temperature. One typical example for both ordinary and recrystallized crystals is illustrated in Fig. 4 a) and b), respectively, in which the soild and the dashed curves show the adsorption curves before and after F-light irradiation, respectively. From these results, we can conclude that the recrystallization technique is advan-

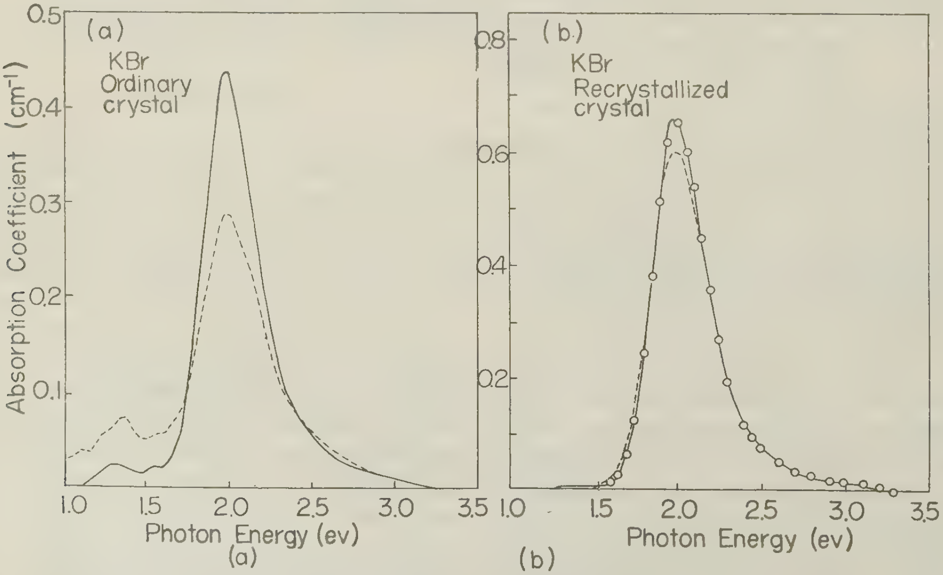

Fig. 4. Absortion coefficient of additively colored KBr crystal against photon energy. a) Ordinary crystal with a 13% plastic deformation; —— before irradiation and --- after ten minutes irradiation with F light. b) Recrystallized specimen a 19% plastic deformation; —— before irradiation and --- thirty minutes irradiation with F light.

tageous to reduce originally present vacancy clusters in the crystal which act to trap photoelectrons to form complex color centers during the F-light irradiation. Furthermore, we proved that the pulse annealing technique is quite effective for deformed crystals to remove vacancy clusters introduced by plastic deformation, as described in § 1. Second, the photoconductances of colored recrystallized crystals tended to increase as the crystal temperature was raised beyond −75°. Subsequent measurements produced the same results when these processes were repeated. On the contrary, the photoconductances of colored ordinary crystals tended to decrease if the crystal temperature raised beyond −75°C and compex color centers were created simultaneously. When these measurements were repeated, we could not obtain reproducible results. For instance, the magnitude of the photoconductance at −50°C in the former case is nearly ten times larger than the maximum value in the latter case. These differences may be attributed to the existence of trapping processes in ordinary crystals due to the vacancy clusters orginally present and the newly created color centers which may act as consecutive traps for photoelectrons[12]. Third, by measuring a secondary current caused by electron bombardment on one surface of KBr crystals, Onuki found that the mean range of conduction electrons in the recrystallized crystals was nearly ten times larger than that in ordinary ones[13]. Fig. 5 shows the saturation behavior of the current responses of both recrystallized and ordinary crystals of about 0.3 mm thickness against an increasingly applied collecting field at room temperature.

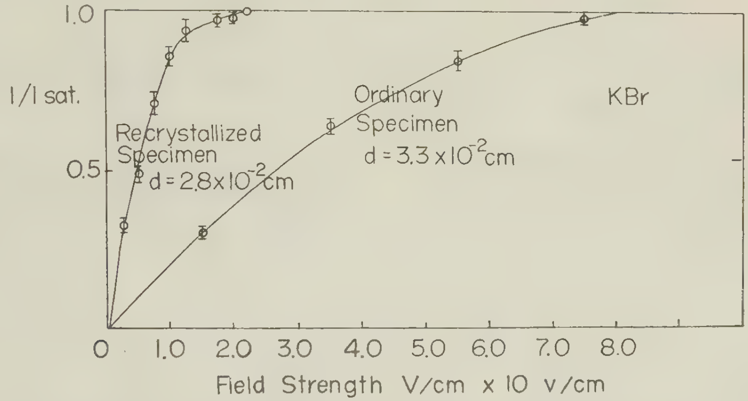

Fig. 5. Normalized secondary current induced by electron bombardment on one side of surfaces of KBr crystal is plotted against the intensity of collecting field strength. The range of conduction electrons in recrystallized crystal is almost ten times larger than that in ordinary crystal.

Comparing these curves with the theoretical curve due to Hecht[14], we can determine the mean ranges of both kinds of crystals. Since the magnitude of the mean range is expressed by a product of electron mobility and mean life time of conduction electrons, if we use the observed value of the electron mobility, $\mu=30\ \mathrm{cm}^2$ per volt-second[15] one can estimate the value of mean life time of conduction electrons in the recrystallized crystal to be in the order of 10^{-8} sec. This value is nearly ten times larger than that in ordinary crystals. If we assume that a cross section of traps responsible for this life time is equal to that of F centers, namely, $1.0\times10^{-14}\ \mathrm{cm}^2$[14], the concentration of corresponding traps can be determined to be in the order of 10^{15} cc, which would be the highest limits.

The potassium bromide crystals were pulled up from the melt as thinly as possible so as to obtain a low concentration of dislocation lines for the recrystallization process. Otsuka et al. have proved by *N.M.R.* studies that the above described procedure is quite suitable for such purpose[16].

§ 3. Experimental Results

a) *Photoconductive measurements*

The photoconductance curve of a colored potassium bromide crystal with 9% plastic strain is shown as the dashed curve in Fig. 6 at the temperature region from 73°K to 223°K.

In the same figure the photoconductance curve of undeformed reference crystal containing the equal amount of F centers is shown with the solid curve. The same photoconductance curve of potassium chloride crystals are shown in Fig. 7 for both undeformed and 18% strained crystals each of which is shown as the solid curve and as the dashed curve in the figure, respectively. The important characteristic of primary interest of these results is that, with

* The first column illustrates the concentration of F centers. The second is the deformation degrees which are expressed by percentage reduction. The sixth is the concentration of dislocation lines determined by *N.M.R.* method (§ 3 (*c*)). The explanations of the other columns will be appeared in § 4.

the exception of the vicinity of the plateau region, the photoconductance of deformed crystals is less than that of undeformed crystals. The plateau of photoconductance is in the range from −125°C to −100°C for KBr from −140°C to −120°C for KCl. The heights of plateaus were found to be inversely proportional to the concentration of *F* centers whithin the range from slightly greater than 10^{15} per cc to 5×10^{17} per cc. This result is excellent evidence that the photoelectrons in the undeformed crystal are trapped only by *F* centers at the temperature below the plateau region[14]. Hence, it appears that the decrease of photoconductance in deformed crystal may be attributed to the shallow traps introduced by plastic deformation. But this interpretation could not be regarded as definite, because other factors which could affect to change the magnitude of photoconductance still remained unexplored. We will revert to discuss these factors in later section.

The result obtained for KBr and KCl containing several concentration are summarized in Table I.

b) *"Current glow" in potassium bromide crystals*

The "current glow", namely, the thermal electric charge release during the warming of a colored KBr crystal containing 3.0×10^{16} *F* centers per cc and with 20% plastic strain is shown in Fig. 8. This crystal had been irradiated at 73°K for one hour with *F*-light. On the contrary, no charge bursts were observed in undeformed KBr crystals during warming from 73°K after *F*-light irradiation.

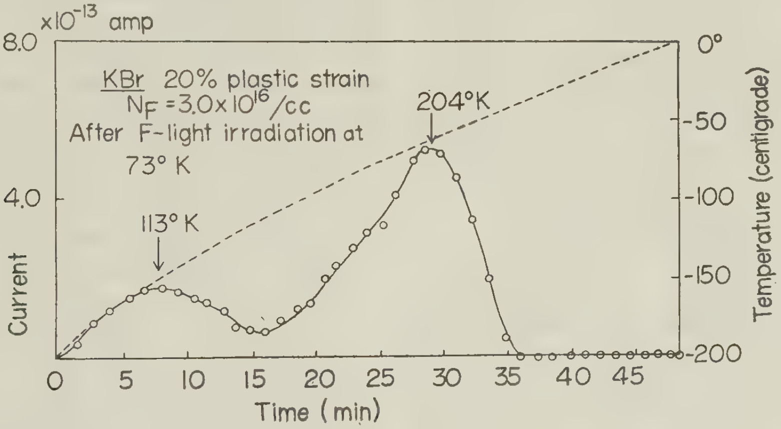

Fig. 8. "Current glow" curve for an additively colored KBr crystal with a 20% plastic strain which has been irradiated for one hour with *F*-light at 73°K. The dashed line shows the variation of temperature of the crystal with time.

Therefore, the current peaks at 113°K and 204°K, in Fig. 8, are characteristic for deformed crystals. These two current peaks may be attributed to the thermal release of electrons from the shallow traps which were created by plastic deformation.

Since the electrons in shallow traps came from *F* centers, being released optically, it is expected that the *F* band in deformed crystals would be bleached during the preliminary irradiation. The *F*-bleachings were measured with the use of Hitachi EPU-2 type spectrophotometer. In the case of undeformed colored crystals, no change was observed in the optical density in the spectral region of both *F* and *F′* bands. This means that an excited electron in an *F* center can hardly be raised thermally into the conduction band at 73°K[14]. Even if a few electrons were raised into it, they may be trapped by the ionized *F* centers causing them to revert into *F* centers unless they reach other *F* centers to form *F′* centers*.

---

* This description is not inconsistent with the Pick's results on the $F\rightarrow F'$ and $F'\rightarrow F$ conversion processes[17),24)]. For instance, in the $F\rightarrow F'$ conversion process, the more the bleaching temperatures increase, the more saturated concentration of bleached *F* centers increase. This may be interpreted in terms of the more predominence of the trapping probability of the negative ion vacancies than that of the *F* centers at low temperatures[25]. The decrease of the quantum efficiency in $F'\rightarrow F$ process due to the increase of temperatures could be interpreted by the same reason as mentioned above.

In the case of *F*-light bleaching of deformed crystals at 73°K, however, there was a slight decrease in the optical density of the *F* band. The saturated values of the decrement of the *F* center density in this case were almost independent of the initial *F* center density and were almost proportional to the deformation degrees; for instance, a saturated decrement of 1.5×10^{15} per cc for a crystal containing 3.0×10^{16} *F* centers per cc and with 27% plastic strain. The *F* band can be recovered by subsequent warming to 100°K.

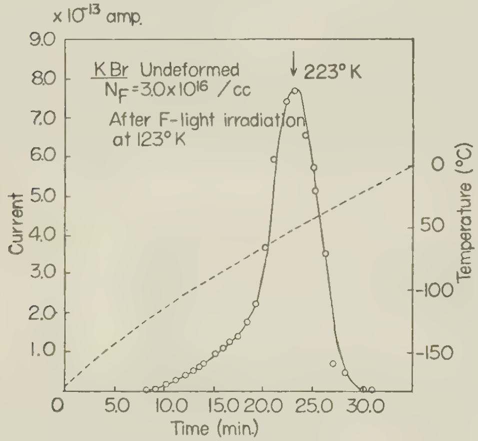

Fig. 9. "Current glow" curve for an additively colored undeformed KBr which has been irradiated for 10 min with *F*-light at 123°K. The dashed line shows the variation of temperature of the crystal with time.

Next, the thermal release curve for undeformed crystals was taken after *F*-light irradiation at 123°K for ten minutes. (Fig. 9) Only a single current peak occurred at 223°K. Exactly the same results were obtained in the case of previous *F*-light irradiation at 173°K. This current glow may be attributed to the thermal destruction of *F′* centers. Optical absorption measurements of the colored and undeformed KBr crystals have shown that *F′*-centers are formed by *F*-light irradiation at both temperatures. More quantitative studies concerning *F*-bleaching are as follows*: When optical measurements were made at liquid oxygen temperature after *F*-light irradiation at 123°K, it was found that the optical density at the peak of the *F* band decreased by approximately 45% of its initial value. After warming this crystal to 173°K subsequently and recooling it rapidly to 100°K, a part of *F′* centers reverted thermally to *F* centers but about 10% of the optical density of the initial *F* centers still remained as *F′* centers. When the crystal was *F*-bleached at 173°K, there was a 15% decrease in the optical density of *F* band. In every case, *F*-bleaching was accompanied with an increase of the *F′* band. Whole *F′* centers can be reverted thermally to *F* centers by a subsequent warming of the crystals to 223°K. These results of optical absorption measurements are consistent with the former description that the current peak at 223°K occurred as a result of the thermal destruction of *F′* centers.

A series of current glow peaks observed in a colored crystal with 18% plastic deformation which had been irradiated with *F*-light both at 123°K and 173°K and then cooled down to 100°K is shown in Fig. 10 *a*) and *b*), respectively. In Fig. 10 *a*), there are three current peaks at 137°K, 204°K, and 290°K, which we denoted as I, II, and III for convenience. In

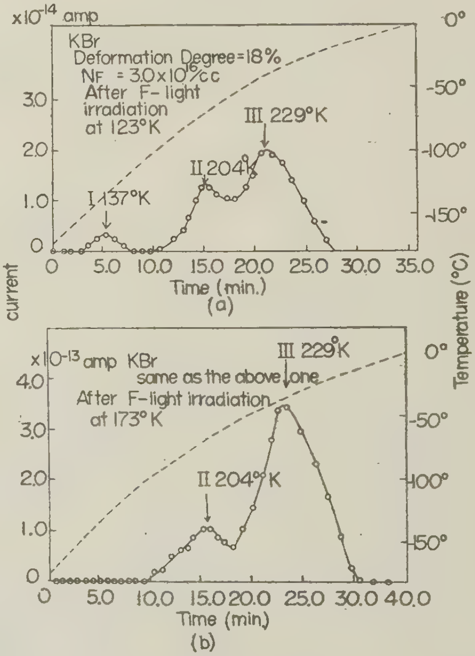

Fig. 10. *a*) "Current glow" curve for an additively colored KBr crystal with a 18% plastic strain which has been irradiated with *F*-light for 10 min at 123°K. *b*) "Current glow" curve for the same sample as that of case *a*) which has been irradiated for 10 min with *F*-light at 173°K. The dashed line shows the variation of temperature of the crystal with time.

---

* These results are somewhat different from Pick's observations[17].

Fig. 10 *b*), peak I disappears and peaks II and III that occur after irradiation at 123°K are also present except that the intensity of peak III becomes larger than that of peak II. Peak I may be considered to be a part of the 113°K peak observed in Fig. 8, if assuming such peaks are caused by the electron release from the traps having an inhomogeneous distribution of energy levels. The idea that the dislocation lines are responsible for this peak I is quite reasonable. Since the dislocation lines in crystals are actually composed of both screw and edge types, it is plausible to assume that trapping levels due to dislocations have an inhomogeneous distribution of energy levels. Peak II is quite consistent with the second peak observed in Fig. 8, which is also caused by a plastic deformation. The interpretation of peak II will be given in § 4. Peak III may be attributed to the destruction of F' band, although there is a slight shift of the peak to higher temperature levels compared with the current glow due to F'-release shown in Fig. 9. Because, as can be confirmed in optical absorption measurements, the creation of F' band at 123°K and 173°K and the subsequent thermal destruction of F' band in deformed crystals are the same as those in undeformed crystals described above.

The most characteristic feature of these results is that the current glow occurred at temperature of 113°K or 137°K signifying that shallow traps were created by the plastic deformation. These shallow traps may be responsible for the decrease of the mean life time of photoelectrons in deformed crystals which was mentioned in § 3 *a*). The temperature at which current peaks were observed are listed in the first column of Table II. The listed temperatures are mean values from several observations and the variation among individual runs was of the order of ±4°C.

The magnitude of the current glow depends on the following two factors; first, the probability that an electron can be removed thermally from a shallow trap to the conduction band and second, the life time of an electron before it is trapped by still deeper traps. If the next two simple assumptions are adopted for these two factors, the method described by Randall and Wilkins[18] in the case of thermoluminescence should be applicable to compute the trap depths for the various glow peaks. First assumption is that the probability of thermal ionization from the original traps p is given by

$$p=s\times\exp(-E/kT) \tag{3.1}$$

where E is the trap depth below the conduction band and s is a frequency factor. Second, a multiple trapping is assumed to be excluded. Then, the trap depth E is related to the temperature T^* of maximum glow by

$$E=kT^*\times\ln s\times\left(1+\frac{\ln(kT^{*2}/\beta E)}{\ln s}\right) \tag{3.2}$$

where β is the warming rate and the frequency factor s is taken to be 10^{10} 1/sec. In the case of a well-separated and appropriately narrow current peak as shown in Fig. 9, another approximate formula derived by Grossweiner[19] can be applicable which permits E and s to be calculated separately from the shape of the observed current temperature curve. According to this analysis, they are given in terms of T^* and T', being the temperature maximum and the temperature at which the increasing current reaches half-maximum, by the following equations:

$$\begin{aligned} &E=1.51\,kT^*T'/(T^*-T') \\ &s=\beta(E/kT^{*2})\exp(E/kT^*) \end{aligned} \tag{3.3}$$

It is still difficult to determine the frequency factor s with high accuracy because of its strong dependence on T^*-T'. In Table II, the trap depths for the various glow peaks calculated by using the equation (3.2) are listed. The trap depth and the frequency factor for F' centers which was calculated by using equation (3.3) is listed in Table II, too.

The charge density of released electrons, N, could be calculated by a time integral of the observed current glow curve, if the life time of the conduction electrons is known at the temperature region where the current bursts are measured. Although the value of life time is not determined yet definitely, we can safely assume it to be 1.0×10^{-8} second as was discussed in connection with Fig. 5. N can be expressed as follows:

$$N=\frac{d}{e\mu\tau VE}\int i\,dt \tag{3.4}$$

where d is the separation of electrodes, e the electronic charge, μ the electron mobility, τ the life time, V a volume of specimen, and E an applied field intensity, respectively. When photoelectrons fill the empty traps entirely under F-light irradiation, the charge density obtained from equation (3.4) would reach a saturation value. A typical example of this saturation curve for the thermal destruction of F' centers is illustrated in Fig. 11. Saturation was reached after about ten minutes irradiation with F-light, which was quite consistent with the results in optical absorption measurements of F-bleaching by irradiation with the light source which was used for current glow measurements. The saturated values for the various traps are listed in the fourth column of Table II. These values may correspond to the density of each trap. It is of interest to note that the density of F' centers is nearly equal to that of optically created F' centers. The tentative assignment of these traps are listed in the last column of Table II, details of which will be discussed in § 4.

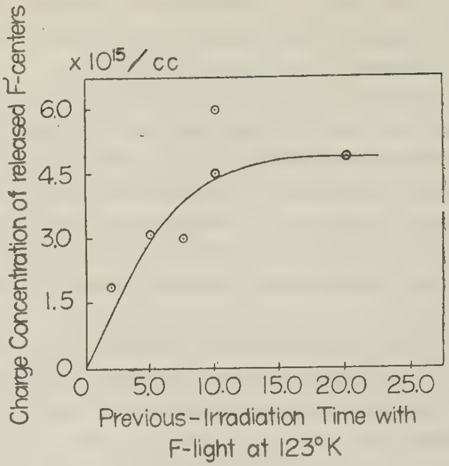

Fig. 11. Concentration of charges released from F' centers in the additively colored KBr crystal containing 3.0×10^{16} F centers per cc against the F-light irradiation time at 123°K.

Table II.

Trap	T^* (°K)	Trap depth (ev)	Frequency factor (1/sec)	Trap density (1/cc)	Assignment
I	113	0.26	Assuming to be 1.0×10^{10}	1.2×10^{14}	Dislocation
II	204	0.48		6.6×10^{14}	Jog
III	229	0.58		3.0×10^{15}	F'
F'	223	0.63	4.0×10^{11}	4.5×10^{15}	

c) *Determination of Dislocation line density through N.M.R.*

N.M.R. method for the determination of dislocation line density in alkali halide crystals had been at first suggested by Watkins[20)] and his findings were largely improved by Otsuka and Kawamura[21)]. They poined out that the observed decrease of a magnitude of nuclear magnetic absorption signal intensity of Br^{79} in deformed KBr crystals is attributed to the second order broadening of the central line of Br^{79}-lines in KBr caused by the introduction of dislocation lines. From this point of view, they have charted the curve showing the relation between dislocation density against deformation degree. The result, however, would not be applicable in our case without taking the special characteristics of our specimens. The following three points were examined with special attention in our present studies;

(1) effects of coloration

(2) effects of pulse annealing after plastic deformation

(3) geometric difference in samples.

We may expect that colored crystals can contain more dislocation lines than uncolored crystals during deformation process due to interaction between dislocation and F centers[22)]. But measurements failed to detect any differences in the dislocation density between uncolored and colored crystals containing 2.0×10^{17} per cc F centers, both of which have been subjected to plastic deformation of 10% strain. Even if such an increase would actually occur, it would be less than 10^8 dislocation line per cm², which is a threshold value detectable by *N.M.R.* technique.

Second, as introduced shortly in § 1, after a deformed crystal was subjected to a pulse annealing process, an increase of the peak intensity together with a simultaneous decrease of a bandwidth in the integrated unclear magnetic resonance absorption signal curve of Br^{79}-line in KBr was observed. This recovering process, obviously, depends on the temperature duration of pulse annealing. For convenience, we defined the recovering rate of *N.M.R.* singnal, R, by the following equation:

$$R = \frac{(I_T - I_R)}{(I_0 - I_R)}, \tag{3.4}$$

where I_T is the peak intensity in the integrated absorption signal curve of a deformed crystal measured after the pulse annealing at the temperature of T, I_R the original peak intensity measured immediately after the plastic deformation, I_0 the peak intensity of the undeformed crystal with the same geometrical construction as the deformed one. Each nuclear magnetic absorption measurement was carried out at room temperature. The numerator of equation (3.4) is inversely proportional to a recovered dislocation density and the denominator is inversely proportional to the dislocation density that has been introduced by plastic deformation. As the proportional constant of both numerator and denominator are equal, R in (3.4) may be called a normalized recovering rate caused by the pulse annealing. Recovering rate R is plotted against the pulse annealing temperature with pulse width of 50 min, 10 min, and 2 min as parameters in Fig. 12. The pulse width is plotted in Fig. 13 against the reciprocal of the characteristic temperature T^* at which temperature the recovering rate reaches its $(1-1/e)$ value in each run. This result shows that the recovering probability per second can be expressed by the following equation:

$$1/\tau = \nu_0 \times \exp(-E/kT^*) \tag{3.5}$$

where E is the activation energy of this process and ν_0 the frequency factor. Although we have no complete knowledge about the activated process which is characterized by above-determined activation energy, it is interesting to note that this energy value ($E = 0.87$ ev) is quite similar to that of the migration of positive ion vacancy. ν_0 is obtained to be 1.0×10^5 per sec.

Hitherto, we treated the recovering process as if dislocation lines were annuled in the crystal by thermal process. But, such a phoenomenon can be interpreted also in terms of the formation of small angle grain boundaries as a result of polygonization or the formation of a cell structure[23]. If these processes occurred predominantly, the dislocation lines would still remain in the crystal and would act as electron traps for conduction electrons. At the present stage, since we have no exact knowledge concerning which of the processes described above is predominant in this thermally recovering process, we did not take into account the result of this observation in analyzing the photoconductive data. Even if the annulment of dislocation lines occurred actually, it is found that, by using equation (3.5), still about one half of them can be expected to remain in the crystal by the pulse annealing at 400°C for 30 sec. Therefor,if we took into account the annulment of dislocation lines, subsequent calculation of the trapping cross section of traps would suffer a difference of factor two.

Third, Otsuka and Kawamura measured the dislocation line density in rod-shaped crystals

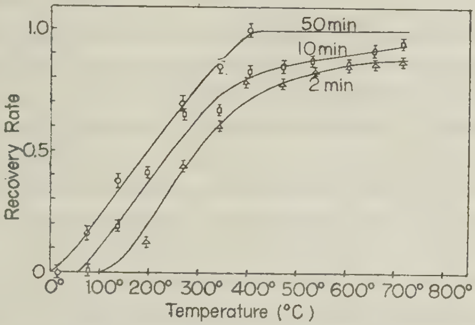

Fig. 12. Recovery rate of Br^{79}-lines in KBr against the pulse-annealed temperature with pulse width of annealing as a parameter.

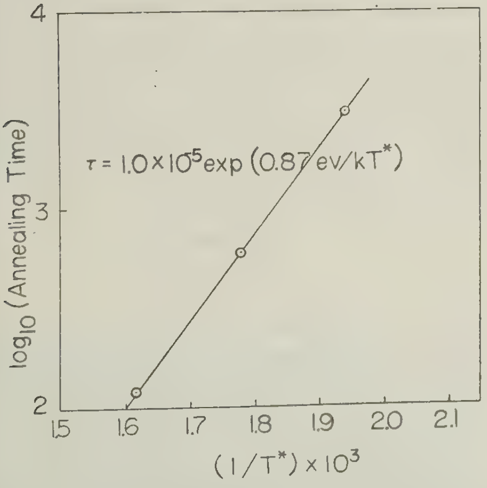

Fig. 13. Pulse-annealed duration against reciprocal of the characteristic temperature T^*.

pressed in the direction of their cylindrical axis. Our deformed crystals used for both photoconductive and current glow measurements were plate-shaped crystals with dimension of about 10×10×2 mm pressed in the direction of their thickness. We may expect that, in the latter case, more dislocation lines may be created than in the former during the deformation process even in the case of the same degree of deformation, because of limited free surfaces through which dislocation lines can escape. In order to verify this expectation, we measured the dislocation density of a plate-shaped specimen deformed in the direction of thickness. From the comparsion with the Otsuka and Kawamura data, we found that the measured density is nearly four times larger than that of theirs, under the same degree of deformation. This evidence quite fits with our expectation. Thus determined dislocation density is listed in the sixth column of Table I for KBr crystals.

§ 4. Discussion

As is well-known, the magnitude of a photoconductance of colored alkali halide crystals depends on the temperature though the opical quantum efficiency, the electron mobility, and the mean life time of conduction electrons[14] Therefore, before discussing the decreasing charactor of photoconductance in deformed crystals described in § 3. *a*), it is necessary to determine in what terms these observations can be interpreted. Fortunately, the experimental fact that the current glow in deformed crystals was observed at the temperature of about 113°K leads us to accept the point of view that new shallow trapping levels are created in deformed crystals during plastic deformation. These shallow traps can enhance a trapping probability for conduction electrons and may contribute primarily to the decrease of mean life time. As we shall show later, the other two factors would not have a marked effect on the temperature dependence of photoconductance. For instance, in order to interpret the decrease of photoconductances in terms of the decrease of the quantum efficiency, one must assume the proximity of dislocation lines and F-centers which results in the considerable variation of the electronic structures of F centers. Then, the following two evidences could be derived. First, the shape and peak location of F band would be changed. Second, under the plastic deformation, the more dislocation lines density would be introduced in the colored crystals than in case of the uncolored crystals. But, these expected evidences are not detected in our observations. (§ 3. *c*)). Therefore, it seems plausible to assume that the invariance of the quantum efficiency together with the uniform distribution of both dislocation lines and F centers*. Furthermore, from the mobility studies[15], the idea that a dislocation line can act to scatter conduction electrons in alkali halide crystals can not be applicable because of its quite short mean free path due to lattice scattering. In n-type germanium, an array of dislocation lines can act as a row of closely spaced acceptor centers which give an appreciable effect on the scattering of electrons[1]. But, in alkali halide, such effect can not be expected because of ionic crystal structure and far lower electronic conductivity compared to germanium.

Trapping effects due to F centers were predominant at the temperature below about 170°K for KBr and 150°K for KCl, respectively. This fact enables us to analyze the characteristic decrease of photoconductances in deformed crystals in these temperature regions. If we assume that shallow traps introduced by plastic deformation act as electron traps, the net mean life time T for plastically deformed crystals can be expressed as follows:

$$1/T=1/T_F+1/T_D\ , \qquad (4.1)$$

where T_F is the mean life time of photoelectrons due to trapping by F centers and T_D the mean life time due to trapping by shallow traps introduced by plastic deformation. Since the magnitude of photoconductance is proportional to the mean lifetime, T_D is calculated from equation (4.1) by using the observed photoconductance as follows:

$$1/T_D=1/T-1/T_F\sim 1/I-1/I_0 \qquad (4.2)$$

and

---

* If the dislocation lines and F centers are uniformly and independently distributed in the crystal, the probability that 10^{16}/cc F centers to be located in the proximity of the dislocation lines must be in the order of 10^{-7}, hence 10^2/cc dislocation lines out of 10^9/cm^2 dislocation lines might combine with the F center, the value of 10^2/cm^2 being too small for the above mentioned evidence to be observed.

$$T_F/T_D = I_0/I - 1 \tag{4.3}$$

where I_0 and I are the photoconductances for the undeformed and deformed crystals, respectively. Thus computed and normalized $1/T_D$ is plotted against temperature by solid line in Fig. 14. The dashed line in this figure shows the temperature derivative of this solid curve. The temperature T^* at which the peak of this derivate curve occurs may be used as the measure of trap depths. T^* are 105°K KBr and 118°K for KCl crystals, respectively.

The order of magnitude of the thermal depths of these shallow traps can be estimated approximately, if assuming that the probability per second for thermal ionization is expressed by the same equation as (3.1), namely, $p = s \times \exp(-E/kT)$, and assuming that the releasing frequency p is one per second at the temperature T^*. Inserting $s = 1.0 \times 10^{10}$ per sec into equation (3.1), the thermal depth E can be computed to be 0.21 ev for KBr and 0.24 ev for KCl crystals, respectively. The latter value would correspond to the thermal depth of trap I listed in Table II obtained from the current glow measurements. As described in §1. and 3, it can be deduced, especially from the optical studies, that these shallow traps are not attributed to point defects such as single vacancies, vacancy clusters, complex color centers etc., but are actually attributed to the characteristic defects caused by plastic deformation. We may speculate that the shallow traps are attributed to either dislocation lines or jogs of the dislocation lines.

A tentative explanation of the shallow traps may be offered by assuming that a dislocation line can trap photoelectrons in this temperature region. In the present experiments, one can estimate the effective trapping width w of dislocation line if the density of dislocation lines N_D (1/cm^2) is known. $N_D w$ and mean life time T_D are related by

$$1/T_D = N_D w u \tag{4.4}$$

where u is a mean thermal velocity. On the other hand, $1/T_F$ is expressed by $N_F \sigma_F u$, where N_F is the density of F centers per cc and σ_F the effective cross section of F center for electron trapping, the value of which can be estimated to be an order of 10^{-14} cm^2 [14]. The ratio of T_F to T_D, which can be obtained with the use of the equation (4.3), maintains at a constant value at low temperature, as shown in Fig. 14, where a release from the traps can be considered negligible. If one inserts equation (4.4) to equation (4.3), one finds

$$\frac{N_D w}{N_F \sigma_F} = \frac{T_F}{T_D} = \frac{I_0}{I} - 1\,, \tag{4.5}$$

from which one can compute $N_D w$. The computed values are summarized in the fourth and fifth column of Table I. Using the values of dislocation densities listed in the sixth column, the trapping widths w are calculated as shown in the last column of Table I. The average value of the effective trapping width of dislocation lines is 9.3×10^{-8} cm, which is a rather reasonable value.

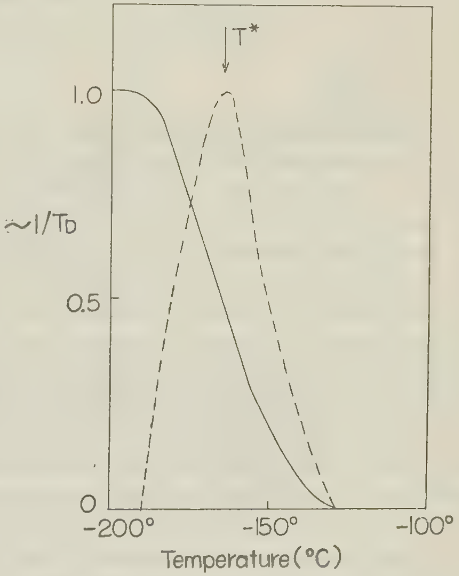

Fig. 14. Reciprocal of the mean life time T_D, which is normalized at the highest value, are plotted against temperature by solid line. Derivative curve of $1/T_D$ is shown by a dashed line.

If this trapping process was attributed only to jogs, $1/T_D$ should be equal to $N_J \sigma_J u$, where N_J is the jog density and σ_J a trapping cross section by jog. If we assume that all electrons which came from bleached F centers would go into jogs, total amount of N_J should be 10^{14} to 10^{15} per cc. By using these values, the order of magnitude of σ_J becomes to be 10^{-13} to 10^{-12} cm^2, which seems to be an unreasonably large. Comparing the observed values of cross sections, we can conclude that the model of dislocation traps is better suited than that of jog traps for explaining the characteristic decrease of photoconductances in deformed crystals.

We would like to advance tentatively the idea that the occurrence of current glow at 204°K, which is also characteristic for plastically deformed crystals, could be attributed to a thermal ionization process from jogs. Adopting this model, we can explain fairly well the occurrence of 204°K peak, though qualitatively. Once electrons trapped along a dislocation line after *F*-light irradiation at 73°K, they move perhaps along the dislocation line until they were trapped by still deeper traps such as jogs, which are located along the dislocation line. These trapped electrons in the jogs would contribute to the 204°K glow peak.

§ 5. Conclusion

By applying ac field on crystals for current measurements and by using single crystal having a high degree of purity, we have confirmed the evidence of trapping processes associated with dislocation lines in plastically deformed colored alkali halide crystals. From the comparison of photoconductances between deformed and undeformed crystals, we can estimate the trap depth of dislocation line to be 0.21 ev for the potassium bromide crystals and 0.24 ev for the potassium chloride crystals, respectively. We obtained also the effective mean trapping width of dislocation line to be 9.3×10^{-8} cm for the potassium bromide crystals, which value is more reasonable than the one obtained by the assumption that the trapping effects are caused by jogs.

Since a dislocation jog could be treated as a point defect having one half of the ionic charge, it could also act as a trap. But, since the net density of jogs is rather small, the trapping due to jogs would not play a role in photoconductive measurements. On the contrary, "current glow" measurement is quite sensitive. "Current glow" measurements gave the thermal depth of jogs to be 0.48 ev.

This evidence of dislocation traps could also throw light on the interpretation of the temperature dependence of photoconductance in undeformed colored crystal at low temperature. Untill now, the decrease of photoconductance in undeformed crystal has been interpreted only in terms of decreasing of the optical quantum efficiency with the decreasing temperature and did not take into account the temperature dependence of mobility[14]. The expected value of photoconductance, which is proportional to the product of the quantum efficiency and the mobilily, is rather flat as the result of the increasing tendency of mobility with the decreasing temperature. Hence, in order to explain the actually observed temperature dependence of photoconductances, it is necessary to either introduce another different mechanism or to add another trapping mechanism besides *F* centers. It seems likely that the trapping role of dislocation lines could contribute to the solution of the problem.

Acknowledgement

The author is indebted to Professor H. Kawamura for his suggestion of this problem and his guidance throughout the course of this study. He also wishes to thank Dr. E. Otsuka and Mr. M. Onuki for many fruitful discussions and suggestions, and Mr. T. Isoi, Mr. Y. Okubo, and Miss S. Miyamoto for technical assistance.

He would express his sincere thanks to Professors T. Nagamiya and J. Itoh, Osaka University, and Professors F. Seitz and R. Maurer, University of Illinois, for their deep interest shown in his work and for their many valuable discussions.

Interaction of Electrons and Holes with Acoustic Waves in Intrinsic Semiconductors

By Nobuo MIKOSHIBA

Electrotechnical Laboratory, Nagatacho, Tokyo

(Received December 14, 1960)

A self-consistent semiclassical theory is given for explaining the characteristics of the interaction of electrons and holes with acoustic waves in intrinsic semiconductors. The ultrasonic absorption coefficient can be written as $A=A_R+A_K$, where A_R is due to the change of the deformation potential energies of electrons and holes caused by their recombination, A_K due to the change of the kinetic energy caused by the intraband transition. The formula of A_R is identical with that used by Southgate in the analysis of his experiments, if the frequency at which $\omega\tau=1$ satisfies the inequality $(ql)^2<3(\tau_0/\tau)$, where ω, q are the angular frequency and the wave number of acoustic waves, and l, τ_0, τ are the mean free path, the intraband relaxation time, the lifetime of electrons or holes respectively. Under such condition as the frequency $\omega=1/\tau$ satisfies $(ql)^2>3(\tau_0/\tau)$, no absorption peak can be expected contrary to the simple phenomenological treatment; A_R becomes smaller than the value of Southgate's formula and is obscured by A_K. As a whole, the characteristics of the interaction is very similar with those in many-valley semiconductors. The acousto-electromotive force is too small to be detectable in experiments.

§1. Introduction

Recently Southgate[1),2)] has proposed a mechanism of the utlrasonic absorption due to the electron-hole recombination for the interpretation of his experiments on Ge[3)] and Si[4)] in the intrinsic region. He has analyzed successfully the experiments by the formula[2)] derived from the theory of Weinreich.[5)] There remain some questions, however, about the applicability of the formula, because Weinreich's theory ignores the so-called collision-drag effect[6),7)] and it may be applicable only to the sufficiently low frequency range.

The object of this paper is to give a more detailed theory taking the collision-drag effect into account and to check the applicability condition of the formula used by Southgate. The method used in this paper is the self-consistent semiclassical approach which has been already applied to simple[8] and many-valley[9] semiconductors in the previous papers (hereafter called I and II, respectively). The merits of the method may be that it involves properly the collision-drag effect and can be applied to all frequency ranges.

We shall take a simple model in which the conduction and valence bands have both the single spherical energy surfaces. We consider the interaction of electrons and holes with longitudinal acoustic waves in the intrinsic region. In semiconductors such as Ge and Si with complex energy surfaces, the similar interaction may be expected in the case of transverse waves. In § 2, we shall set up basic equations for the internal electric field E, the internal current densities, J_n and J_p, and the local fluctuations of the number densities, n and p, where n and p refer to electrons and holes, respectively. In § 3, we shall calculate the ultrasonic absorption due to the electron-hole recombination in various frequency ranges. The absorption due to the intraband transition are calculated in § 4. In § 5, the acousto-electric effect is discussed to check whether it is detectable in experiments. In § 6, we shall compare the absorption due the recombination with that due to the intraband transition in various frequency ranges, and discuss the absorption peak expected in intrinsic and many-valley semiconductors.

§ 2. Basic Equations

We make the following approximations throughout this paper.

(a) The effect of the charge of moving impurities on the internal electric field is neglected. The effect of impurities is taken into account implicitly only in the lifetime of electrons or holes.

(b) The velocity dependences of the lifetime τ and the intraband relaxation times, τ_n and τ_p, are neglected. This approximation does not alter all the results except a numerical factor in the high frequency range.

(c) We classify the loss mechanism of the acoustic energy into two parts. One is due to the change of the deformation potential energies of electrons and holes caused by their recombination. When n or p deviates from the local equilibrium fluctuation, n_{eq} or p_{eq}, n or p relaxes to n_{eq} or p_{eq} in the lifetime, being accompanied with the energy transfer from acoustic to lattice systems. The other is due to the change of the kinetic energy caused by the intraband transition. When the distribution fuction f of electrons or holes deviates from the local equilibrium distribution f_0, f relaxes to f_0 in the intraband relaxation time, being accompanied with the kinetic energy transfer. These situations are very similar with those in many-valley semiconductors.[9]

(d) It is assumed that the recombination has no influence on the local space charge. Then, the difference of n_{eq} and p_{eq} can be put equal to $(n-p)$.

It is necessary, for the determinations of E, n, p, J_n and J_p, to solve Maxwell's equation, the equation of continuity and the Boltzmann equation. Maxwell's equation is written as

$$\frac{\partial}{\partial t}\left(\boldsymbol{J}_n+\boldsymbol{J}_p+\frac{\varepsilon}{4\pi}\cdot\frac{\partial \boldsymbol{E}}{\partial t}\right)=-\frac{c^2}{4\pi}\mathrm{curl}\cdot\mathrm{curl}\,\boldsymbol{E}\,, \tag{2.1}$$

where ε is the dielectric constant, c is the light velocity. Since the local velocity of the lattice varies as $u\propto\exp[i(\omega t-qz)]$, we get

$$E=\frac{4\pi i}{\omega\varepsilon}(J_n+J_p) \tag{2.2}$$

for longitudinal waves.

The equations of continuity for electrons and holes are given by

$$\left.\begin{aligned}&\frac{\partial}{\partial t}(ne)+\frac{\partial J_n}{\partial z}+\frac{e}{\tau}(n-n_{eq})=0\,,\\&\frac{\partial}{\partial t}(-pe)+\frac{\partial J_p}{\partial z}+\frac{(-e)}{\tau}(p-p_{eq})=0\,,\end{aligned}\right\} \tag{2.3}$$

respectively, where e is the charge of an electron. The local equilibrium fluctuations associated with the recombination, n_{eq} and p_{eq}, are determined as follows. The well-known relation[10)]

$$N^2=\text{const.}\ T^3\exp(-E_g/kT) \tag{2.4}$$

holds in thermal equilibrium in the absence of acoustic waves, where N is the number density of electrons (holes), E_g the energy gap between the conduction and valence bands. When acoustic waves are being propagated, the energy gap changes into E_g-Cu/V, where V is the sound velocity, $C\equiv C_n+C_p$ is the sum of the deformation potential constants for electrons and holes. Then, from (2.4) we get

$$(N+n_{eq})\cdot(N+p_{eq})=N^2\exp(Cu/VkT)\,. \tag{2.5}$$

Making use of (2.5) and the approximation (d),

$$n_{eq}-p_{eq}=n-p\ , \tag{2.6}$$

we obtain

$$\left.\begin{aligned} n_{eq}&=\frac{1}{2}(n-p)+NCu/2VkT\ ,\\ p_{eq}&=\frac{1}{2}(p-n)+NCu/2VkT \end{aligned}\right\} \tag{2.7}$$

in the case of $Cu/V\ll kT$. Then, we get from (2.3) and (2.7)

$$\left.\begin{aligned} n&=\frac{q}{2\omega e}(J_n+J_p)+\frac{1}{1+i\omega\tau}\left\{\frac{iq\tau}{2e}(J_n-J_p)+\frac{NCu}{2VkT}\right\},\\ p&=\frac{q}{2\omega(-e)}(J_n+J_p)+\frac{1}{1+i\omega\tau}\left\{\frac{iq\tau}{2e}(J_n-J_p)+\frac{NCu}{2VkT}\right\}. \end{aligned}\right\} \tag{2.8}$$

To set up the Boltzmann equation, we should take two facts into account; (1) the collision-drag effect and (2) the force, exerted on electrons or holes, due to the deformation potential, together with the internal electric field E. Thus, the Boltzmann equation for electrons can be written as

$$\frac{\partial f_n}{\partial t}+(\boldsymbol{v}\cdot\boldsymbol{\nabla}_r)f_n+\frac{e}{m_n}(\boldsymbol{E}_n'\cdot\boldsymbol{\nabla}_v)f_n=-\frac{f_n-f_{n0}(|\boldsymbol{v}-\boldsymbol{u}|)}{\tau_n}\ , \tag{2.9}$$

where m_n is the effective mass and

$$E_n'\equiv E-iC_nq^2u/\omega e\ . \tag{2.10}$$

The distribution function can be solved as

$$\left.\begin{aligned} f_n&=f_{n0}(|\boldsymbol{v}-\boldsymbol{u}|)-\Psi_n(\boldsymbol{v})\cdot\partial f_{n0}/\partial v\ ,\\ f_{n0}(\boldsymbol{v})&\equiv\exp\left[\frac{1}{2}m_n(v_{n1}^2-v^2)/kT\right],\\ v_{n1}^2&\equiv\left(\frac{2kT}{m_n}\right)\ln\left\{2^{1/2}\pi^{3/2}\left(\frac{\hbar^2}{m_nkT}\right)^{3/2}(N+n)\right\}, \end{aligned}\right\} \tag{2.11}$$

where

$$\Psi_n(\boldsymbol{v})\equiv\frac{a_nA_n}{ql_n}\cdot\frac{x}{1-ia_nx}+\frac{a_nB_n}{ql_n}\cdot\frac{v_{n0}}{v}\cdot\frac{1}{1-ia_nx}-ux-B_n\frac{v_{n0}}{v} \tag{2.12}$$

for longitudinal waves and we put for brevity as

$$\left.\begin{aligned} &v_{n0}^2 \equiv 3kT/m_n\,, \qquad l_n \equiv \tau_n v\,, \\ &a_n \equiv ql_n/(1+i\omega\tau_n)\,, \qquad x \equiv \cos\theta\,, \end{aligned}\right\} \tag{2.13}$$

and

$$\left.\begin{aligned} &A_n \equiv \frac{eE\tau_n}{m_n} - i\frac{C_n\tau_n q^2 u}{m_n\omega} + u\,, \\ &B_n \equiv nv_{n0}/3N\,. \end{aligned}\right\} \tag{2.14}$$

Then, the local current density,

$$\boldsymbol{J} = \frac{2em^3}{h^3}\int_0^\infty \boldsymbol{v}f(v)d^3\boldsymbol{v}\,,$$

is calculated as

$$J_n = \frac{3NeP_{n0}}{ql_{n0}}\left(\frac{A_n}{a_{n0}} + iB_n\right), \tag{2.15}$$

where

$$l_{n0} \equiv \tau_n v_{n0}\,, \qquad a_{n0} \equiv ql_{n0}/(1+i\omega\tau_n) \tag{2.16}$$

and the modified Pippard's function,[8),9)]

$$\left.\begin{aligned} P_{n0} &\simeq \frac{1}{3}(ql_{n0})^2 - \frac{1}{3}(ql_{n0})^4 \qquad (ql_{n0} \ll 1)\,, \\ &\simeq 1-(3\pi/2)^{1/2}(ql_{n0})^{-1} \qquad (ql_{n0} \gg 1) \end{aligned}\right\} \tag{2.17}$$

is used. The equations, (2.9)-(2.17), are identical in form with those in the paper II. By replacing (n, e) with $(p, -e)$, we can obtain the quantities for holes as

$$J_p = -\frac{3NeP_{p0}}{ql_{p0}}\left(\frac{A_p}{a_{p0}} + iB_p\right). \tag{2.18}$$

The self-consistent solutions for E, n, p, J_n and J_p can be obtained from (2.2), (2.8), (2.15) and (2.18). Here we give the results for J_n and J_p:

$$\left.\begin{aligned} &J_n + J_p = Neu\cdot X/Z\,, \\ &J_n - J_p = Neu\cdot Y/Z\,, \end{aligned}\right\} \tag{2.19}$$

where

$$\begin{aligned} X \equiv {} & \frac{iC}{2kT\omega\tau}(P_{n0}\beta_n - P_{p0}\beta_p) - \frac{3P_{n0}}{ql_{n0}a_{n0}}\left(i\frac{C_n}{3kT}\cdot\frac{(ql_{n0})^2}{\omega\tau_n} - 1\right)(1+P_{p0}\beta_p) \\ & + \frac{3P_{p0}}{ql_{p0}a_{p0}}\left(i\frac{C_p}{3kT}\cdot\frac{(ql_{p0})^2}{\omega\tau_p} - 1\right)(1+P_{n0}\beta_n)\,, \end{aligned} \tag{2.20}$$

$$\begin{aligned} Y \equiv {} & \left\{i\frac{CP_{n0}\beta_n}{2kT\omega\tau} - i\frac{P_{n0}}{a_{n0}}\cdot\frac{C_n}{kT}\cdot\frac{ql_{n0}}{\omega\tau_n} + \frac{3P_{n0}}{ql_{n0}a_{n0}}\right\}\left\{1 - i\frac{6P_{p0}}{ql_{p0}a_{p0}}\cdot\frac{(\omega_p\tau_p)^2}{\omega\tau_p} - i\frac{P_{p0}}{\omega\tau_p}\right\} \\ & + \left\{i\frac{CP_{p0}\beta_p}{2kT\omega\tau} - i\frac{P_{p0}}{a_{p0}}\cdot\frac{C_p}{kT}\cdot\frac{ql_{p0}}{\omega\tau_p} + \frac{3P_{p0}}{ql_{p0}a_{p0}}\right\} \\ & \qquad \times\left\{1 - i\frac{6P_{n0}}{ql_{n0}a_{n0}}\cdot\frac{(\omega_n\tau_n)^2}{\omega\tau_n} - i\frac{P_{n0}}{\omega\tau_n}\right\}, \end{aligned} \tag{2.21}$$

$$\begin{aligned} Z \equiv {} & 1 - i\left(\frac{3P_{n0}}{ql_{n0}a_{n0}}\cdot\frac{(\omega_n\tau_n)^2}{\omega\tau_n} + \frac{P_{n0}}{2\omega\tau_n}\right)(1+P_{p0}\beta_p) \\ & - i\left(\frac{3P_{p0}}{ql_{p0}a_{p0}}\cdot\frac{(\omega_p\tau_p)^2}{\omega\tau_p} + \frac{P_{p0}}{2\omega\tau_p}\right)(1+P_{n0}\beta_n) + \frac{1}{2}(P_{n0}\beta_n + P_{p0}\beta_p)\,, \end{aligned} \tag{2.22}$$

$$\left.\begin{aligned} &\omega_n^2 \equiv 4\pi Ne^2/m_n\mathcal{E}\ , &&\omega_p^2 \equiv 4\pi Ne^2/m_p\mathcal{E}\ ,\\ &\beta_n \equiv (\tau/\tau_n)/(1+i\omega\tau)\ , &&\beta_p \equiv (\tau/\tau_p)/(1+i\omega\tau)\ . \end{aligned}\right\} \tag{2.23}$$

The appropriate approximations of (2.19) to various frequency ranges will be given in the following sections.

§ 3. Ultrasonic Absorption due to Recombination

According to the assumption (c) in § 2, the ultrasonic absorption coefficient $\varLambda$ is written as

$$\varLambda = \varLambda_R + \varLambda_K\ , \tag{3.1}$$

where $\varLambda_R$ is the component due to the recombination and $\varLambda_K$ is due to the intraband transitions. We shall calculate $\varLambda_R$ in this section. When the local fluctuation, n or p, deviates from n_{eq} or p_{eq}, the deformation potential energy, $-Cqu/\omega$, is transferred from acoustic to lattice systems in the lifetime τ owing to one recombination. Thus, the energy W_R absorbed per unit volume and unit time becomes

$$\left.\begin{aligned} &W_R = W_R^n + W_R^p\ ,\\ &W_R^n = \frac{1}{2}\,\mathrm{Re}\left[\left(-\frac{Cqu/\omega}{2\tau}\right)^*(n-n_{eq})\right],\\ &W_R^p = \frac{1}{2}\,\mathrm{Re}\left[\left(-\frac{Cqu/\omega}{2\tau}\right)^*(p-p_{eq})\right]. \end{aligned}\right\} \tag{3.2}$$

Then, from the definition of the absorption coefficient we get

$$\varLambda_R \equiv 2W_R/\rho|u|^2V = \frac{NC}{2\rho V^3\tau}\,\mathrm{Re}\left[\frac{i\omega\tau}{1+i\omega\tau}\left(\frac{C}{kT}-\frac{J_n-J_p}{Neu}\right)\right], \tag{3.3}$$

where ρ is the mass density of materials. In (3.2) we should remark two points; (1) the reason why there is no term involving the energy gap is that it vanishes taking the time or space average and (2) the factor 2 in the denominator in the bracket is due to the fact that one recombination gives rise to a decrease of $(n+p)$ by 2.

First, we shall consider $\varLambda_R$ in the low frequency range where $ql_{n0} \sim ql_{p0} \ll 1$. It is convenient to consider separately three cases;

(A): $$0 \ll (ql_{n0})^2 \ll \frac{3kT}{|C|}\cdot\frac{\tau_n}{\tau}\ ,$$

(B): $$\frac{3kT}{|C|}\cdot\frac{\tau_n}{\tau} \ll (ql_{n0})^2 \ll \frac{3\tau_n}{\tau}\ ,$$

(C): $$\frac{3\tau_n}{\tau} \ll (ql_{n0})^2 \ll 1\ ,$$

where

$$6\omega_n^2/q^2 \gg v_{n0}^2\ , \qquad \omega\tau_n \ll 1$$

are common to all cases. Although we specify three cases by the quantities of electrons, this classification holds approximately for the same quantities of holes. The approximate expressions of (J_n-J_p) and $\varLambda_R$ are calculated as follows.

(A):

$$J_n - J_p \cong 2Neu\ , \tag{3.4}$$

$$\varLambda_R \cong \frac{NC^2}{2\rho V^3kT}\cdot\frac{\omega^2\tau}{1+(\omega\tau)^2}\ . \tag{3.5}$$

(B):

$$J_n - J_p \simeq 2Neu \cdot \frac{Cq}{V} \cdot \frac{\tau_n \tau_p}{m_p \tau_n + m_n \tau_p} \cdot \frac{\omega\tau}{1+i\omega\tau}\,, \tag{3.6}$$

$$\Lambda_R \cong \frac{NC^2}{2\rho V^3 kT} \cdot \frac{\omega^2\tau}{1+(\omega\tau)^2} \left\{ 1 - \frac{4}{(3\tau_n/\tau)/(ql_{n0})^2 + (3\tau_p/\tau)/(ql_{p0})^2} \cdot \frac{1}{1+(\omega\tau)^2} \right\}. \tag{3.7}$$

(C):

$$\begin{aligned} J_n - J_p \cong Neu \cdot \frac{C}{kT} \Bigg\{ 1 &- \frac{1}{2} \left(\frac{3\tau_n/\tau}{(ql_{n0})^2} + \frac{3\tau_p/\tau}{(ql_{p0})^2} \right)(1+i\omega\tau) \\ &+ \frac{1}{4} \left(\frac{3\tau_n/\tau}{(ql_{n0})^2} + \frac{3\tau_p/\tau}{(ql_{p0})^2} \right)^2 (1+i\omega\tau)^2 \Bigg\}\,, \end{aligned} \tag{3.8}$$

$$\Lambda_R \cong \frac{NC^2\omega^2\tau}{2\rho V^3 kT} \cdot \frac{1}{4} \left(\frac{3\tau_n/\tau}{(ql_{n0})^2} + \frac{3\tau_p/\tau}{(ql_{p0})^2} \right)^2 . \tag{3.9}$$

Next, we shall calculate Λ_R in the sufficiently high frequency range such as

(D): $ql_{n0} \gg 1\,, \quad 6\omega_n{}^2/q^2 \ll v_{n0}^2\,, \quad \omega\tau \gtrsim 1\,, \quad \omega\tau_n \lesssim 1\,,$

where electrons and holes may interact independently with acoustic phonon beams. In fact, we get

$$\left. \begin{aligned} J_n &\cong \frac{Neu}{kT} \cdot C_n (1+i\omega\tau_n) \left(1 + \frac{i\omega\tau_n}{P_{n0}} \right)^{-1}, \\ J_p &\cong \frac{N(-e)u}{kT} \cdot C_p (1+i\omega\tau_p) \left(1 + \frac{i\omega\tau_p}{P_{p0}} \right)^{-1} \end{aligned} \right\} \tag{3.10}$$

and

$$\Lambda_R \cong \left(\frac{3\pi}{2} \right)^{1/2} \frac{NC\omega}{2\rho V^2 kT\tau} \left(C_n \frac{\tau_n}{v_{n0}} + C_p \frac{\tau_p}{v_{p0}} \right), \tag{3.11}$$

which is very small compared with Λ_K in (4.8). We shall discuss the obtained results in § 6.

§ 4. Ultrasonic Absorption due to Intraband Transition

As has been shown in the papers I and II, the ultrasonic absorption coefficient Λ_K due to the change of the kinetic energy caused by the intraband transition is given by

$$\Lambda_K = \Lambda_K{}^n + \Lambda_K{}^p\,, \tag{4.1a}$$

$$\Lambda_K{}^n = -\frac{2m_n{}^4}{\rho |u|^2 V \tau_n h^3} \int_0^\infty \frac{\partial f_{n0}}{\partial v} v^3 \, dv \int_{-1}^{1} dx \int_0^{2\pi} d\phi \, |\Psi_n(v)|^2 \tag{4.1b}$$

and the similar formula for $\Lambda_K{}^p$. The approximate expressions for $(J_n + J_p)$ and the calculated formulae for $\Lambda_K{}^n$ and $\Lambda_K{}^p$ are tabulated as follows.

(A):

$$J_n + J_p \cong \frac{\varepsilon q^2 u}{8\pi e} (C_n - C_p) \frac{1-\Delta}{1+\delta/2}\,, \tag{4.2a}$$

where

$$\delta \equiv \frac{m_n}{m_p} \cdot \frac{\tau_p}{\tau_n} - 1\,, \qquad \Delta \equiv \delta \cdot \frac{C/2(1+i\omega\tau) - C_p}{C_p - C_n}\,, \tag{4.2b}$$

$$\Lambda_K{}^n \cong \frac{NC^2\omega^2\tau_n}{4\rho V^3 kT} \cdot \frac{1}{1+(\omega\tau)^2} \left\{ 1 + \frac{1}{3} q^2 v_{n0}^2 \tau^2 \left(2 \cdot \frac{m_n/\tau_n}{m_n/\tau_n + m_p/\tau_p} \right)^2 \right\} \tag{4.3}$$

and the similar formula of $\Lambda_K{}^p$ obtained by replacing the subscript n with p.

(B):

$$J_n+J_p \cong \frac{\mathcal{E}q^2u}{8\pi e}(C_n-C_p)\left\{\frac{1-\Delta}{1+\delta/2}+\frac{(\Delta+\delta/2)(1+\delta)}{(1+\delta/2)^2}\cdot\frac{\tau_n}{m_n}\cdot\frac{q^2kT\tau}{1+i\omega\tau}\right\}, \tag{4.4}$$

$$\Lambda_K{}^n \cong \frac{NC^2\omega^2\tau_n}{4\rho V^3kT}\cdot\frac{1}{1+(\omega\tau)^2}\left[1+\frac{1}{3}q^2v_{n0}^2\tau^2\left(2\cdot\frac{m_n/\tau_n}{m_n/\tau_n+m_p/\tau_p}\right)^2\right.$$
$$\left.\times\left\{1-\frac{4}{(3\tau_n/\tau)/(ql_{n0})^2+(3\tau_p/\tau)/(ql_{p0})^2}\cdot\frac{1}{1+(\omega\tau)^2}\right\}\right] \tag{4.5}$$

and the similar formula of $\Lambda_K{}^p$.

(C):

$$J_n+J_p \cong \frac{\mathcal{E}q^2u}{8\pi e}(C_n-C_p)\left(1-\frac{\Delta+\delta/2}{1+\delta}\cdot\frac{m_n}{\tau_n}\cdot\frac{1+i\omega\tau}{q^2kT\tau}\right), \tag{4.6}$$

$$\Lambda_K{}^n \cong \frac{NC^2\omega^2}{4\rho V^3kT}\cdot\frac{3\tau_n}{(ql_{n0})^2} \tag{4.7}$$

and the similar formula of $\Lambda_K{}^p$.

(D): $$\Lambda_K{}^n \cong \left(\frac{3\pi}{2}\right)^{1/2}\frac{NC_n{}^2\omega}{\rho V^2kTv_{n0}} \tag{4.8}$$

and the similar formula of $\Lambda_K{}^p$.

The comparison of these formulae with those due to the recombination will be discussed in § 6.

§ 5. Acoustoelectric Effect

The acousto-electromotive force F can be defined as the average *dc* force exerted by acoustic waves on an electron or a hole.[11] As in many-valley semiconductors[9] effective forces responsible for the acoustoelectric effect have two components, one associated with the recombination of electrons and holes and the other associated with the intraband transition. Weinreich's relation[12] between the ultrasonic absorption coefficient and the acousto-electromotive force must hold separately for electrons and holes. Thus, we can write as

$$F=F_R{}^n+F_R{}^p+F_K{}^n+F_K{}^p, \tag{5.1}$$

$$\left.\begin{aligned} F_R{}^n&=\Lambda_R{}^n\gamma/NeV, & F_R{}^p&=\Lambda_R{}^p\gamma/N(-e)V,\\ F_K{}^n&=\Lambda_K{}^n\gamma/NeV, & F_K{}^p&=\Lambda_K{}^p\gamma/N(-e)V, \end{aligned}\right\} \tag{5.2}$$

where $\gamma\equiv\rho|u|^2V/2$ is the acoustic energy flow density. From (2.7), (2.8), (3.2) and (3.3) we get $\Lambda_R{}^n=\Lambda_R{}^p$. Then,

$$F_R\equiv F_R{}^n+F_R{}^p=0, \tag{5.3}$$

i.e., the effect due to electrons associated with the recombination is just cancelled by the effect due to holes.

Using the formulae of Λ_K in § 4, we tabulate the formulae of F in various frequency ranges as follows.

(A) and (B):

$$F \cong \frac{C^2\omega^2}{4\rho eV^4kT}\cdot\frac{\gamma}{1+(\omega\tau)^2}\left\{(\tau_n-\tau_p)+\frac{1}{3}\left(2\cdot\frac{m_n/\tau_n}{m_n/\tau_n+m_p/\tau_p}\right)^2q^2\tau^2(v_{p0}^2\tau_n-v_{p0}^2\tau_p)\right\}. \tag{5.4}$$

(C): $$F \cong \frac{C^2\omega^2\gamma}{4\rho eV^4kT}\left[\frac{3\tau_n}{(ql_{n0})^2}-\frac{3\tau_p}{(ql_{p0})^2}\right]. \tag{5.5}$$

(D):
$$F \cong \left(\frac{3\pi}{2}\right)^{1/2} \frac{\omega\gamma}{\rho e V^3 kT}\left(\frac{C_n^2}{v_{n0}} - \frac{C_p^2}{v_{p0}}\right). \tag{5.6}$$

It will be discussed in the next section whether the effect is detectable in experiments.

§ 6. Discussions

(1) *Absorption Coefficient*

From the simple phenomenological treatment of the recombination of electrons and holes given in Appendix I, we can expect in general the absorption peak in the Λ-T diagram at the temperature of $\omega\tau(T)=1$, if $\tau(T)$ is the monotonously decreasing or increasing function of T. As has been shown in § 3, however, this is not the case if the frequency at which $\omega\tau=1$ does not satisfy the inequality

$$(ql_{n0})^2 < 3(\tau_n/\tau)\ , \qquad (\omega\tau=1). \tag{6.1}$$

In the sufficiently low frequency range such as (A), the absorption coefficient Λ_R in (3.5) is identical with the formula used by Southgate[2] and is much larger than Λ_K in (4.3). In this range

$$\frac{\Lambda_R}{\Lambda_K} \cong \frac{\tau}{\frac{1}{2}(\tau_n+\tau_p)} \sim \frac{\tau}{\tau_n} \gg 1\ . \tag{6.2}$$

Even in the higher frequency range such as (B), Λ_K is yet smaller than Λ_R. From (3.7) and (4.5) we get

$$\frac{\Lambda_R}{\Lambda_K} \cong 1 \Bigg/ \left[\frac{1}{2}\left\{\frac{(ql_{n0})^2\tau}{3\tau_n}\left(2\cdot\frac{m_n/\tau_n}{m_n/\tau_n+m_p/\tau_p}\right)^2 + \frac{(ql_{p0})^2\tau}{3\tau_p}\left(2\cdot\frac{m_p/\tau_p}{m_n/\tau_n+m_p/\tau_p}\right)^2\right\}\right]$$
$$\sim 1 \Bigg/ \left[\frac{(ql_{n0})^2\tau}{3\tau_n}\right] \gg 1\ . \tag{6.3}$$

Thus, in good approximation Southgate's formula (3.5) can be used for the analysis of the experimental curve of Λ in the vicinity of the peak, if the frequency $\omega=1/\tau$ is in the range (A) or (B).

If the frequency $\omega=1/\tau$ is in the range (C), the situations are very different from those of (A) and (B). In this range, Λ_R becomes smaller than the value of Southgate's formula and is obscured by Λ_K. From (3.9) and (4.7) we obtain

$$\frac{\Lambda_R}{\Lambda_K} \cong \frac{1}{2}\left\{\frac{3\tau_n}{(ql_{n0})^2\tau} + \frac{3\tau_p}{(ql_{p0})^2\tau}\right\} \ll 1\ . \tag{6.4}$$

In the sufficiently high frequency range such as (D), we get from (3.11) and (4.8)

$$\frac{\Lambda_R}{\Lambda_K} \cong \frac{C}{2}\left(\frac{C_n}{v_{n0}}\cdot\frac{\tau_n}{\tau} + \frac{C_p}{v_{p0}}\cdot\frac{\tau_p}{\tau}\right) \Bigg/ \left(\frac{C_n^2}{v_{n0}} + \frac{C_p^2}{v_{p0}}\right) \sim \frac{\tau_n}{\tau} \ll 1\ . \tag{6.5}$$

Then, if $(ql_{n0})^2 > 3(\tau_n/\tau)$ is satisfied, the absorption due to the recombination can be neglected compared with that due to the intraband transition.

We take up, for example, the sample of Ge of Southgate in which the absorption peak by acoustic waves of 100 Kc/s was observed at $T \cong 690$°K. If we take the values of parameters as $\tau \sim 10^{-6}$ sec, $\tau_n \sim 10^{-12}$ sec, $V \sim 5\times10^5$ cm/sec, $m_n \sim 0.91\times10^{-28}$ g, we get

$$(ql_{n0})^2 \sim 5\times10^{-9} \quad \text{and} \quad 3(\tau_n/\tau) \sim 3\times10^{-6}\ .$$

Thus, the condition (6.1) is satisfied. Since the lifetime of electrons or holes is very much longer than the intraband relaxation time, the condition (6.1) will be satisfied in ordinary situations.

As will be shown in Appendix II, the characteristics of the absorption coefficient Λ_R and

Λ_K in various frequency ranges in intrinsic semiconductors are remarkably similar with that of Λ_p due to the intervalley transition and Λ_K due to the intravelley transition in many-valley semiconductors. The condition (6.1) and the equations (6.2)–(6.5) hold in form in many-valley semiconductors. If we tentatively take the values of parameters in n-Ge as τ (intervalley relaxation time)$\sim 10^{-10}$ sec, $\omega = 10^{10}$ sec^{-1}, τ_0 (intravalley relaxation time)$\sim 10^{-12}$ sec, $T = 100$°K, we get

$$(ql_0)^2 \sim 2\times 10^{-1} \quad \text{and} \quad 3(\tau_0/\tau) \sim 3\times 10^{-2}\,.$$

Then, the condition (6.1) does not hold. Since the intervalley relaxation time is $\sim 10^{-10}$ sec or somewhat longer in n-Ge, it would be difficult to observe the peak[13] of the absorption or the acoustoelectric effect due to the intervalley transition in ordinary situations.

In Figs. 1 and 2 we give the schematic Λ-ω diagrams in intrinsic and many-valley semiconductors respectively, assuming tentatively that the condition (6.1) holds in intrinsic and does not hold in many-valley semiconductors.

(2) *Acoustoelectric Effect*

The acoustoelectric effect due to the intervalley transition by transverse waves in n-Ge has been observed by Weinreich, Sanders and White.[14] They have analyzed the experiment using the formula nearly identical with (A II 5). In intrinsic semiconductors, there is no acoustoelectric effect due to the recombination of electrons and holes. The

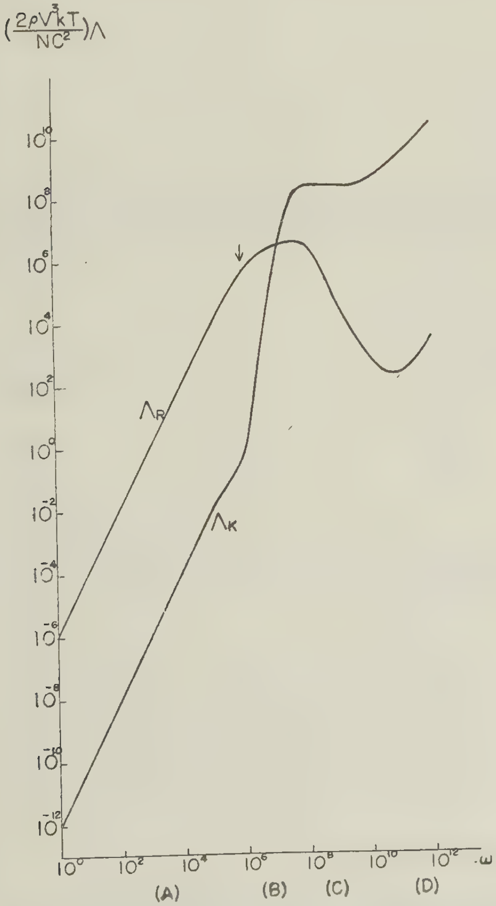

Fig. 1. The schematic Λ-ω diagram in intrinsic semiconductors, where we assume that $\tau_n = 10^{-12}$ sec, $\tau = 10^{-6}$ sec, $T = 690$°K, $m_n = 0.91\times 10^{-28}$ g and $V = 5\times 10^5$ cm/sec. The arrow shows the frequency used by Southgate[1)-4)].

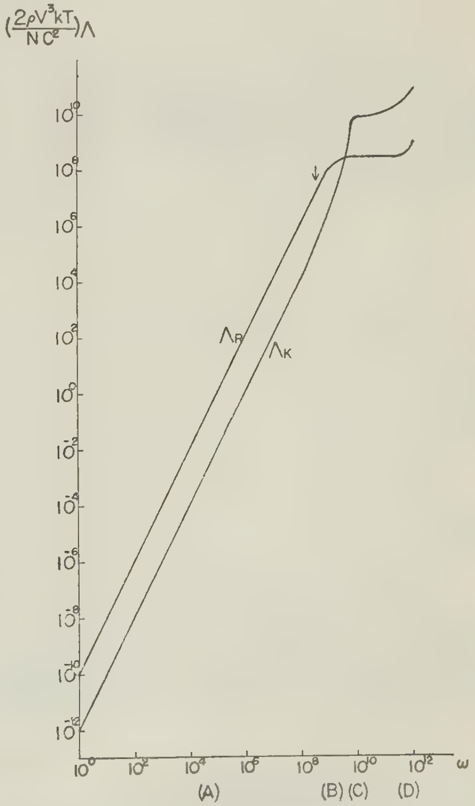

Fig. 2. The schematic Λ-ω diagram in many-valley semiconductors, where we assume that $\tau_0 = 10^{-12}$ sec, $\tau = 10^{-10}$ sec, and $T = 100$°K. The arrow shows the frequency used by Weinreich, Sanders and White[14].

non-vanishing effect is due to the intraband transitions. Comparing (5.4), (5.5), (5.6) with (A II 5) we have the conclusion that the effect in intrinsic semiconductors is too small to be detectable in experiments at present.

The author should express his thanks to S. Gonda for drawing of Figs. 1 and 2.

Appendix I

Simple Phenomenological Treatment

The present author has presented a simple phenomenological theory of the ultrasonic absorption due to electron transfer mechanism in the previous paper.[11] In solids the elastic stiffness constant can be written as

$$c=c_0-c_t\,, \tag{AI 1}$$

where c_0 is the component associated with the stress-induced changes of the electrostatic energy, the exchange energy between ion cores and so forth, c_t is the component associated with electron transfer mechanism. In the problem of acoustic waves we must take into account the relaxation of the energy associated with c_t and we put

$$c=c_0-c_t/(1+i\omega\tau)\,. \tag{AI 2}$$

Solving the equation of acoustic waves, we get

$$\Lambda=\frac{c_t}{\rho V^3}\cdot\frac{\omega^2\tau}{1+(\omega\tau)^2}\,, \tag{AI 3}$$

which shows the peak at $\omega\tau=1$ in the Λ-T diagram.

The calculation of c_t in intrinsic semiconductors are carried out as follows. When there is the strain $\partial R/\partial z$ (R: displacement of the lattice) in the specimen, the bottom of the conduction band and the top of the valence band are raised by $C_n(\partial R/\partial z)$ and lowered by $C_p\cdot(\partial R/\partial z)$, respectively. Then, from (2.4) or (2.5) we obtain

$$\Delta\equiv n_{eq}=p_{eq}=-\frac{NC}{2kT}\cdot\frac{\partial R}{\partial z}\,. \tag{AI 4}$$

If we denote the potential energy of electrons and holes by U, we can write

$$c_t\equiv(U_{\omega\tau\to\infty}-U_{\omega\tau\to 0})/(\partial R/\partial z)^2\,. \tag{AI 5}$$

Since

$$\left.\begin{aligned}U_{\omega\tau\to\infty}&=NC\cdot(\partial R/\partial z)\,,\\ U_{\omega\tau\to 0}&=(N+\Delta)\cdot C\cdot(\partial R/\partial z)\,,\end{aligned}\right\} \tag{AI 6}$$

we get

$$c_t=\frac{NC^2}{2kT}\,. \tag{AI 7}$$

Thus, from (AI 3) and (AI 7) we obtain (3.5). In this phenomenological treatment we ignore the absorption due to the intraband transition.

Appendix II

Many-Valley Semiconductors

In the previous paper II, we have derived the formulae of Λ_p due to the intervalley transition and Λ_K due to the intravalley transition in many-valley semiconductors. In the following, we shall make more careful consideration of the frequency ranges and show the complete correspondence between Λ_p and Λ_R in § 3. Using the basic equations in the paper II, we obtain the following results, which hold for both longitudinal and transverse waves.

(A) and (B):

$$\Lambda_p \cong \frac{NC^2}{2\rho V^3 kT}\cdot\frac{\omega^2\tau}{1+(\omega\tau)^2}\left\{1-\frac{2}{3}(ql_0)^2\frac{\tau}{\tau_0}\cdot\frac{1}{1+(\omega\tau)^2}\right\}, \tag{AII 1}$$

$$\Lambda_K \cong \frac{NC^2}{2\rho V^3 kT}\cdot\frac{\omega^2\tau_0}{1+(\omega\tau)^2}\left\{1+\frac{1}{3}q^2 v_0^2\tau^2\left(1-\frac{2(ql_0)^2\tau}{3\tau_0}\cdot\frac{1}{1+(\omega\tau)^2}\right)\right\}, \tag{AII 2}$$

where $2N$ is the total electron number density, $C\equiv C^{(+)}-C^{(-)}$ is the difference of the deformation potential constants between (+) and (−) valleys; τ_0, l_0, v_0, τ are the intravalley relaxation time, the average mean free path, the average thermal velocity, the intervalley relaxation time, respectively.

(C):

$$\Lambda_p \cong \frac{NC^2\omega^2\tau}{2\rho V^3 kT}\left(\frac{3\tau_0/\tau}{(ql_0)^2}\right)^2, \tag{AII 3}$$

$$\Lambda_K \cong \frac{NC^2\omega^2}{2\rho V^3 kT}\cdot\frac{3\tau_0}{(ql_0)^2}. \tag{AII 4}$$

In all cases including (D) we can see the complete correspondence of Λ between many-valley and intrinsic semiconductors, if we replace as

$C\equiv C_n+C_p\rightarrow C\equiv C^{(+)}-C^{(-)}$,

τ (lifetime)→τ (intervalley relaxation time),

$m_n,\ m_p\rightarrow m,\qquad \tau_n,\ \tau_p\rightarrow\tau_0,\qquad v_{n0},\ v_{p0}\rightarrow v_0,\qquad l_{n0},\ l_{p0}\rightarrow l_0$

in the formulae of intrinsic semiconductors. In many-valley semiconductors, however, there is the acoustoelectric effect due to the intervalley transition. Using Weinreich's relation we obtain

$$F=F_p+F_K\cong\frac{C^2\gamma}{4\rho e V^4 kT}\cdot\frac{\omega^2\tau}{1+(\omega\tau)^2}\left\{1-\frac{1}{3}(ql_0)^2\frac{\tau}{\tau_0}\cdot\frac{1-(\omega\tau)^2}{1+(\omega\tau)^2}\right\} \tag{AII 5}$$

in (A) and (B).

Growth and Dissolution Prosseses of GASH Crystal

By Terutaro NAKAMURA, Kikuo OHI and Hiroko KUBOTA*

Department of Physics, Ochanomizu University, Otsuka, Tokyo

(Received December 28, 1960)

Growing process of GASH crystal was observed. If a droplet of saturated GASH solution on a slide glass is heated from upper side, platelets obtained afloat on the drop show six-rayed-star-shaped terraces. The mechanism of terrace formation is ascribed to bunching of progressing atomic steps. On the other hand, if heated from lower side, some platelets obtained at the bottom of the droplet are large and thick, which show dislocation etch pits on etching, while some remain small and thin showing no pits on etching. It appears that the growing process is not diffusion-controlled but follows the screw dislocation mechanism.

Dissolution process of GASH crystal was observed. Dissolution takes place by progression of macroscopic steps, which are nucleated book at crystal edges and at dislocation emergence points. The kinetics is controlled by diffusion and macroscopic steps are understood as bunching of atomic steps.

§ 1. Introduction

At a very low supersaturation, crystal growth takes place by the spreading of individual layers of atomic scale across the advancing surface. Solute atoms from a surrounding mother solution are incorporated into the crystal lattice only at the peripheral steps of the uncompleted atomic layers. In completion of the layer, new layers and growth steps are required for continued advance of the surface.

It was recongnized by Gibbs that new layers on a perfect surface are formed by two-dimensional nucleation. It was shown theoretically that two-dimensional nucleation proceeds at substantial supersaturation. Experimental observations, however, indicated that crystals grow at much smaller supersaturation than the theoretical value. In 1949, Frank¹⁾ pointed out that interesection of a screw dislocation on a crystal surface provides a perpetual source of growth steps at very low supersaturations. A detailed analysis of crystal growth from vapor phase was made by Burton, Cabrera and Frank²⁾ on this model. Their analyses were based on the assumption of local equilibrium between the crystal and vapor phase at the growth step. This is equivalent with the assumption that the process of crystal growth is never controlled by the diffusion.

Recently, however, diffusion-controlled growth of crystals draws attention, related with growth of dendrites, growth of crystal whiskers, or anomalous growth of crystals caused by extremely small amount of impurity. In the diffusion-controlled growth, supersaturation is generally high, and advancing faces are not perfect but "non-singular",** in other words, of higher index. Solute atoms can attach to every point of the surface which is everywhere terraced.

The advance of curved surface can be described as progression of individual steps of atomic scale. In progression of many steps of atomic scale on the advancing surface of crystals, the velocity of an individual step is not usually constant, but depends on inclination of the surface in some cases, or on extremely small amount of adsorbed impurity atoms in other cases which hinder the motion of the steps and acts as a poison. The non-uniformity of the velocity of individual step causes overtaking of slower steps by faster ones, which is understood as a shock wave in the flood problem, and was treated by Frank⁵⁾ using the mathematics called kinematic wave theory due to Lighthill and Witham[6]. This shock wave is nominated as " bunching ", and there were some experiments which seemed to observe the bunching[7].

---

* Now at Hitachi Ltd., Musashi Works.

** It was shown by Herring³⁾ that the perfect or low-index surface of the crystal in the equilibrium state corresponds to pointed cusp of polar plot of surface free energy. This surface requires the screw dislocation mechanism for growth at low supersaturation, and Frank⁴⁾ suggested that this surface may be called "singular" face, while continuously curved surface may be called "non-singular".

The dissolution process, in which a crystal is exposed to very high undersaturation, overall kinetics are controlled by diffusion. In the process of etch pit formation, for the study of dislocations in crystals, kinetics are also limitted by diffusion.

The present paper describes the observations of growth and dissolution processes of guanidinium aluminum sulfate hexahydrate (usually abbreviated as GASH), which is known to be ferroelectric. Dislocations in GASH were observed by etching technique[8],[9],[10]. This substance crystallizes in a hexagonal plate, showing a perfect cleavage perpendicular to the (0001) axis, which is identical to the ferroelectric axis. Space group is $P31m$[11]. Etch pits are triangular, and " positively " pointed on the (0001) face, while " negatively " pointed on the $(000\bar{1})$ face.

In the present paper it is shown that the growth of GASH crystal from aqueous solution is, in one case, diffusion-controlled, and in the other case, not controlled by diffusion but dislocations really play parts. It is also shown that in the dissolution process, which is controlled by diffusion, bunching is remarkably observed, and dislocations provide dissolution centers.

§ 2. Growth Process

A droplet of aqueous solution was put on a slide glass and process of growth was observed under a microscope. Appearance of growing crystals depends sharply on the ways of heating, whether the drop is heated with an electric lamp from the upper side, or heated by lighting with a projector from the lower side.

If heated from the upper side, water vaporizes from the free surface of the drop, and the region near the free surface becomes more highly supersaturated, hence nucleation occurs on the surface, and small platelet having edges of about 0.1 mm grows and is afloat on the surface of the droplet. On the other hand, if heated from the lower side, nucleation occurs at the bottom of the droplet and small platelet of the similar size grows in the bottom part. This situation is probably resulted from the facts that, at room temperature solubility is little dependent on temperature and the region between supersolubility curve and solubility curve is rather wide. Energy provided by heating will promote nucleation.

Among crystal platelets obtained by heating from the upper side, a number of crystals exhibit six-rayed star patterns as shown in Photo. 1. This six-rayed star forms a macroscopic terrace, i.e. the part of the star is advanced from the remaining surface area by presumably several tenths of micron in the order of magnitude. Axes of rays form 60° to each other, and the vortex angle of ray α (Fig. 1) is different star by star. Length of the ray is also different star by star. The star is generally situated at the center of the plate. In an individual star, the lengths of the three rays directed in a-axes are almost equal, and those in b-axes are also almost equal, but an inclination is found that the a-axial ray is somewhat longer than the b-axial ray.

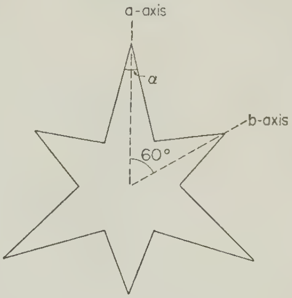

Fig. 1. Shape of six-rayed star, schematic.

Dislocation etch pits were observed on a crystal with the pattern of six-rayed star. No special relations were found between the sites of the dislocation etch pits and the site of six-rayed star.

Mechanism of the formation of six-rayed star will be explained as follows. A crystal floating on the surface of the droplet will be covered by a film of highly supersaturated solution. Transport of solute atoms from the solution into the crystal will be controlled by diffusion. The interface between the solution and the crystal, not singular but of high index, will be considered to be everywhere terraced in atomic scale. Crystal growth will take place by the progression of atomic steps, and bunching will be formed if step velocity is not everywhere constant. This view is supported by the fact that larger crystals which have grown afloat on the solution of the surface have a non-singular face with maroscopic terraces roughly parallel to the star-shaped terrace (Photo. 2). Note here that the remaining faces, which have been immersed in the solution during the growth process, however, are singular.

Crystal platelets obtained by heating from the lower side are clearly divided into two groups. Crystals belonging to the first group (shown as A in Photo. 3) remain thin and small, while those belonging to the second group (shown in the same photograph) show higher growth rate and grow up to thicker crystals. Crystals belonging to the second group which are smaller than A at the earlier stage (a) in the series of photographs become larger than A at the later stage (c). When crystals grow up to a certain size, water is added to the droplet and dislocation etch pits are observed (d). It is very remarkable that no etch pit was observed on the crystals belonging to the first group, while several pits were observed on the crystals of the second group.

It was generally found that the growth rate of crystals increases with increasing dislocation density.

These facts clearly show that in this case the supersaturation is low, the local equilibrium exists between the crystals and the liquid phase at the growth step, and steps accompanied by the screw dislocations are essential for the crystal growth.

§ 3. Dissolution Process

GASH crystal is easily soluble in water. When a drop of distilled water is dripped on the cleaved surface of the crystal under a microscope, it is clearly observed that dissolution takes place by nucleation and remarkable lateral motion of macroscopic steps.

These steps will be understood as the bunching of steps of atomic scale. Over-all kinetics are controlled by the diffusion. Nucleation sites of the macroscopic steps are crystal edges and emergence points of dislocations on a surface.

Steps created at crystal edges

Since the gradient of concentration is highest at the edges of a crystal, dissolution takes place at the edges. In this process, over-all kinetics is controlled by diffusion, the interface between the crystal and the liquid is non-singular, and bunching results in macroscopic steps. It is observed as if macroscopic steps are nucleated at the crystal edges.

The shape of macroscopic steps created at crystal edges are shown in Photo. 4, being almost parallel to the crystal edges. Aspects of the step motion should be divided into two periods, i.e. “adolescence” and “senescence”.

In the adolescence (Photo. 5), steps progress in higher speeds, followed by step nucleation at the crystal edges. In this period, the majority of steps seems to have almost the same height, which was measured to be the order of several tenths of micron from an electron-microscopic study with a low-angle shadowing. The macroscopic steps are not rectangular shouldered (a) but sloping shouldered (b), as shown in Fig. 2. The angle θ in Fig. 2 (b) seems to amount about 10° from the electronmicroscopic study.

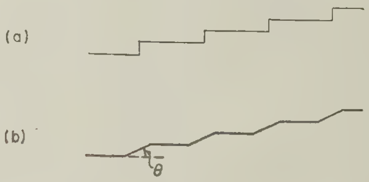

Fig. 2 (a). Steps with rectangular shoulders. (b) Steps with sloping shoulders.

In the senescence, since the crystal edge is no longer sharp, and the gradient of the concentration is no longer high, no steps are created at the crystal edges, but the region where the group of the macroscopic steps swept away remains to be a smoothly curved surface. In this region, it is generally observed that some hillocks are left behind the group of moving steps, as shown in Photo 6. The height of the hillocks is much larger than that of adolescence, exceeding the order of several microns. Formation of the hillocks left behind will be understood, if there is a hindrance of the step motion, such as immobile adsorbed impurity molecules.

In the senescence, in which the creation and motion of steps no longer take place, dissolution is brought about mainly by the lateral shrinkage of periphery of the crystal in the plane of (0001). This aspect can be seen in Photo. 8 (a) and (b).

Steps created at emergence points of Dislocations

Triangular steps as shown in Photo. 7 are created and sent out from the emergence point of a dislocation. The creation of steps at certain definite points supports the conclusion of the previous works that the etch pits correspond to dislocation[8),9)].

Since the undersaturation is very high, the dissolution showing a spiral pattern, which might be seen at screw dislocations, does not take place, but the following process is observed. The initial attack of water to the crystal face gives rise to a small triangular pit at the dislocation emergence point as

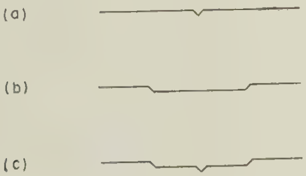

Fig. 3 (a), (b), (c). Process of nucleation and sending out of steps at a dislocation emergence point.

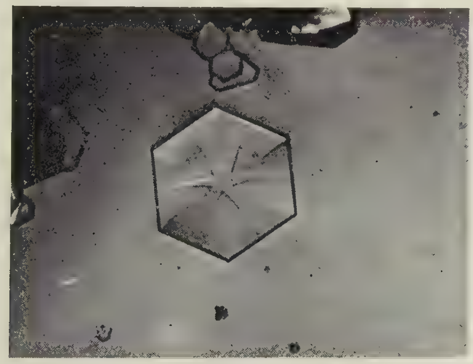

Photo. 1. Photomicrograph of a crystal platelet with a six-rayed star pattern.

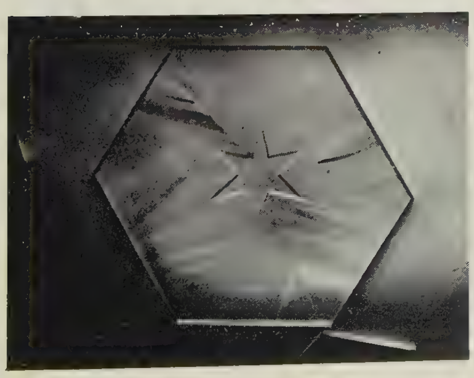

Photo. 2. Photomicrograph of a crystal plate with a star-shaped terrace, together with macroscopic terraces roughly parallel to it.

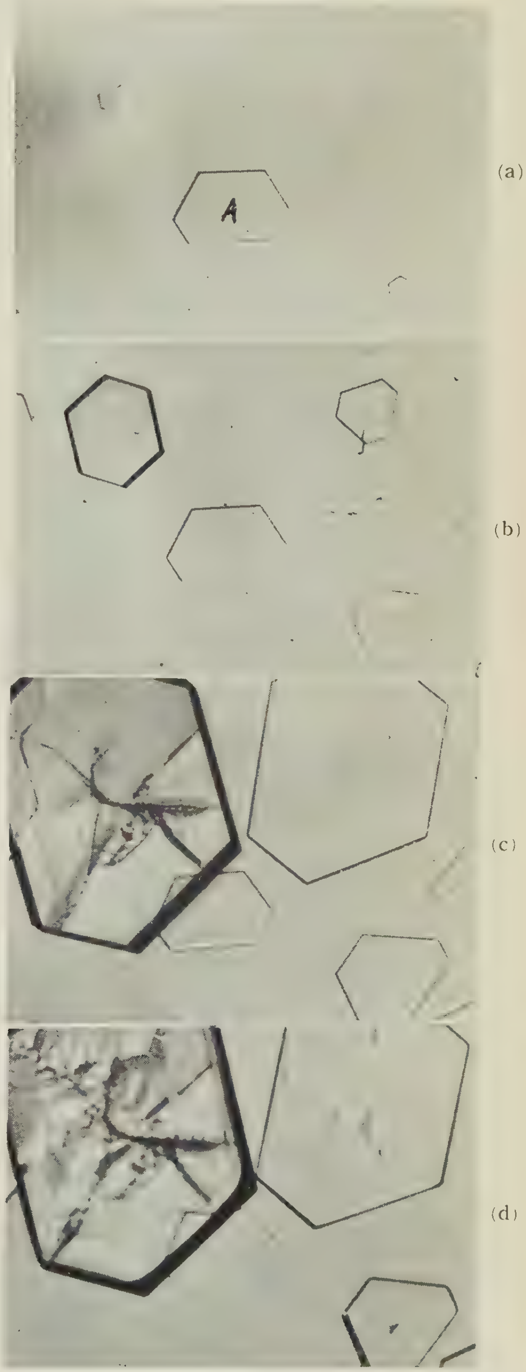

Photo. 3. Photomicrographs of crystals obtained by heating from the lower side. Crystal A remains thin and small during the growth process and shows no dislocation etch pits by an etching treatment.

shown in Fig. 3 (a). When the depth of the pit reaches a certain amount, pit does not grow deeply any more, a triangular step moves so that the pit becomes flat (Fig. 3 b). Strained part in the vicinity of the dislocation is preferentially dissolved again, forming a pit (Fig. 3 (c)). Periodical repetition of this process causes intermittent nucleation and sending out of triangular steps.

Penetrating dissolution

On the top and the bottom faces of a very thin piece of crystal, a couple of etch pits are clearly observed simultaneously, which correspond to the couple of the end points of a dislocation that penetrates the sample, as shown in Photo 8 (a). Note that triangular steps around each dislocation on the both faces are " oppositely sensed ", owing to the trigonal symmetry of GASH crystal.

The observation of " penetrating dissolution " along the dislocation line provides a

conclusive evidence for the identification of etch pits with dislocation emergence points.

Interference of two kinds of steps

It is frequently observed that steps created at crystal edges coalesce with each other at the "top of a mountain" which acts as if it were a sink of steps. At the sink, macroscopic steps are triangular, of which sense is "opposite" to that of dislocation etch pits (Fig. 4). This situation will be understood, if we suppose that the rate of lateral progress of macroscopic step is dependent on orientation, i.e. the rate is highest in the *b*-directions, as shown by the arrows in Fig. 4.

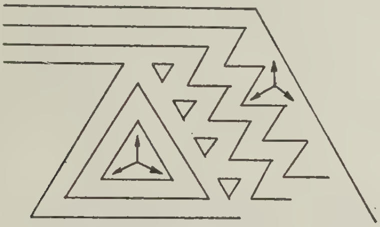

Fig. 4. Shape of steps, directions of the highest rate of lateral progress of steps, and apparent sinks of steps.

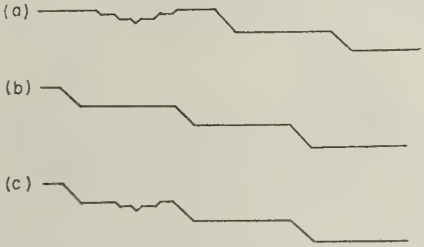

Fig. 5. Interference of steps created at a dislocation emergence point and those created at a crystal edge.

The height of steps, which have been created at a crystal edge, is generally larger than that of steps, which are sent out from a dislocation emergence point (Fig. 5 (a)). Hence the group of triangular steps starting from the dislocation is sometimes "swept" away by the flow of steps from the crystal edge (Fig. 5 (b)). After being swept away, however, close observation can find the continual step creation at the dislocation emergence point on the wider step nucleated at the crystal edges (Fig. 5 (c)).

§ 4. Discussion

GASH shows a characteristic appearance of macroscopic steps and growth pattern of six-rayed star. These phenomena are understood as bunching of progressing steps, so it is conceived that GASH has a characteristic behavior of easy formation of bunching.

Since the phenomena do not seem to be impurity sensitive, it is very likely that the reason for the easy formation of bunching in GASH crystal is not impurity effect but intrinsic one, probably due to the direction dependence of the strength of chemical bond. Crystal structure of this substance[12] suggests that bonding in the {0001} plane is much stronger than that in the ⟨0001⟩ direction, in agreement with the perfect cleavage parallel to the {0001} plane. Surface free energy between aqueous solution and the {0001} face will be, therefore, much smaller than those for other faces. In diffusion-controlled growth or dissolution process, the smoothly curved interface will be then apt to take a stepped form as shown in Fig. 2 (a), in order to make the surface free energy lower. Steps with rectangular shoulders as Fig. 2 (a) are, however, not stable, because diffusion current in the diffusion-controlled process is highest at the rectangular shoulders. Thus the resultant steps must be sloping shouldered as shown in Fig. 2 (b).

Acknowledgement

It is highly acknowledged that an information on observations of remarkable step flow on the surface of GASH crystal in dissolution process was offered by Dr. H. Hirabayashi and Dr. H. Toyoda of Electrical Communication Laboratory, Nippon Telegragh and Telephone Public Corporation, which stimulated the authors to initiate the present work.

This work was financially supported in part by a Grant in Aid for Fundamental Scientific Research from the Ministry of Education.

"Angular Distribution of Electrons Suffering Characteristic Energy Loss in Passage through Metal Films"

By Hiroshi WATANABE

Hitachi Central Research Lab. Kokubunji, Tokyo, Japan

(Received January 27, 1961)

The distribution in energy and angle of 20—25 kv electrons scattered by Al, Ag and Au evaporated films was measured with an electron velocity analyser of Möllenstedt type. The energy resolution is about 5×10^{-5}, and the angular resolution better than 5×10^{-4} radian. The angular distribution of the characteristic energy loss was compared with Ferrell's calculation. (Phys. Rev. **101** ('56) 554). The comparison shows that the experimental result is consistent with a simple Bohm-Pines' approach provided that a correction is made for finite resolution of both energy and angle.

§1. Introduction

In the electron energy loss experiment the characteristic energy loss values which we call "eigenloss" values were measured for the large number of elements and compounds.(1) Some people investigated the dependence of the loss value upon the crystal structures,(2) the accelerating voltage,(3,4) the scattering angles(5) and others.(1) A few were reported on the intensity distribution of electrons scattered elastically and inelastically. Marton and his coworkers studied the distribution in energy and angle of 20 kv electrons scattered by thin foils of C, Al, Ni, Cu, Au, Al_2O_3 and formvar. They used an energy analyser of magnetic type having the resolution better than 0.1 % in energy ($\Delta E/E\leq10^{-3}$) and 10^{-3} radians in angle.

Based upon the Bohm-Pines' theory of plasma excitation in metal electrons, Ferrell calculated the angular distribution of the intensities of the eigenloss electrons.(7) He compared the results with the experimental data obtained by Marton and co-workers, and found two significant discrepancies between the theoretical and experimental curves. First, the theoretical intensity at small angles falls short by a considerable amount of accounting for the observed intensity. Second, at large scattering angles the theoretical curve is somewhat stronger than observed. His explanation of the first discrepancy, which is perhaps the more striking one, is that the intense no-loss beam superposes on the eigenloss intensity at small scattering angles because of the insufficient energy resolution of the instrument.

In 1949, Möllenstedt(8) devised a new electron velocity analyser of extremely high resolution. In the analyser the large chromatic aberration of an electrostatic lens is utilized, and the energy resolution better than 5×10^{-5} is easily obtained. In 1960, the present author(9) constructed an analyser of Möllenstedt type with which the angular distribution of electrons scattered inelastically as well as elastically is studied. The resolution of the analyser is about 5×10^{-5} in energy, and better than 5×10^{-4} radians in angle.

Using this instrument the angular distribution of the eigenloss electrons was obtained on evaporated Al, Au and Ag films. The results and the comparison with Ferrell's calculation are described in this paper.

§ 2. Experiment

Figure 1 shows a schematic diagram of the electron optical system of the velocity analyser. A focusing lens and a reducing lens project the reduced diffraction pattern on a plane with a fine slit, and then the part of the projected pattern passing through the fine slit is analysed by the analyser lens. The pattern on the plane of the fine slit and energy loss spectrum obtained in the analysis are shown schematically in (b) and (c) of Fig. 1. Fig 1c gives the relation among energy loss, scattering angle and intensity of scattering electrons.

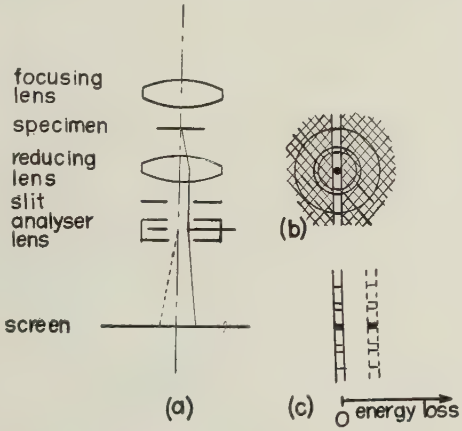

Fig. 1. (a) Schematic diagram of the electron optical system. (b) Diffraction pattern on the fine slit plane. (c) Energy loss spectrum on the final screen.

The intensity measurement was carried out with photometric method. The relative intensity scale was obtained as follows. A shadow image of an aperture diaphragm is shifted discontinuously during the exposure by a magnetic deflector, the electric current through which deflector is varied step-wise in time. An example of the photographic plates thus obtained is shown in Fig. 2a. The microphotometric record of the plate and a curve representing the relative exposure *vs* the distance from the dark line on the photometric record are shown in Figs. 2b and 2c, respectively. A microphotometric record of a photographic plate developed at the same time with the scale plate can be

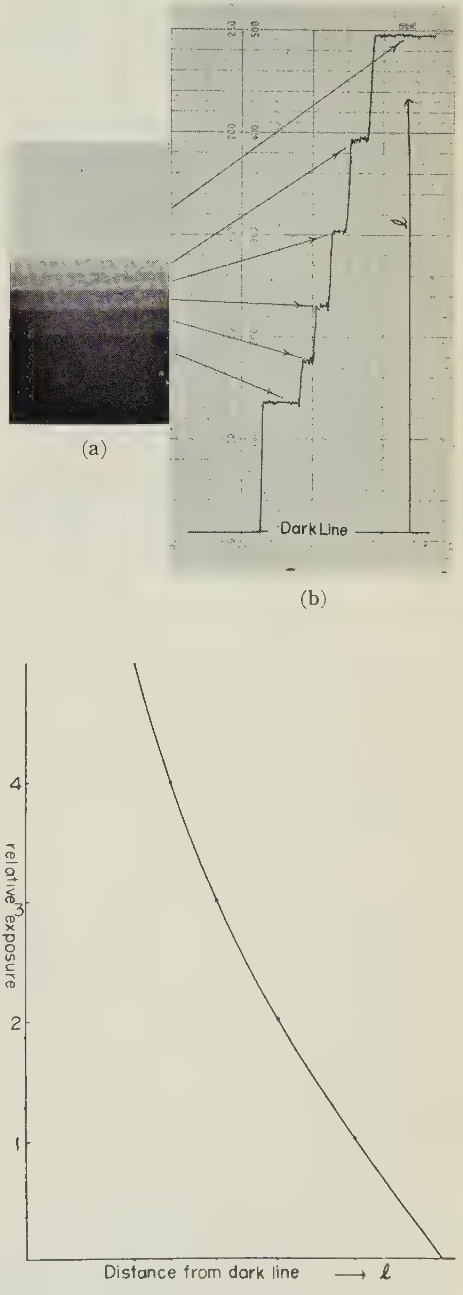

Fig. 2. (a) Exposure steps. (b) Microphotomeritc record of the plate in (a). (c) Relative exposure *vs* distance from dark line.

converted into the relative intensity by means of the intensity scale. The accuracy of this exposure scale is determined by the stability of the electron beam current during the exposure as well as by the accuracy of the exposure time. The stability of the electron beam was tested by recording the characteristic X-ray intensity emitted from the surface of a copper block irradiated by the electron beam. The change of the intensity was less than 1% per minute in the test. The stability of the electron beam current is believed to be better than 1% per minute in the present experiment. The accuracy of the exposure time was tested with a stop-watch. The maximum fluctuation of the exposure time of 5 sec was 0.3 sec, that is, the accuracy is better than 6%. Thus, the accuracy of the exposure scale used in the present experiment is better than 6%.

(b)

Fig. 3. (a) Loss-angle diagram of 25 kv electrons scattered by Al film. (b) Relative intensity *vs* scattering angle for arcs I and II.

§ 3. Experimental Results

Figure 3a shows a loss-angle diagram of 25 kv electrons scattered by an Al evaporated film of about 250 Å thick.

The two arcs I and II in the small angle region indicate that the energy loss value increases with the scattering angle, and they originate from the plasmon excitation in the metal electrons(5). The relative intensity measured along arcs I and II are given in Fig. 3b. The half-value width of bote curves are 2.7×10^{-3} and 4.2×10^{-3} radians, respectively.

Fig. 4a is a cartographic representation of the diagram. The abscissa is the scattering angle, the ordinate energy loss in electron volt unit, and the contours of equal intensity in arbitrary scale. Figure 4b gives the intensity *vs* angle curve at $\Delta E=24$ ev.

Figure 5a shows a cartographic plot of a loss-angle diagram of 25 kv electrons scattered by an Ag evaporated film of about 250 A thick, and Fig. 5b is the intensity *vs* angle

(b)

Fig. 4. (a) Cartographic plot of a loss-angle diagram of 20 kv electrons scattered by Au film. (b) Relative intensity *vs* scattering angle at $\Delta E=24$ ev.

curve at $\Delta E=3.4$ ev.

§ 4. Discussions

The energy loss peaks of Al (15 ev), Au (24 ev) and Ag (3.4 ev) are believed to be originated from the plasmon excitation. Ferrell[7] calculated the differential scattering cross section of electrons exciting one plasmon of energy $\hbar\omega_p$. His result is

$$p(\hbar\omega_p)d\Omega=\frac{d\Omega}{2\pi a_0}\cdot\frac{\theta_E}{\theta^2+\theta_E{}^2}\,, \qquad (1)$$

where $\theta_E=\Delta E/2E$

a_0: Bohr radius

E: accelerating voltage.

Equation (1) is plotted on Figs. 3b, 4b and 5b, being normalized to the experimental values at $\theta=4\times10^{-8}$ radians in Figs. 3b and 4b, and at $\theta=1\times10^{-3}$ radians in Fig. 5b. In cases of Al and Au in Figs. 3b and 4b the calculated values are larger than the experimental ones at angles smaller than 4×10^{-3} rad., and they are smaller than the experimental ones at larger angles. The same tendency in case of Au was observed by Marton and coworkers.

Ferrell treated the problem in more detail, taking the contribution from the multiple scattering into account. The observed eigenloss beam consists of three different parts, (a) electrons scattered first elastically and then exciting a plasmon, (b) electrons exciting a plasmon and then scattered elastically, (c) electrons exciting a plasmon and then lost by inelastic scattering. Summing up these electrons Ferrell obtained the resultant angular distribution in a form of definite integral. The result of the numerical integration for the case of 20 kv electrons exciting a plasmon in Au is presented by the dotted line in Fig. 4b. It agrees with the present experimental result better than the solid line of equation (1) does.

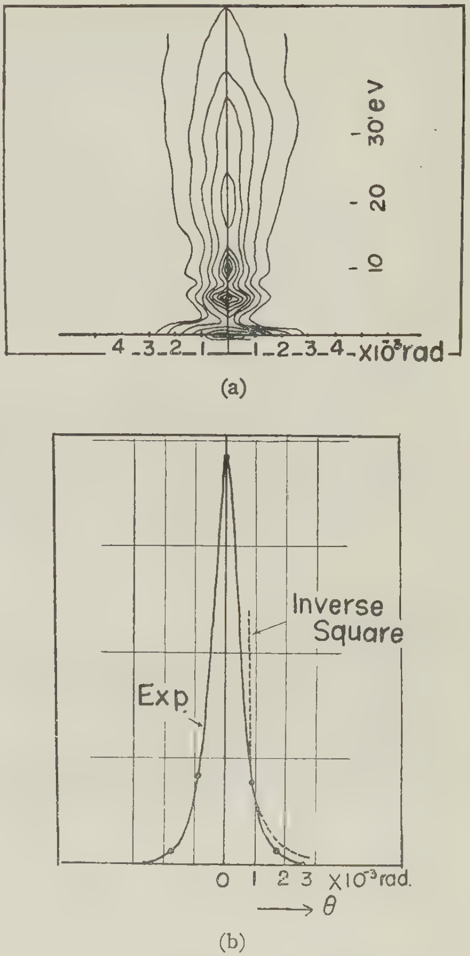

Fig. 5. (a) Cartographic plot of a loss-angle diagram of 25 kv electrons scattered by Ag film. (b) Relative intensity *vs* scattering angle at $\Delta E=3.4$ ev.

Marton and co-workers' experimental result plotted in Fig. 4b agrees with neither the present experiment nor Ferrell's calculations. Since they were forced to sacrifice energy resolution in order to achieve high angular resolution, the superposition of the intense no-loss beam on the eigen-loss beam may cause the large scattering intensity at small angles in their result. In the present experiment both the energy and angular resolutions are high enough to seperate completely the no-loss beam from the eigenloss beam.

§ 5. Conclutions

The relations among scattering intensity, angle and energy loss value were experimentally observed, and represented in cartographic plots. The angular distribution of eigenloss process was compared with Ferrell's calculations.

The following conclusions are drawn from the present experiment.

(a) The plasmon excitation probability given by equation (1) does not agree with the experiment on Al, and Au.

(b) Ferrell's calculation on Au in which the effect of multiple scattering is taken into account agrees with the experimental curve, although his calculation is based upon equation (1).

This agreement means that the eigenloss in Au at 24 ev is caused by the plasmon excitation in Au.

The similar treatment of the plasmon excitation probability in other materials is desired for the further study of plasmon excitation phenomena in solids.

Domain Structure of $NaNO_2$

By Shoichiro NOMURA, Yohko ASAO,
and Shozo SAWADA
Department of Physics, Tokyo Institute of Technology

(Received January 31, 1961)

The 180° domains along the *b* direction in $NaNO_2$ single crystals were observed by the etching method at room temperature. The domain boundaries lie parallel to (100). The virgin crystal prepared from the aqueous solution is almost of single-domain, but, after having once been heated above the Curie temperature, it has nearly the same domain structure as the crystal prepared from the melt. These domains were ascertained to be the ferroelectric ones from experiments with *dc* field. By the alkali etchant the positive end of the domain was more rapidly etched than the negative one, and nearly the contrary result was obtained for the acid etchant. The fact that the domain boundaries lie parallel to (100) would be intimately related with the thermal motion of NO_2^- radicals.

§ 1. Introduction

It has been revealed that $NaNO_2$ is ferroelectric below the transition temperature near 160°C.[1] The crystal symmetry of $NaNO_2$ at room temperature is orthorhombic, its space group being $C_{2v}^{20}(Imm)$.[2,3,4] Passing through the transition temperature, it changes to $D_{2h}^{25}(Immm)$, though the crystal structure still remains orthorhombic. The atomic arrangement in the unit cell of $NaNO_2$ at room temperature is schematically shown in Fig. 1. The unit cell contains two $NaNO_2$ molecules and has a polar axis along the *b* direction.

As in the case of other ferroelectrics, a domain structure is expected to appear also in $NaNO_2$ crystal. It is considered, however, that only 180° domain would be realized in $NaNO_2$, owing to its crystal symmetry. So the observation of the domain pattern should be performed, as is well known, not by the method using a polarized-light microscope but the etching method or the colloid method.

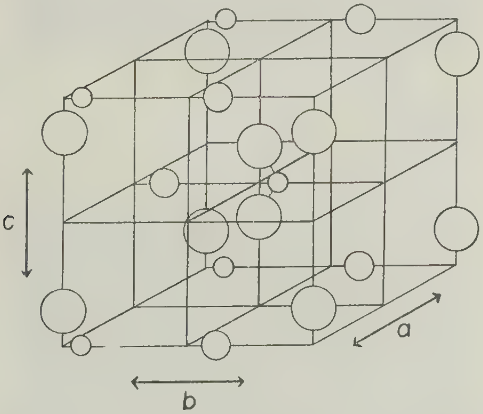

Fig. 1. Parallel perspective drawing of $NaNO_2$ structure at r.t.. Large, medium and small circles represent oxygen, sodium and nitrogen, respectively. The unit cell size is $a=3.55$Å, $b=5.56$Å, $c=5.38$Å.

In this paper, the ferroelectric damain patterns of $NaNO_2$ visualized by the etching method at room temperature are shown and some effects on the domains due to the heat treatment and the application of the electric field one are discribed. It is considered that the feature of the domain boundary is intimately connected with the behavior of NO_2^- radicals in the crystal. Some discussions on it are presented.

§ 2. Preparation of Crystals

Since $NaNO_2$ has a rather low melting point of 277°C and has an adequate curve of solubility into water, single crystals were easily prepared by either the fusion method or the solution method.

In the former case, however, a careful precaution should be taken against humidity because of a considerable deliquescence of $NaNO_2$. $NaNO_2$ powder (special grade in JP) charged in a glazed alumina-crucible of about 400 cc content was first dried at about 100°C during 48 hrs. under the pressure of 10^{-2} mmHg. Next the crucible was set in a vertical electric-furnace, and there the temperature was raised up to *ca* 280°C. Then the crucible was slowly cooled down by lifting it upwards along the axis of the furnace with the aid of a servomotor, while the input power of the furnace was kept constant during the process. A crystal was first nucleated floating on the center of the liquid surface, and then developed towards the wall side of the crucible. In the crystallization process, some stress was applied to the grown-up crystal when it reached the wall of the crucible, and further in the cooling process on account of an anisotropy in the thermal expansion coefficients. Consequently it was cracked into several blocks of which sizes were 1∼3 cm^3 on the average. When we need a crystal of larger size, it was necessary to pick up the grown-up crystal from the melt before it touched the wall side or to flow out the liquid from the crucible in the midst of the cooling process. The crystal prepared was transparent, slightly yellowish and showed the cleavage parallel to $(10\bar{1})$ or (101) planes. The angles between these cleavage surfaces calculated from the X-ray data[2] are shown in Fig. 2, where α and β are 66°52′ and 113°8′, respectively. The angles determined with optical microscope for our crystals agreed well with them.

In the latter case, the method of evaporation was adopted. A saturated aqueous solution of $NaNO_2$ of *ca* 200 cc was gradually dehydrated by conc. sulphuric acid in a desiccator during about ten days. The desiccator was set in a thermostat kept at 35±0.5°C. A little crystal mounted on a glass plate was used as a seed. The obtained tabular crystal was prismatic, elongated along [100], as shown in Fig. 3. As several prismatic crystals generally grew piling on their (001) faces each other, the shape of the grown-up crystal became rather complicated. The dimensions of the obtained crystal were 2 cm×1 cm×0.5 cm at most.

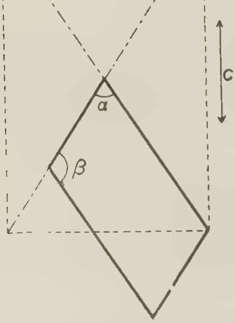

Fig. 2. Angles between the cleavage surfaces (101) and $(10\bar{1})$ denoted by the full lines. The rectangle surrounded by the dashed lines is a projection of $NaNO_2$ unit cell on the b plane and the directions of cleavage are shown by the chain lines.

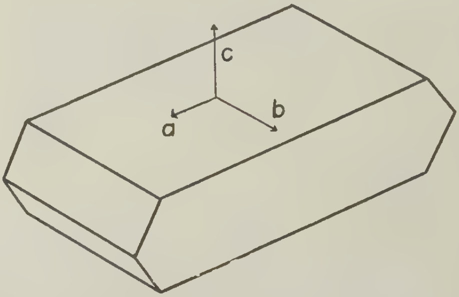

Fig. 3. A prismatic tabular crystal prepared by the solution method.

§ 3. Observation of Ferroelectric Domains

Before etching the crystal, it was necessary to polish its surfaces in order to eliminate a pre-etching effect due to the humidity in air. It was on the *b* surface, perpendicular to the polar axis, that the observations were made. Any patterns were not observed on the other surfaces except the *b* surface, as is expected. As the cleavage does not occur parallel to this face, the crystal was cut perpendicular to the *b* axis with a wet string. The surfaces were polished first with a fine sandpaper and then with a soft filterpaper. Photo. 1 shows the *b* surface before the etching, where any distinguished pattern cannot be seen with the exception of scratches in polishing. 10% NaOH aqueous solution was most used as the etchant and the time required for the etching varied from a few to several tens of seconds, depending upon the desired degree of development of the patterns. Photo. 2 is the etch pattern near the edges of the crystal, where many parallel stripes lie along the *c* direction. Its enlarged picture is exhibited in Photo. 3.

The interval between the stripes, which is the width of the domain, varies considerably according to the place and the specimen. In a virgin crystal prepared by the solution method, any parallel stripes could not be seen. After a heat treatment above the Curie temperature, however, some stripes appeared, though the pattern was somewhat different compared with that shown in Photo. 3. Photos. 4 (a), (b) represent these situations. Supposing that the pattern is resulted from the ferroelectric domains, the crystal shown in Photo. 4 (a) is considered to be composed of a single domain. The effect due to the heat treatment was also recognized on the crystal prepared by the melting method, although the detection was rather difficult because the stripes were fine. It may generally be said that the interval between the stripes

observed on the crystal prepared by the solution method is much larger compared with that by the melting method.

A wedge-shaped pattern can be seen in Photo. 4 (b) and its point is enlarged in Photo. 5.

§ 4. Field Fffect

By observing the etching pattern of the crystal treated by *dc* electric field, it is possible to determine whether it really corresponds to the ferroelectric domain or not, furthermore the sense of the polarization of 180° domain. To ascertain the vanishing of the domain structure in the paraelectric phase by etching the crystal in this temperature-region is also desirable, but such an experiment is not to be easily made.

The $NaNO_2$ crystal shows the *D-E* hysteresis loop for 50 c/sec *ac* field near the transition temperature, and the coercive field observed at 143°C is about 2.3 kv/cm.[1] But the loop does not open out at room temperature even for the field of 25 kv/cm, owing to its high coercive field. While, it was shown by our etching experiments that the sense of the polarization can be pretty easily reversed in the case of the *dc* electric field. The same result about the effect of electric field upon the domain structure was obtained for both of the crystal prepared by the fusion method

(a) the upper face,
(b) the lower face.

and that by the solution method.

The etch pattern of the crystal before applying the *dc* field was first checked, which is shown in Photo. 6 (a). Then the field treatment was performed as follows. The air-drying silver-paste electrode, of which area was about one tenth of the crystal surface, was attached on the middle of the *b* faces and 2.5 kv/cm *dc* field was applied on it at 120°C during one hour. After removing the electrodes and reetching the crystal, an effect distinctly appeared as is seen in Photos. 6 (b), (c). Any stripe could not be found not only on the part where the electrodes had been attached but also on a larger region beyond it. The same result was obtained even at room temperature by applying the *dc* field of 5 kv/cm during half an hour and if the field was applied more longer, the part without stripes generally became more larger. The stripes reappeared after the poled crystal was once heated above the Curie temperature.

Photos. 6 (b) and (c) are the etch patterns by ammonia obtained on the plus side of the applied field and the minus side,* respectively, where we can see a difference between their etching appearances especially on the part under the electrodes, the plus side being smoother than the minus side. Thus it was easy to discern the sense of the polarization by comparing the roughness of the etched surface. The roughness is considered to depend upon the etching rate and further a step should be formed along a domain boundary owing to the difference of etching rate on plus- and minus-surfaces. Observing the part including the domain boundary, we could easily judge which side was more attacked. It was concluded that the etching rate by the alkali etchant of the positive end was more rapid than that of the negative end and contrary by the acid etchant.

For ascertaining that a domain runs through the crystal along the *b* direction, the location of the domain boundary observed on the upper face of the crystal was compared with that on the lower one by adjusting the focus of the microscope on the both faces without turning over the crystal plate. The similar patterns were observed on the two faces, although the sight of the lower one was a little less clear than the upper one. This situation is shown in Photos. 7 (a) and (b). It may be concluded therefore that a domain runs through the crystal from one face to the opposite one. Further, Photo. 6 and Photo. 7 show that the domain can easily take any shape after an application of the electric field on the crystal.

§ 5. Discussion

It has become clear that the etch patterns observed in our experiments are due to the 180° ferroelectric domain, running through the crystal along the *b* direction. It is considered that the etching rate is determined not only by the chemical activity of the etchant, but also by the electrostatic interaction between the ions in the etchant and the polarization charge appearing on the crystal surfaces. As by the electrostatic interaction the anion drifts towards the positive end of the crystal and the cation towards the negative one, the density of the anions will increase near the positive end and that of the cations near the negative one.**

Considering the case of alkali-etchant, for example, NaOH, we have Na^+ as the positive ion. Supposing that the Na^+ is inactive to $NaNO_2$, it will be natural that the etching rate on the negative end is slower than that on the positive one. A similar interpretation will be possible in the case of other alkali-etchants. In the case of acid, it is presum-

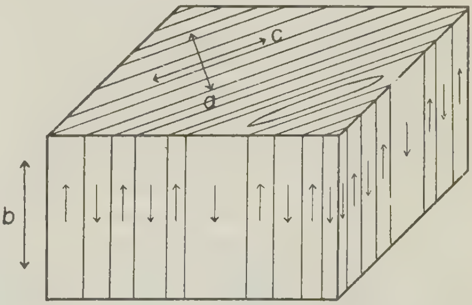

Fig. 4. A schematic model of the domain structure of $NaNO_2$. Side faces are the cleavage ones and the arrows represent the sense of spontaneous polarization.

---

* The plus- and minus-sides are the surfaces connected to the + and − terminals of the battery, respectively.

** The positive- and negative-ends are the surfaces on which the positive- and negative- polarization charge appear, respectively.

ably the cation H^+ that plays an active role for the reaction and leads to the contrary result to alkali-etchant. It is noticeable, however, that the situation is contrary in barium titanate,[7] which is insoluble into water: for example, the etching rate on the positive end was more rapid than that on the negative one when HCl etchant was used.

From our experimental results, we can draw a typical model of the domain structure, including a wedge-shaped domain as shown in Fig. 4, where the sense of the spontaneous polarization is indicated by arrows. The fact that the domain boundary in the natural state only appears parallel to the (100) plane, has to be interpreted in connection with the atomic arrangement in the crystal. Projecting the atomic arrangement of $NaNO_2$ on its (010) plane, we may obtain an illustrative pattern shown in Fig. 5. The cleavage faces, parallel to the (101) or $(10\bar{1})$ planes are indicated there by the chain lines. The strength of the bonding which acts across these faces is considered to be rather weak owing to its large interatomic distance. Supposing that the parts marked A and B represent the antiparallel 180° domains, respectively, their boundaries will probably be located as shown by the full line *pq*. As the O–O distance in NO_2^- radical is 2.09A[2,4], the degree of the overlapping of the oxygen atoms across these planes is not so large. But if the boundary is parallel to the (001) plane, the boundary will be compelled to become a notched face as shown by the dotted line *st*. Comparing these two cases, we may conclude that the latter case occurs less probably than the former. As to why the boundary does not appear parallel to the (101) or $(10\bar{1})$ planes, the situation is not clear, but it might be said that the shape of NO_2^- radical and the character of its thermal motion can not permit the boundary to stand still along these planes. In any cases, however, the difference between their lattice energies would be small, judged from the fact, mentioned in § 4, that the domain can take any shape after an application of the electric field.

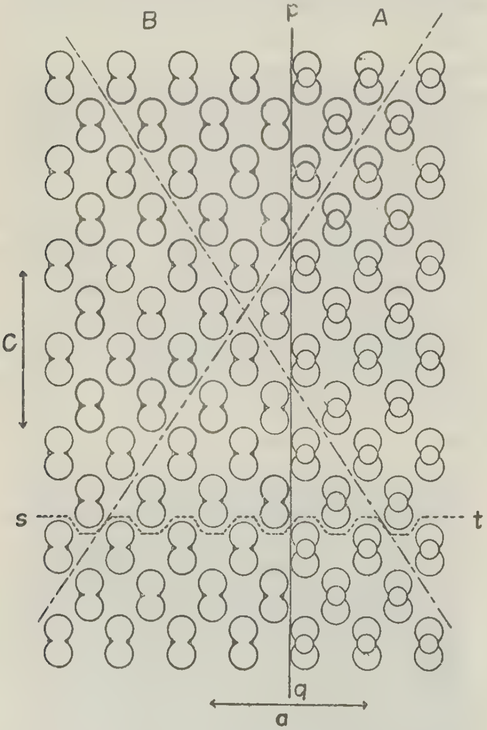

Fig. 5. A projection of the atomic arrangement on the *b* plane in $NaNO_2$ crystal, containing two antiparallel domains. Each unit in the figure represents a superposed projection of Na^+ and NO_2^-. The domain boundary is considered to be located as shown by the full line *pq* and a virtual boundary running along the *a* direction is represented by the notched dashed-line *st*. The directions of cleavage are indicated by the chain lines.

It is probably sure from the X-ray data that the ferroelectricity in $NaNO_2$ is due to the alignment of NO_2^- radicals along the *b* direction, the complete disordering of their sense along the *b*-direction being realized above the Curie temperature.[5,6] From other properties of $NaNO_2$, e.g., the thermal properties,[8] however, it is supposed that the misalignment of NO_2^- would possess some probability to occur also in the ferroelectric phase, so that the domain-wall motion will easily take place with the aid of the thermal vibration of NO_2^- radicals and will presumably show a strong dependence upon the frequency of applied field, because of a short-range interaction between NO_2^- radicals. The reason why the coercive field obtained in the *D–E* hysteresis loop for the *ac* field of 50 c/sec is so different from that of *dc* one seems to be due to this cause.

We may imagine that in a pure and stress-free crystal the sense of the polarization of the whole crystal will be controlled completely by a weak field applied to any point of the crystal, of which strength is of the same order as or a little less than the coercive field.* Qualitative experiments are now in progress. There are many interesting subjects concerning the dynamical properties of the domain-wall motion, but they will be described in a subsequent paper.

The authors wish to express their hearty thanks to Dr. I. Yoshida and Mr. T. Kawakubo for their cooperations in experiments and valuable contributions in discussions.

---

* This means a threshold value of static field in which the domain wall motion begins.

Perfectness of Macrodomains of $BaTiO_3$ Crystals

By Kêitsirô Aizu and Osamu Nakada

Hitachi Central Research Laboratory, Kokubunji, Tokyo

(Received January 11, 1961)

Statistico-thermodynamical investigation is made on the size and density of reversely-polarized microdomains contained within a unidomain *c*-plate (or a macrodomain of a multidomain *c*-plate) of $BaTiO_3$ in thermal equilibrium at room temperature, with or without constant electric field applied. Microdomains treated here are confined to ones running through the crystal plate from the surface on the one side to the surface on the other side. It is found that a thinner crystal plate contains more reversely-polarized microdomains, and a plate thicker than about 2×10^{-6} cm contains practically no reversely-polarized microdomains. Reversely-polarized microdomains tend to disperse rather than coalesce, and can hardly be depressed by electric field. Just below the Curie temperature, it is expected that the critical thickness is considerably larger than the above value, since the domain-wall energy per unit area is fairly small.

§1. Introduction

It is generally assumed that a $BaTiO_3$ *c*-plate, in the most stable state, is polarized in the one sense everywhere. But, alternatively, it is conceivable that a unidomain *c*-plate of $BaTiO_3$, in spite of the apparent uniformity of polarization under an opitical microscope, may contain more or less reversely-polarized microdomains. This paper aims to investigate statistico-thermodynamically the size and density of reversely-polarized microdomains which might be contained within a unidomain *c*-plate of $BaTiO_3$ in thermal equilibrium at room temperature with or without constant electric field applied.

Among microdomains, three types are conceivable. The first type of microdomains run through the crystal plate from the surface on the one side to the surface on the other side, the second rise from the surface on either side and end in the interior of the crystal plate, and the third lurk in the interior of the crystal plate. In this paper, only the first type of microdomains are considered. The occurrence of such reversely-polarized microdomains increases on the one hand the internal energy of the crystal plate, but at the same time increases its entropy, too. The former increase is proportional to the thickness of the crystal plate, while the latter increase is independent of the thickness. Therefore, it is expected that the density of reversely-polarized microdomains is larger for a thinner crystal plate.

§ 2. Foundation

Let us consider a unidomain *c*-plate of $BaTiO_3$. A row of unit cells running through the crystal plate perpendicularly to its face is referred to as a *cell-row*. All the unit cells belonging to one cell-row are assumed to be polarized either in the normal sense or in the reverse sense. (Which sense is normal is arbitrary.) A pair of a normal cell-row and a reverse cell-row in planar contact with each other is referred to briefly as a *normal-reverse cell-row pair*. (W. Kinase and H. Takahashi[1] calculated that the thickness of 180° domain walls of $BaTiO_3$ is nearly zero lattice-unit. This is taken into consideration.) When normal-reverse cell-row pairs exist, it is assumed, as an approximation, that a fixed energy increment γ occurs per unit area of their contact planes. Let the crystal plate be L lattice-units thick and contain N cell-rows of which n are reverse and $N-n$ are normal. A cell-row has four other cell-rows in planar contact around it. The central cell-row is referred to as *i-paired* when i of the four are polarized in the opposite sense to it. Let the crystal plate contain n_i i-paired reverse cell-rows and m_i i-paired normal cell-rows ($i=0, 1, 2, 3, 4$). Let the densities of reverse, i-paired reverse, and i-paired normal cell-rows be x, x_i, and w_i, respectively. That is,

$$x=n/N\,, \qquad x_i=n_i/N\,, \qquad w_i=m_i/N\,. \tag{2.1}$$

It follows that

$$\left.\begin{array}{ll}\sum n_i=n\,, & \sum m_i=N-n\,,\\ \sum x_i=x\,, & \sum w_i=1-x\,.\end{array}\right\} \tag{2.2}$$

The probabilities of one cell-row being reverse and being normal are x and $1-x$ respectively, so the probability of one reverse cell-row being i-paired and that of one normal cell-row being i-paired are respectively

$$q_i={}_4C_i\,x^{4-i}(1-x)^i\,, \qquad p_i={}_4C_i\,x^i(1-x)^{4-i}\,. \tag{2.3}$$

The probability of $(n_0, n_1, \cdots, m_3, m_4)$-or shortly (n_i, m_i)-state, wherein n_i reverse cell-rows are i-paired ($i=0, 1, 2, 3, 4$) and m_i normal cell-rows are i-paired ($i=0, 1, 2, 3, 4$), is

$$\frac{n!}{\Pi\, n_i!}\Pi\, q_i^{n_i}\cdot\frac{(N-n)!}{\Pi\, m_i!}\Pi\, p_i^{m_i}\,. \tag{2.4}$$

It is necessary and can be verified easily that the sum of (2.4) over every combination (n_i, m_i) satisfying (2.2) is unity. The number of those configurations wherein n of N cell-rows are reverse is

$$\frac{N!}{n!(N-n)!}\,. \tag{2.5}$$

Ω, the number of configurations of (n_i, m_i) state, is equal to the product of (2.4) and (2.5), so

$$\Omega=\frac{N!}{\Pi\, n_i!\,\Pi\, m_i!}\Pi\, q_i^{n_i}\,\Pi\, p_i^{m_i}\,. \tag{2.6}$$

The entropy (increment) S of the crystal in (n_i, m_i) state is:

$$\begin{aligned}S&=k\log\Omega\\ &=Nk(-\sum x_i\log x_i-\sum w_i\log w_i\\ &\qquad+\sum x_i\log q_i+\sum w_i\log p_i)\,.\end{aligned} \tag{2.7}$$

Here k is the Boltzmann constant.

Let the crystal contain N^* normal-reverse cell-row pairs. Since there occurs energy increment equal to $ac\gamma L$ (a, c: the lattice constants) per one normal-reverse cell-row pair, the internal energy (increment) U of the crystal in (n_i, m_i) state is:

$$U=ac\gamma LN^*\,. \tag{2.8}$$

The number of normal-reverse cell-row pairs is $\sum in_i$ if counted about reverse cell-rows, and is $\sum im_i$ if counted about normal cell-rows. However, in order to maintain the symmetry between the set x, x_i and the set $1-x$, w_i, as required physically, it is improper to set either

$$N^*=\sum in_i \qquad \text{or} \qquad N^*=\sum im_i$$

because either would come to break the symmetry. It will therefore be assumed that $\sum in_i$ and $\sum im_i$ contribute to N^* with certain weights, as

$$N^*=\varphi(1-x)\sum in_i+\varphi(x)\sum im_i\,. \tag{2.9}$$

Here $\varphi(x)$ is a certain function of x satisfying

$$\varphi(x)+\varphi(1-x)=1\,. \tag{2.10}$$

Especially if $\varphi(x)=\text{const.}$, (2.9) becomes a simple arithmetical mean. When n is given, the largest value that $\sum in_i$ takes is $4n$ and the smallest value 0, and the largest value that $\sum im_i$ takes is $4(N-n)$ and the smallest value 0. Therefore when $n_0, \cdots, n_4$ fluctuate within the limits of (2.2), N^* fluctuates at most by $4n\varphi(1-x)$, and when $m_0, \cdots, m_4$ fluctuate within the limits of (2.2), N^* fluctuates at most by $4(N-n)\varphi(x)$. Since one normal-reverse cell-row pair consists of one normal cell-row and one reverse cell-row, the set $n_0, \cdots, n_4$ and the set $m_0, \cdots, m_4$ should have equivalent effects on N^*, so is assumed

$$4n\varphi(1-x)=4(N-n)\varphi(x)\,,$$

i.e.,

$$\frac{\varphi(x)}{x}=\frac{\varphi(1-x)}{1-x}\,. \tag{2.11}$$

Thus from (2.10) and (2.11)

$$\varphi(x)=x\,, \tag{2.12}$$

from (2.9) and (2.12)

$$\begin{aligned} N^*&=(1-x)\sum in_i+x\sum im_i \\ &=N\{(1-x)\sum ix_i+x\sum iw_i\}\,, \end{aligned} \tag{2.13}$$

and from (2.8) and (2.13)

$$U=Nac\gamma L\{(1-x)\sum ix_i+x\sum iw_i\}\,. \tag{2.14}$$

If P is the total polarization of the crystal and P_s is the spontaneous polarization per unit volume of the crystal,

$$P=P_sa^2cL(N-2n)=NP_sa^2cL(1-2x)\,, \tag{2.15}$$

At temperature T and electric field E, the free energy $\varPhi$ of the crystal in (n_i, m_i) state is:

$$\varPhi=U-EP-TS\,. \tag{2.16}$$

The actual state is sought as the one having the lowest free energy. Substituting (2.7), (2.14), and (2.15) into (2.16), solving the variational equation $\delta\varPhi=0$ in allowance for (2.2), and resetting the solution for the sake of convenience, the result is:

$$\frac{x}{1-x}\left\{\frac{x\exp\left(-\frac{ac\gamma L}{kT}x\right)+(1-x)}{x+(1-x)\exp\left(-\frac{ac\gamma L}{kT}(1-x)\right)}\right\}^4 \exp Y\exp\frac{2EP_sa^2cL}{kT}=1\,, \tag{2.17}$$

$$\begin{aligned} Y=4&\left\{1-\frac{ac\gamma L}{kT}x(1-x)\right\} \\ &\times\frac{(2x-1)\exp\left(-\frac{ac\gamma L}{kT}\right)-x\exp\left(-\frac{ac\gamma L}{kT}x\right)+(1-x)\exp\left(-\frac{ac\gamma L}{kT}(1-x)\right)}{\left\{x+(1-x)\exp\left(-\frac{ac\gamma L}{kT}(1-x)\right)\right\}\left\{x\exp\left(-\frac{ac\gamma L}{kT}x\right)+(1-x)\right\}}\,, \end{aligned} \tag{2.18}$$

$$\left.\begin{aligned} x_i&=x\left\{x+(1-x)\exp\left(-\frac{ac\gamma L}{kT}(1-x)\right)\right\}^{-4}q_i\exp\left(-i\frac{ac\gamma L}{kT}(1-x)\right)\,, \\ w_i&=(1-x)\left\{x\exp\left(-\frac{ac\gamma L}{kT}x\right)+(1-x)\right\}^{-4}p_i\exp\left(-i\frac{ac\gamma L}{kT}x\right)\,. \end{aligned}\right\} \tag{2.19}$$

Thus the means has been obtained to calculate those x, x_i, and w_i which make the free energy minimum.

§ 3. Thick Crystal Plates

Applying (2.17), (2.18), and (2.19) to thick crystal plates, it is found that as $L\to\infty$, then $x\to 0$ or $x\to 1$, irrespective of magnitude and sign of electric field. In case $x\to 0$, for sufficiently large L,

$$x\approx\exp\left(-\frac{4ac\gamma L}{kT}\right)\exp\left(-\frac{2EP_sa^2cL}{kT}\right)\,, \tag{3.1}$$

and

$$U\approx\frac{4\gamma x}{a}\,,\qquad S\approx\frac{U}{T}+\frac{2EP_sx}{T}+\frac{kx}{La^2c}\,,\qquad \varPhi+EP_s\approx-\frac{kTx}{La^2c}<0\,. \tag{3.2}$$

Since $\varPhi+EP_s$ is negative, this state is found to be certainly more realizable than the state of perfection ($x=0$). In case $x\to 1$, for sufficiently large L,

$$1-x \approx \exp\left(-\frac{4ac\gamma L}{kT}\right)\exp\frac{2EP_sa^2cL}{kT}\,. \tag{3.3}$$

In general, a crystal plate has two states of minimum free energy, corresponding to (3.1) and (3.3) respectively. The free-energy difference between these states is

$$2EP_s-\frac{2kT}{La^2c}\exp\left(-\frac{4ac\gamma L}{kT}\right)\sinh\frac{2EP_sa^2cL}{kT}\,. \tag{3.4}$$

When $E>0$, the state (3.1) has the lowest free energy and is most stable, while the state (3.3) is metastable, and when $E<0$, situations interchange. When E is present, the depressions of free energy which the metastable state and the most stable state have from the state of perfection nearer to each are different from each other, and the former is deeper than the latter, so (3.4) differs from $2EP_s$. When $E=0$, either the state (3.1) or the state (3.3) has the lowest free energy and is most stable.

In the state (3.1),

$$\begin{aligned}
&x_i \approx {}_4\mathrm{C}_i \exp\left\{-(16-3i)\frac{ac\gamma L}{kT}\right\}\exp\left\{-(5-i)\frac{2EP_sa^2cL}{kT}\right\},\\
&x_4 \approx x\,,\\
&w_i \approx {}_4\mathrm{C}_i \exp\left(-4i\frac{ac\gamma L}{kT}\right)\exp\left(-i\frac{2EP_sa^2cL}{kT}\right),\\
&w_0 \approx 1\,, \qquad w_1 \approx 4x\,.
\end{aligned} \tag{3.5}$$

Since $x_4 \approx x$, almost all the reverse cell-rows present are found to be four-paired, that is, isolated, thus it is reasonable that $w_1 \approx 4x$, what might not have resulted if N^* had been assumed otherwise than (2.13). Incidentally it is found that as $L\to\infty$, then $\sum in_i\to 0$, $\sum im_i\to 0$, and besides $(\sum in_i-\sum im_i)/\sum in_i\to 0$, displaying $\sum in_i \approx \sum im_i$.

$$P_s=260\ \text{erg}\cdot\text{volt}^{-1}\cdot\text{cm}^{-2}\ ,$$
$$\gamma=1.4\ \text{erg}\cdot\text{cm}^{-2}\ ,$$

and

$$k=1.38\times10^{-16}\ \text{erg}\cdot\text{deg}^{-1}$$

were used. γ would be like the energy per unit area of macroscopic 180° domain walls. Here γ was assumed to be equal to the value by W. Kinase and H. Takahashi.[1] On the units used in the tables, E, volt·cm^{-1}; U, Φ, erg·cm^{-3}; S, erg·deg^{-1}·cm^{-3}; P/P_s, %. According to Table I., in case $L=50$, reverse cell-rows are very sparse and almost all isolated. According to Table II., in case $L=20$, the density of reverse cell-rows gets to an order of some %, and P is about 97% of P_s. Electric field of 10^4 volt·cm^{-1} can hardly drop the density of reverse cell-rows. Most of reverse cell-rows present are four-paired, but three-paired ones are appreciable, too. When an electric field of 10^4 volt·cm^{-1} is applied, the free-energy depressions of the most stable and metastable states from the state of perfection nearer to each are 3.5×10^5 and 5.0×10^5 erg·cm^{-3} respectively, and the free-energy difference between the most stable and metastable states is 4.9×10^6 erg·cm^{-3}, which is about ten times as large as either of the former two. It is to be noted that the numerical values above calculated are subject to alteration if the estimate of γ is changed.

§ 5. Conclusion

A unidomain c-plate of BaTiO$_3$ thicker than about 2×10^{-6} cm in thermal equilibrium at room temperature can contain in the most stable state practically no reversely-polarized microdomains, whether a positive constant electric field is applied or not. The thinner crystal plate, however, comes to contain reversely-polarized microdomains, which can hardly be depressed by electric fields. Reversely-polarized microdomains tend to disperse rather than coalesce. The critical thickness 2×10^{-6} cm is extremely small, so that usual crystal plates are far thicker. Therefore, if should not be thought that macrodomains of a BaTiO$_3$ c-plate with usual thickness contain any reversely-polarized microdomains, in thermal equilibrium at room temperature. Just below the Curie temperature, however, the critical thickness is expected to be considerably larger, since the domain-wall energy per unit area is fairly small. In this paper, the domain-wall energy per unit area has been assumed 1.4 erg·cm^{-2} at room temperature. If this estimate is changed, the critical thickness suffer alteration. The nearest-neighbor approximation assumed on calculation of the internal energy may be somewhat rough, so that the value 2×10^{-6} cm may not have an exact meaning. In this paper, the second and third types of microdomains, as mentioned in the introduction, have not been considered. They differ from the first type treated here in that the increase of the internal energy caused by the occurrence of each of them is independent of the thickness of the crystal plate and their distribution is three-dimensional. The treatment of them is much more complicated. There seems to be a possibility of their existing in macrodomains in thermal equilibrium.

The authors wish to thank Dr. H. Kitagawa for his encouragement and discussing this work. The authors are also grateful to the colleagues in the laboratory for discussing on this paper.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 16, No. 5, MAY, 1961

Study of the Texture of the Boundary of Etched and Ground Regions of Quartz Plate by X-ray Diffraction*

By Einosuke FUKUSHIMA and Hiroshi NIMURA
Department of Physics, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo, Japan

(Received October 26, 1960)

The boundary effect, i.e. the anomalous enhancement of transmitted reflection from the boundary of the etched and ground regions of a quartz plate (E. Fukushima. Acta Cryst. **7** (1954) 459) is studied by an X-ray photographic method. By this method it is found that at the boundary a fairly large strain is produced and the strained layer extends to a deeper layer in the crystal than at the ground region. The influence of annealing on the boundary effect is also studied by a Bragg spectrometer. The anomalous enhancement is reduced by the annealing at the temperature of about 400°C.

From the above results and some supplemental experiments on the ground surface, a model of the zone of strain at the boundary region is proposed and the mechanism of zone formation is considered.

§ 1. Introduction

It is known that the intensity of X-ray reflection from crystals is greatly increased by grinding the surface. It has been reported moreover by one of the present authors (E.F.)[1] that, when a boundary line separating the etched and ground regions on one surface of quartz plate is prepared, the intensity of transmitted reflection from a net plane parallel to the boundary line is found to be anomalously higher at the boundary region even than one at the ground region on the surface. From this "boundary effect", it was inferred that a fairly large strain is produced at the boundary region and the strain gradient is perpendicular to the boundary line and parallel to the surface.

Kato[2,3] investigated the nature of the lattice distortion at the boundary region by means of a double spectrometer. He showed that; (i) for quartz crystals, the half widths of transmitted reflection curves are almost the same at the boundary, ground and etched regions, (ii) the boundary effect is erased by etching the crystal surface in hydrofluoric acid for only a few seconds and (iii) the effect is observed also in $NaClO_3$ crystals, while in calcite the effect is very small. Then he concluded that the boundary effect is due to the reduction of "primary" extinction caused by the elastic strain accumulated there.

Recently, Ishii and Kohra[4] also found the corresponding effect for germanium single crystals with the use of the anomalous transmission.

In the present work, after the boundary effect was confirmed by means of a Bragg spectrometer as in the previous paper[1] (§ 2), the distribution of strain in crystal beneath the boundary region was observed by an X-ray photographic method (§ 3) and the influence of annealing on the boundary effect was studied by means of the spectrometer (§ 4). Some supplemental experiments were also made (§ 5) to interpret more thoroughly the results obtained by the X-ray studies. Finally a strain model of the boundary region was proposed.

§ 2. Boundary Effect

Boundaries were prepared in the same way as in the previous paper[1]: after one surface of quartz plate was ground with 600 mesh carborandum, a part of it was etched. In the present case boundaries as shown in the upper left in Fig. 1 were prepared, where the shadowed regions denoted as *G* are ground regions and the other denoted as *E* is etched region. A beam of MoKα radiation from a source of an appearent size $1\times1\,mm^2$ was collimated by vertical slits about $8\times0.2\,mm^2$ and made to fall upon the range s_1-s_2 in the part $a-b$ on the plate. In this range, boundary line a_0-b_0 is parallel to the plane $(02\bar{2}2)$ which is normal to the surface and was used as the reflecting plane. A quartz plate used was of X-cut and 0.80 mm thick. By moving horizontally the plate the intensities of transmitted reflection were measured at different positions from the etched region to the ground one. In the peak value curve against horizontal positions in the specimen sketched (the p–x curve according to Kato$^{2)}$), the anomalous enhancement of intensity is observed in the range denoted as B on the abscissa. The width of this range amounts to about 0.5 mm. But the true value is estimated as about 0.3 mm after the correction for the width of incident X-ray beam.

---

* Read at Fifth International Congress of IUC in Cambridge. August 1960.

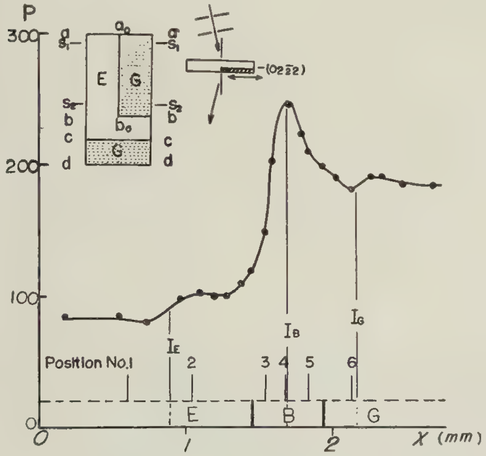

Fig. 1. Peak value curve against horizontal positions in a quartz plate sketched (p–x curve). In this sketch the shadowed regions denoted as G are the ground regions and the other region denoted as E is the etched region. Measurements were carried out only on the upper part s_1-s_2 and the reflection from $(02\bar{2}2)$ plane was used.

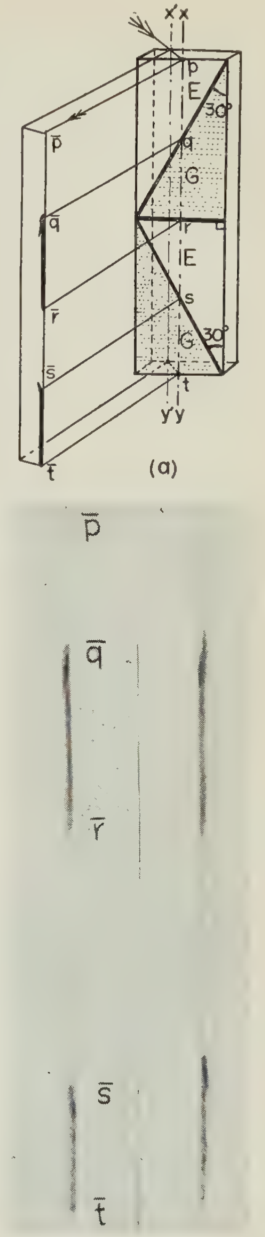
§ 3. Observations by the Photographic Method

Diffraction photographs were taken with the same reflecting plane $(02\bar{2}2)$ as in § 2 for the following two cases. The X-ray film was mounted in front of G. M. counter and the width of incident X-rays was reduced to 0.1 mm.

(3.1) *Boundary lines oblique to the reflecting plane* In this case boundary lines oblique to the reflecting plane were prepared. In Fig. 2 (a) the irradiated part is indicated by the



$(0\bar{2}22)$ $(0\bar{2}22)$
(b) (c)

Fig. 2. (a): Schematic illustrations of the specimen and the difiraction pattern. Regions denoted as E or G on the surface are etched or ground regions respectively. The irradiated part is indicated by the line x–y on the transmission side and the line cuts the boundary lines at q, r and s. (b): Diffraction pattern taken in the same arrangement as in (a). Letters denoted correspond to those in (a). (c): Pattern taken by the reflection of opposed sign against (b) and by keeping the incident and transmission sides of the surfaces unchanged.

line connecting x' and y' on the incident side and by the line connecting x and y on the transmission side. The line x–y runs through two E and two G regions and cuts the boundary lines at q, r and s. The boundary lines at q and s make the same angle of 30° to the reflecting plane, but in different directions. The boundary line at r is normal to the reflecting plane. Positions denoted as $\bar{q}$, $\bar{r}$ and $\bar{s}$ at the right margin of a diffraction pattern schematically drawn correspond to q, r and s on the boundaries respectively. The diffraction pattern obtained is shown in Fig. 2 (b). In the ranges $\bar{q}$–$\bar{r}$ and $\bar{s}$–$\bar{t}$, the intensity is, as expected, high, because the reflections came from the ground surface. At $\bar{q}$ and $\bar{s}$ the intensity is more enhanced, while at $\bar{r}$ the enhancement is scarcely seen. This result is consistent with the previous conclusion[1] that the boundary effect is observed for the transmitted reflection from a reflecting plane parallel to the boundary line and can not be observed for the reflection from a reflecting plane perpendicular to the boundary line, because the directions of the boundaries at q and s have parallel components to the reflecting plane, while the direction of the boundary at r has not.

Here will be paid attention to the shapes of reflections at $\bar{q}$, $\bar{r}$ and $\bar{s}$. It is seen that, at $\bar{q}$ and $\bar{s}$, black areas are extended deeply to the interior of the pattern like a tail, the direction of which at $\bar{q}$ is downward and that at $\bar{s}$ upward, while at $\bar{r}$ the extension is hardly seen. These extended black areas are, hereafter, called simply "extensions" with some exceptions.

Fig. 2 (c) shows a pattern taken at nearly the same position as in Fig. 2 (b), but with the reflection of opposed sign, where the incident side of the surface was kept to be unchanged. (Orientations of the quartz plate in Fig. 2 (b) and Fig. 2 (c) in relation to the in cident direction of X-rays are represented schematically by the ones in Fig. 6 (a) and Fig. 6 (b) respectively.) Each of the extensions in the pattern in Fig. 2 (c) extends in the parallel but opposite direction to the corresponding one in Fig. 2 (b).

(3.2) *Boundary lines parallel to the reflecting plane* The specimen, the p–x curve of which is shown in Fig. 1, was used and the lower part from b to d was also used as a reference part in the present case. The boundary line

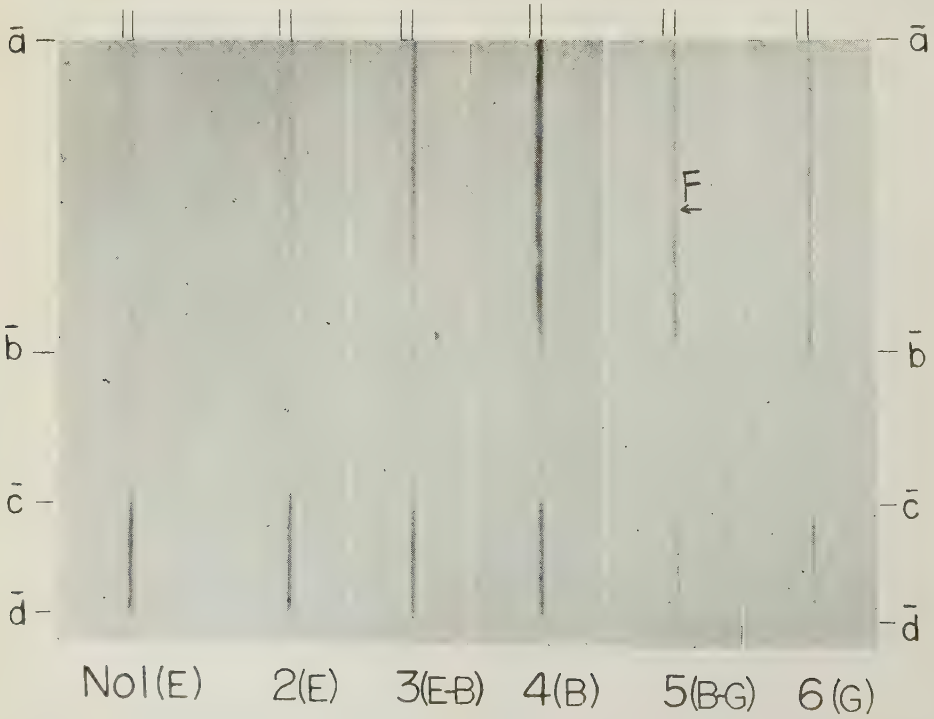


Fig. 3. Diffraction patterns taken at the horizontal positions numbered in Fig. 1. Lower part b–d in the specimen sketched in Fig. 1 is also used in the present case as a reference part.

a_0–b_0 in the upper part from a to b (Fig. 1) is parallel to the reflecting plane and the effect of this boundary was studied by the same photographic method as used in (3.1). Patterns obtained are shown in Fig. 3. These patterns were obtained at the positions numbered on the abscissa of the p–x curve in Fig. 1 and they have the corresponding serial numbers. Features in each pattern will be observed in the part $\bar{a}$–$\bar{b}$ along the pattern. The patterns No. 1 and 2 belong to the etched region. The intensities at the left and right margins of them, corresponding to the incident and transmission sides of the surface, are nearly the same and somewhat higher than at the interior of the pattern. The pattern No. 3 was obtained at the transient region from the etched region to the boundary region. The intensity of the right side margin becomes higher than the left. In the pattern No. 4, which was taken just at the position of the boundary, the margin intensity is the highest and the black area extends deeply to the interior of the pattern. In the transient region from the boundary to the ground region the black area splits into two as shown, for example, by F in the pattern No. 5. The pattern No. 6 was obtained at the ground region and both the margin intensity and the extension of the black area are not so large as in No. 4 and are nearly the same as in the part $\bar{c}$–$\bar{d}$ in that pattern.

Unfortunately the photographing conditions for each pattern were not exactly the same. Accordingly, it is impossible to compare directly the margin intensities or the extensions for all patterns. However, a qualitative comparison can be made by referring to the part $\bar{c}$–$\bar{d}$ of each pattern. Since the homogeneity is expected in the " ground region " in the part c–d on the specimen (Fig. 1), the margin intensity and extension in the corresponding parts $\bar{c}$–$\bar{d}$ of the patterns No. 4 and No. 6 should be the same if the photographing conditions are the same. Then without a serious error the effects of the boundary and ground regions would be compared by the aid of the part $\bar{a}$–$\bar{b}$ and part $\bar{c}$–$\bar{d}$ in the pattern No. 4. In this pattern the width of the extension in the part $\bar{a}$–$\bar{b}$ amounts to about 1/2 of the total width of the pattern and that in the part $\bar{c}$–$\bar{d}$ is about 1/4. The thickness of the specimen is 0.80 mm and accordingly their widths correspond to thicknesses about 0.4 mm and 0.2 mm.

§ 4. The Influence of Annealing on the Boundary Effect

The influence of annealing on the boundary effect was studied, where the $(01\bar{1}0)$ reflection was used and the p–x curves were obtained for three specimens of thickness 0.8 mm. Specimen 1 was annealed successively at 220°C, Specimen 2 at 440° and Specimen 3 at 570°. Measurements were made after the specimens were cooled. After the annealing the reductions of I_B and I_G were observed, while the variation of I_E was not found with the experimental error of 5 %. In Fig. 4, the values of $(I_X-I_E)/(I_{XO}-I_E)$ are plotted against annealing time for three specimens, where I_X means I_B or I_G, and I_{XO} means its initial value. The rates of reductions were large at the beginning of a series of annealings at each temperature, and remarkable for I_B more than for I_G. The data are not yet analysed quantitatively, but the followings can be inferred from the experimental results: No change had occured in the degree of perfection in the interior of the specimens, for the variation of I_B was scarcely detected during the present heat treatments. Thus the reductions of I_B and I_G are attributed to the reduction of strain near the surfaces at the boundary and ground regions. The larger the reduction of I_G is, the more that of I_B is.

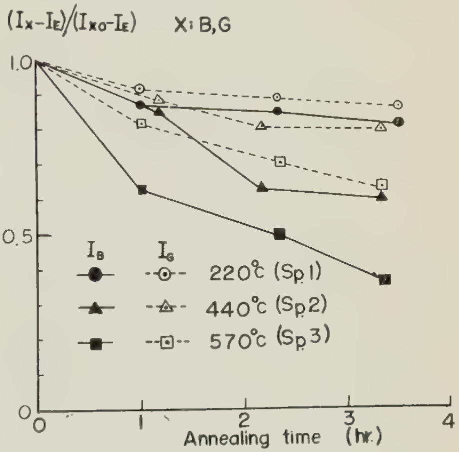

Fig. 4. Plots of $(I_X-I_E)/(I_{XO}-I_E)$ versus annealing time.

Thus it may be said that the magnitude of the strain at the boundary region depends on the one at ground region.

§ 5. Supplemental Studies of Ground Surface

Before proceeding to the nature of the strain beneath the boundary region, a few other results are presented here.

(5.1) *Scratch patterns* By scratching a polished surface of quartz plate with an edge corner of razor under the load of about 1 Kg weight and by etching it in NH_4F solution for about 3 minutes the V-shaped patterns[5] were observed along the scratching direction (Fig. 5). Similar patterns are known for glass[6] and diamond[7] too. The common feature of these patterns is that the shape is always concave to the scratching direction. The patterns are, then, thought to be the tension cracks pulled by a friction between the edge and the surface.

By grinding with carborandum, such cracks would be also produced more finely, densely and in random directions.

(5.2) *Bending of very thin plate by grinding and its easy recovery by etching* It is known that, by grinding one surface of a very thin plate, the surface is bent convexly backward.[8,9] The experiment was made here on a narrow rectangular plate of X-cut, 0.156 mm in thickness and 20 mm in length. By grinding one surface with 600 mesh carborandum, the bending of about 70 cm in radius was observed. This bending was released almost completely by a short etching for about 2 seconds in HF acid (46 %) at 25°C. The reduction of the thickness by this etching was not found and might be less than 1μ if existed.

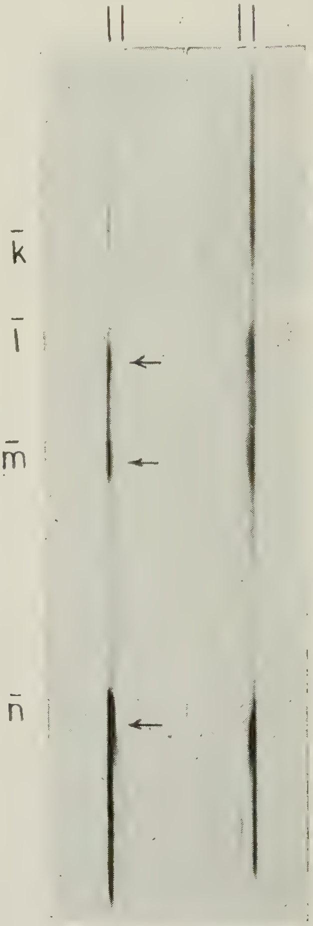
§ 6. Discussions and Conclusions

(6.1) *A strain model at the boundary* In



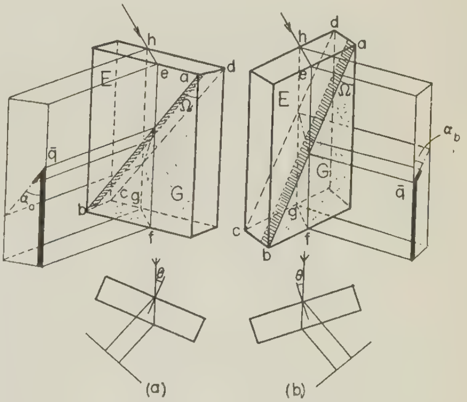
$(0\bar{2}2\bar{2})$ $(02\bar{2}2)$
(a) (b)

Fig. 8. (a): Diffraction pattern taken by the arrangement as shown in Fig. 7 (a). (b): Diffraction pattern taken by the arrangement as shown in Fig. 7 (b).

the diffraction patterns in Figs. 2 (b), (c) and 3, it is observed that the intensity of reflection in the positions corresponding to boundaries which have parallel component to the reflecting plane is greatly enhanced, while in the positions corresponding to boundaries perpendicular to the reflecting plane the intensity enhancement is absent. This result is consistent with previous observations[1,2] by means of a single or double crystal spectrometer.

Moreover, by present photographic method it was found that in the position $\bar{q}$ and $\bar{s}$ in Figs. 2 (b) and (c) the black areas extend to the interior of the patterns deeply like a tail. Such "extension" looks more remarkable in the case of the boundary parallel to the reflecting plane (the part $\bar{a}$–$\bar{b}$ in the pattern No. 4 in Fig. 3). Here, we consider that the intensity distribution in the diffraction pattern represents the topograph of strain distribution in the specimen. Then it will be inferred that the strain exists actually to a deeper layer in the specimen at the boundary region than at the ground region. The strained layers beneath the boundary and ground regions are hereafter, called "the zone of strain". It will be plausible to consider that the width of the extension of the black area is determined from the depth of the zone of strain beneath the surface and the intensity of reflection depends on the strain gradient in the zone of strain.*

Shapes of the extensions at $\bar{q}$ and $\bar{s}$ in Figs. 2 (b) and (c) will be explained by the following illustrations. Figs. 6 (a) and 6 (b) concern with the position q, for instance. Here the width of the zone of strain at the boundary region is neglected and zone of strain is assumed to extend perpendicular to the surface. That is, the zone of strain exists on the plane *abcd* which is normal to the surface and contains the boundary line. The sheet of the incident X-ray beams is expressed by the plane *efgh*. The direction of extension in the pattern is then determined from the projected line of the intersection line of the plane *abcd* and the plane *efgh*. The angle of the direction of the extension to that of the margin is expressed by $\alpha_a=\alpha_b=\tan^{-1}[(2\cos\theta\tan\Omega)/m]$ for both arrangements of Figs. 6 (a) and 6 (b), where Ω is the angle of the boundary line to the reflecting plane, m the vertical magnification and θ is Bragg angle. The equality of α_a and α_b holds actually for the extensions at $\bar{q}$ in Figs. 2 (b) and (c). This supports the above assumption that the zone of strain exists almost perpendicular to the surface. But the value of α's measured is about 10°, which differs greatly from the one, 43.5°, calculated by the above expression. To explain this discrepancy, the widths of both the zone and the incident X-rays will be needed



Figs. 6. (a) and (b): Schematic illustrations to explain the difference in the directions of the extensions of black areas at $\bar{q}$ in Figs. 2 (b) and (c).

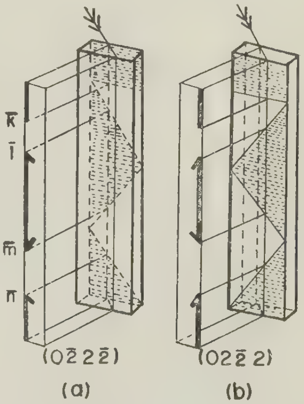


Fig. 7. Schematic illustration of a quartz plate and the diffraction pattern. (a): Boundaries on the incident side of the plate, (b): those on the transmission side.

---

* One of the present authors (E.F.) has measured the intensity of transmitted reflection from different parts of a quartz plate to which a mechanical stress was applied, and came to the conclusoin that the reduction of the extinction effect is proportional to the strain gradient perpendicular to the reflecting plane and not to the strain itself.

to be taken into account.

To study the nature of the lattice distortion in the zone of strain beneath the boundary region, a photographic method as shown schematically in Figs. 7 (a) and (b) was used: in the case (a) boundary lines are set on the incident side of a specimen and a pattern is taken, while in the case (b) the boundary lines are set on the transmission side by turning over the specimen and a pattern is taken again. The corresponding patterns are shown in Figs. 8 (a) and (b) respectively. In the surroundings of the extensions at $\bar{l}$, $\bar{m}$ and especially at $\bar{n}$ in Fig. 8 (a), anomalous reduction of intensity is observed as indicated by arrows, while in Fig. 8 (b) the reduction of intensity is absent. (A boundary line corresponding to $\bar{k}$ is perpendicular to the reflecting plane and neither the extension nor the anomalous reduction of intensity are observed.) This anomalous reduction of intensity in Fig. 8 (a) means that the greater part of the X-rays which satisfies the reflecting condition is reflected from the zone of strain on and near the surface at the boundary region which is set on the incident side of the surface, and thus the intensity of reflection at the interior of the crystal is reduced greatly more than that at the interior beneath the ground or etched region. This means also that the lattice in the zone of strain beneath the boundary region hardly misoriented against the lattice in the perfect region in the crystal. Therefore, it may be said that the boundary effect, i.e. anomalous enhancement of intensity is due to the reduction of so-called " primary " extinction in the zone of strain.[1,2]

The splitting of the extension into two, for instance, at the position indicated by F in the pattern No. 5 in Fig. 3 will be attributed to the fact that the reflection takes place separately in two zones of strain beneath the boundary and ground regions and thus it is concluded that the border of the zone beneath the boundary region is steeper to the surface than the incident angle of X-rays, $\theta=12°15'$, as illustrated in Fig. 9.

From above considerations and the experimental results shown in Figs. 1 and 3, a model of the zone of strain beneath the boundary and ground regions is proposed in Fig. 10. In the zone beneath the boundary region, the gradient of the strain is perpendicular to the boundary line (normal to the plane of figure) and parallel to the surface. The gradient is especially large in the area shaded darkly. In the zone beneath the ground region the strain gradients are present in all directions parallel to surface. Here, the depths of the zones of strain could not be determined quantitatively. According to the experiment by Sakisaka[11] the thickness of the strained layer beneath the ground surface of quartz is about 0.1 mm. On the other hand, if in our present photographs the width of the extension is assumed to express direclty the depth of the zone of strain, the depth of the zone beneath the ground region is calculated as about 0.2 mm as stated in (3.2).

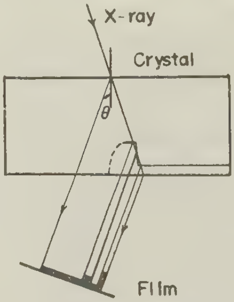

Fig. 9. Schematic illustration to explain the splitting of the extension.

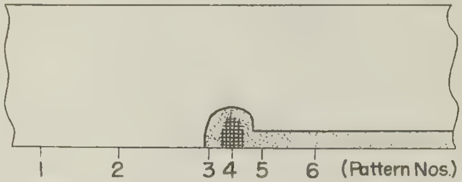

Fig. 10. Side view of the zone of strain derived from the results shown in Figs. 1 and 3.

Here, if the value given by Sakisaka is applied in the present case the depth of the zone of strain beneath the boundary region amount to about 0.2 mm or slightly more, while the depth beneath the ground region is about 0.1 mm.

(6.2) *Texture of the ground surface and the zone formation at the boundary* From the results of the supplemental experiments in § 5, the followings are inferred: Fine cracks produced by grinding the surface are forced to open by debris in them[2] and as a result the surface bending occurs. The crystal is then subjected to the stress by these cracks and the elastic strain would be generated to a considerably deep layer. In this zone of strain, two types of strain will be present: The one strain varies with short period, ideally with the same period as the cracks (Fig. 11) (a) and the other strain is a uniform, positive strain which is superposed.

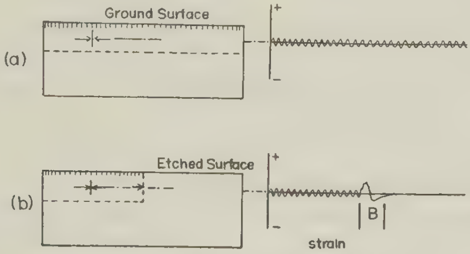

Fig. 11. (a): Schematic illustration of the variation of the strain component parallel to the ground surface. Uniform, positive strain by the bending of the plate is omitted in this figure. (b): Schematic illustration of the magnitude and variation of the strain at the boundary region.

For relatively thick crystals as used in the present X-ray studies, however, the bending by the surface grinding could not be detected. In this case the uniform, positive strain is constrainedly restricted, since the deformation of the plate as a whole is almost absent. The larger stress field is supposed to be conserved in this case than one in the case where the stress is considerably relaxed through the bending of the plate. This stress field is, on the average, compression.

When a part of the surface is etched, the cracks become easily inactive (5.2) probably through the dissolving or removing of the debris in them, and the elastic strains beneath this part disappear. The balance of the compression stress holds no longer at the boundary and new strain would appear in the layer beneath the boundary region, as illustrated in the range B in Fig. 10 (b). In this range the strain will be larger and its period will be long, while at the ground region the period is short. This will be the reason why the zone of strain extends to a deeper layer at the boundary than at the ground region as found in the present X-ray studies. It will be these strain fields that are responsible mostly for the enhancement of reflection intensity at the boundary and ground regions.

The reductions of I_B and I_G by annealing (§ 4) are considered to be attributed to the deformation of the debris in cracks by the creep at high temperature and under high pressure.

Recently, Yoneda¹²⁾ found the anomalous enhancement of the intensity of X-ray reflection from an edge of a ground surface as well as a boundary region of a quartz plate and showed that, at the edge, the strain was generated to a deeper layer than at the portion of the ground surface far from the edge. He considered that nearly the same strain distribution would be formed at the boundary region too. We also think that the similar situation will be realized between the edge and boundary.

E. Aerts, S. Amelinckx and W. Dekeyser¹³⁾ have reported the surface hardenning at the boundary between irradiated and unirradiated regions of NaCl crystal. We consider that a very close relation must exist between the results by them and us.

In conclusion the authors should like to express their sincere thanks to Prof. Ryozi Uyeda of Nagoya University and Prof. Akiya Ookawa of Gakushuin University for their helpful discussions and suggestions. We are greatly indebted also to Mr. Toshio Shinada, the chief of Kinsekisha Laboratory, for his kind discussions and indispensable help. This work was supported by the Scientific Research Fund granted by the Ministry of Education.

222-Reflection from CuCl in Electron Diffraction

By Fuminori FUJIMOTO

Institute of Physics, College of General Education, University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received January 9, 1961)

The 222-reflection of electron diffraction from CuCl is theoretically and experimentally studied. Ratio of the integrated intensity of the 222-reflection to that of the 111-reflection is calculated by expansion of the scattering matrix and by the solution of Mathieu equation. Calculated results by the both methods agree sufficiently with each other up to the grain size 140 A for 41.3 kV electrons.

The CdS detector and, in addition, the CdS monitor are used in the intensity measurement. The experimental values of the integrated intensity are found to be smaller than the theoretical values at small grain sizes of crystallites. It is, however, confirmed that the ratio of integrated intensity of the 222-reflection to that of the 111-reflection is nearly proportional to the square of grain size and the wave-length, in qualitative accordance with theory.

The 420-reflection is also measured. Dependence of the integrated intensity on wave-length is the same as that of the 222-reflection.

§ 1. Introduction

In electron diffraction, the reflection which is completely or nearly forbidden by kinematical theory has been often observed and studied theoretically by several workers[1)–5)]. Heidenreich[4)] observed abnormally strong 222-reflections from Ge and Si having the diamond structure even in Debye patterns, and attributed the phenomenon to the accidental interactions between the 311- and $\bar{1}$11-reflections. However, Hoerni[5)] pointed out that the intense 222-reflection is also expected from the systematic interactions among *lll*-reflections, and integrated that the intensity of the 222-reflection can attain to a half of the 111-reflection for a thick crystal.

On the other hand, it was reported by Germer[3)] that the intensity ratio of the 222- to the 111-reflection from CuCl decreases rapidly with the decrease of the grain size estimated from the line breadth of Debye rings. A similar phenomenon has been also recently observed in the 222-reflection from Ge[6)].

Applying the dynamical theory developed by the scattering matrix[7)], the author calculated the integrated intensity of the 222-reflection from Ge, and obtained for thin crystals the results that the contribution of the systematic interactions is much larger than the accidental interactions in the 222-reflection and the integrated intensity ratio of the forbidden reflection caused by the systematic interactions to the ordinary reflection is proportional to the square of the crystal thickness and of the wave-length, and that the integrated intensity ratio of the forbidden reflection caused by the accidental interactions such as the 420-reflection, to that due to systematic interactions such as the 222-reflection is independent of the wave-length and is inversely proportional to the crystal thickness[8)].

Table I. Characteristics of CdS detector and monitor.

	Slit width mm	Cryst. width mm	Applied voltage Volt	n	Gain
Detector	0.03	0.67	1.5	0.98	3.5×10^7 (41.3 kV) 2.1×10^7 (23.5 kV)
Monitor	0.08	1.00	1.5	0.93	2.2×10^6 (41.3 kV) 1.3×10^6 (23.5 kV)

In the present paper, we made the similar numerical calculations on the integrated intensities of the 111- and 222-reflections from CuCl by the method proposed by Hoerni making use of the Mathieu function, and checked the range of crystal thickness within which the formula previously deduced by the author is applicable.

The intensity of Debye patterns from CuCl of various grain sizes was measured for various wave-lengths by using the CdS detector developed by us[9], and we performed a quantitative comparison of the 222-reflection between experiment and theory. Further, a qualitative study on the 420-reflection, which is considered to be caused by the accidental interactions exclusively, was also carried out. In the present study, the accuracy of the intensity measurements could be considerably improved by the use of an additional CdS monitor.

§ 2. Experimental

A conventional diffraction camera with a forcussing lens was used. The distance between detector and specimen, and that between plate and specimen were 22.6 and 23.7 cm, respectively. At the front of the specimen, a slit with the diameter 0.08 or 0.25 mm was set. Five specimens having different thicknesses were prepared on collodion films successively by vacuum evaporation in in the camera. The accelerating voltages were 41.3 and 23.5 kV.

The arrangement of the CdS detector was the same as described previously. Another CdS crystal used as monitor was set at about 1 cm apart from the beam stop. The crystals used for the detector and monitor in the present study correspond to the samples No. 8 and 2 described in the previous paper, respectively, and their characteristics are tabulated in Table I, where n is the parameter in the well known formula $i\propto I^n$, i and I being the electron-bombardment-induced-current (EBIC) and the electron intensity, respectively. The parameter n and the gain change to a small extent after the exposure to air. Detailed characteristics are given in the previous paper. Examples of the characteristic curves of the

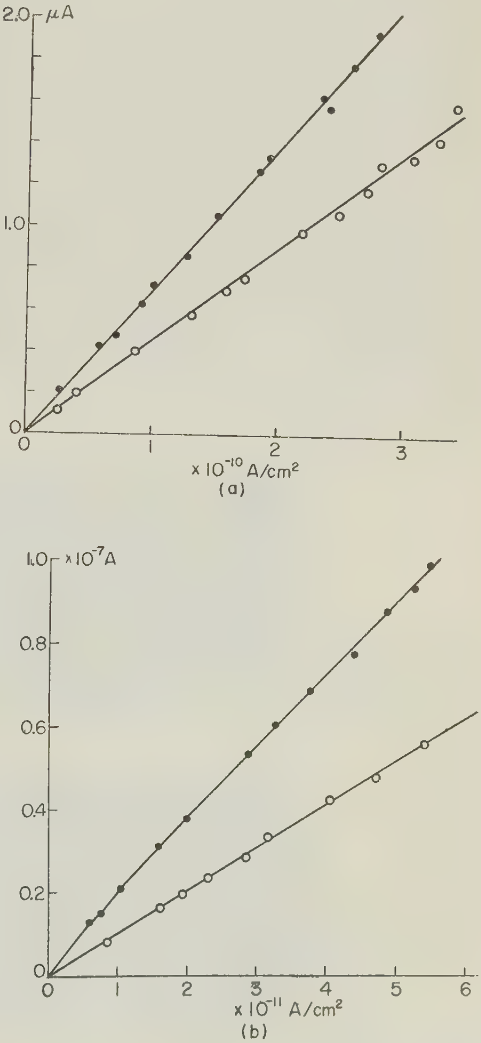

Fig. 1. Characteristic curves for (a) detector and (b) monitor.
●: 41.3 kV; ○: 23.5 kV.

detector and monitor are shown in Fig. 1 (a) and (b), respectively. During the experiment, the characteristic curves were measured at each time after the vacuum was broken.

The incident-beam intensity was controlled so as the EBIC of the detector at the 111-reflection becomes about 1.5 μA, in order to eliminate the error caused by the response time of EBIC. For 41.3 kV, the smaller slit before the specimen was usually used. When the grain size was smaller than 100 A, the diffracted intensity from CuCl gradually decreased by the vaporization of specimen during the measurement and, to avoid this effect, the current density of electrons on the specimen was reduced by using a larger slit and decreasing the total current. For 23.5 kV, the larger slit was used.

The intensity curve for each specimen was measured several times. Long-time fluctuation of the incident intensity was usually within 3%. We corrected the observed diffracted intensities by the EBIC of the monitor assuming the linear relation. When the observed intensity is to be corrected for the change of the monitor current amounting to 10% the error introduced by the linear approximation is 1% with a monitor crystal for which $n=0.9$. The corrected intensity curves coincided with each other within 1%.

The effect of the width of the detector on the line breadth of the observed line profile was as follows. If the sensitive region of detector is assumed to possess a square profile and the intensity profile of ring to be the Cauchy type, the apparent line bread this 5% larger than the true breadth when the slit width is 0.4 of the true breadth. The difference of the apparent breadth from the true one decreases rapidly with the increase of the line breadth. As, in the present experiment, the slit width of the detector was 0.03 mm and the minimum value of the measured line breadth was 0.12 mm, the effect of slit width could be neglected even for the smallest line breadth.

Some examples of the intensity curves of Debye patterns are shown in Fig. 2, in which (a) and (b) are the curves for CuCl with the grain size about 120 A for 41.3 and 23.5 kV, respectively. The intensity scale for the middle and outer parts of the Debye patterns are enlarged respectively twice and 4 times of that for the inner part, by changing the input resistance of a recorder of 2 mV in full scale. The speed of detector was usually 2 mm/min and the running speed of recorder was 8 cm/min.

§ 3. Theory

The crystal structure of CuCl is the ZnS

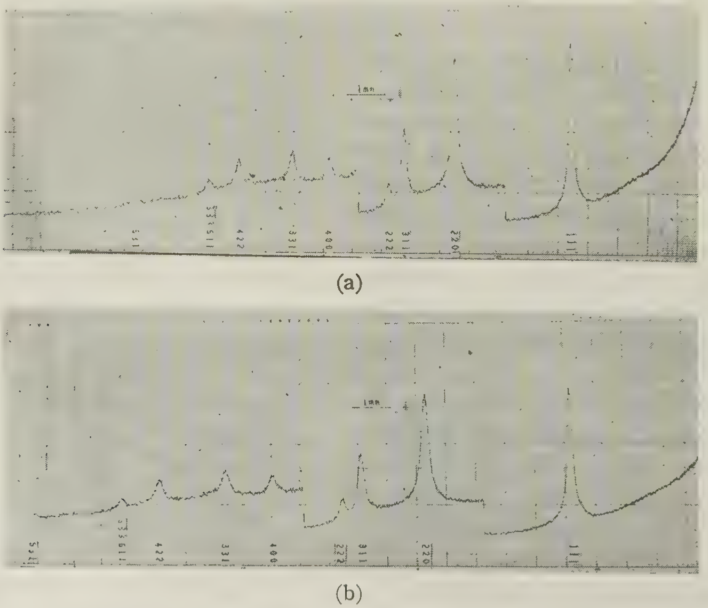

Fig. 2. Intensity curves from CuCl with grain size 120A. The middle and outer parts of the intensity curves are enlarged twice and 4 times of that of the inner part. (a) for 41.3 kV, (b) 23.5 kV.

type with the lattice constant $a_0=5.406$ A and the magnitude of structure factors for the 111- and 222-planes are given by $4(f^2{}_{\text{Cu}}+f^2{}_{\text{Cl}})^{1/2}$ and $4(f_{\text{Cu}}-f_{\text{Cl}})$, respectively, in which f is the atomic scattering factor for electrons. In Table II, the Fourier coefficients calculated from the X-ray scattering factors given by Berghius et al.[10] and James and Brindley[11] are tabulated.

Table II. Fourier potentials of CuCl calculated from X-ray scattering factors given Berghius et al. and James and Brindley.

	Berghius et al.	James & Brindley	
		Hatree	Interpolation
111	6.15 eV	7.3 eV	6.2 eV
222	0.56 eV	0.75 eV	0.29 eV

The author previously deduced the intensity formula for the forbidden 222-reflection from Ge by the use of expansion of the scattering matrix, taking account of the 0-, 111- and 222-waves, assuming the parallel-sided crystal. We can apply the same formula in calculating the intensity of the 222-reflection from CuCl, since the structure factor for the 222-reflection is considerably smaller than that for the 111-reflection as seen from Table II.

The ratio between the total intensities along Debye rings of the 111-reflection and the 222-reflection is given by

$$\frac{J_{222}}{J_{111}}=\frac{\sqrt{2}}{8}v^2{}_{111}\left(\frac{D}{2k}\right)^2\left\{1-\frac{1}{18}\left(\frac{D}{2k}\right)^2 b^4{}_{111}\right\}, \tag{1}$$

where D is the crystal thickness, $k=2\pi/\lambda$, $b_{111}=2\pi/d_{111}$. The Fourier coefficient v_{hkl} is related to the crystal potential $V(\boldsymbol{r})$ given by the following formula:

$$-\frac{8\pi^2m}{h^2}V(\boldsymbol{r})=\sum_h v_h \exp(i\boldsymbol{b}_h\boldsymbol{r})\,. \tag{2}$$

In order to determine the applicable range of (1) with respect to the thickness D, the higher terms should also be calculated. However, such a calculation is very tedious. In order to see the influence of the neglected higher terms, therefore, we compared the calculated result of (1) with the result obtained by the method assuming the harmonic potential as was developed by Hoerni, although this method includes some ambiguities as discussed later.

The solution based on the harmonic potential can be obtained as follows. Assuming v's to be zero except v_{111} and $v_{\bar{1}\bar{1}\bar{1}}$ in (2), we have the following harmonic potential as

$$-\frac{8\pi^2m}{h^2}V(\boldsymbol{r})=2v_{111}\cos b_{111}x\,,$$

where x is the coordinate in the direction of b_{111} and is parallel to the crystal surface. The Schrödinger equation for such a potential reduces to the Mathieu equation, for which the solution of period π and 2π and corresponding eigen values have been tabulated[12]. Through these solutions and eigen values, the normalized eigen vector $\boldsymbol{\psi}^i$ with the components $\psi^i{}_h$ and "Ampassung" ζ^i belonging to i-th wave field can be easily calculated in the case when k_τ/b_{111} is integer or half integer. Here k_τ indicates the tangential component of the incident wave vector. The intensity of the diffracted beam from the crystal is given by

$$I_h=\sum_{ij}\psi_h{}^{i*}\psi_0{}^{i*}\psi_h{}^{j*}\psi_0{}^{j}\exp i(\zeta^i-\zeta^j)D\,.$$

Although the calculation of the intensities at the position where k_τ/b_{111} is neither integer nor half integer is very difficult, we can interpolate between the discrete values reasonably for small values of the crystal thickness. The intensities at larger crystal thickness may be

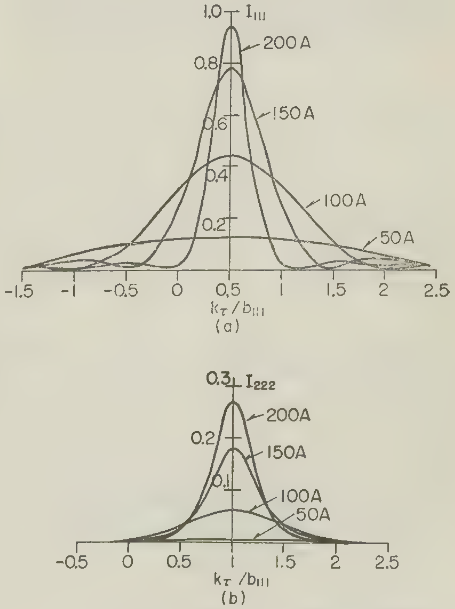

Fig. 3. Rocking curves obtained from the solution of Mathieu equation for various thickness. (a) 111-reflection, (b) 222-reflection.

obtained by considering the successive variation of intensity with thickness.

As shown in Table II, the calculated values of the Fourier coefficients depend on the choice of the atom form factor. In the present numerical calculation of the integrated intensities of the 111- and 222-reflections, the value 6.2 eV for the 111-potential was adopted. Fig. 3 (a) and (b) show the intensity curves of the 111- and 222-reflections calculated for 41.3 kV at various thickness by assuming the harmonic potential. The abscissa indicates the magnitude relating to the tangential component of incident wave vector. The integrated intensity ratio of the 222- to 111-reflection obtained by the numerical integration of Fig. 3 is given by Curve 2 in Fig. 4.

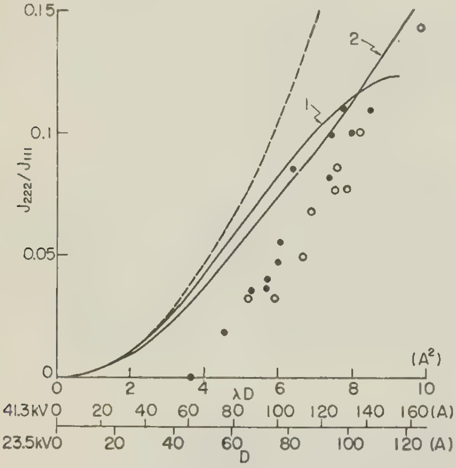

Fig. 4. Integrated intensity ratio J_{222}/J_{111} as the function of λD. Curve 1 shows the calculated values from the expansion of scattering matrix and the dotted line indicates the first term of Eq. (1). Curve 2 shows the calculated values from Mathieu function. Black and white circles are experimental results for 41.3 and 23.5 kV respectively.

The integrated intensity ratio calculated from (1) is given by Curve 1 in Fig. 4, where the dashed line corresponds to the first term of (1).

Curves 1 and 2 are in a satisfactory agreement with each other in the range up to $\lambda D=8$, suggesting that the relation (1) may be applied for $\lambda D<8$ at least.

§ 4. Experimental Results

i) *Grain Size*

In investigating the intensity variation with the grain size, the estimation of the latter quantity is very important. The grain size is usually obtained from the line breadth through the formula[13]

$$\frac{B}{\lambda L}=\frac{1}{D}+\eta\frac{2\sin\theta}{\lambda}\,, \qquad (3)$$

where B is the line breadth, L the camera length, η the mean strain and θ the Bragg angle. In Fig. 5, the values $B/\lambda L$ of each reflection are plotted against $2\sin\theta/\lambda$ on two specimens, where the values of B are corrected by substracting the half breadth of primary beam, 0.028 mm; black circles and triangles represent the values at 41.3 kV and white ones represent those at 23.5 kV.

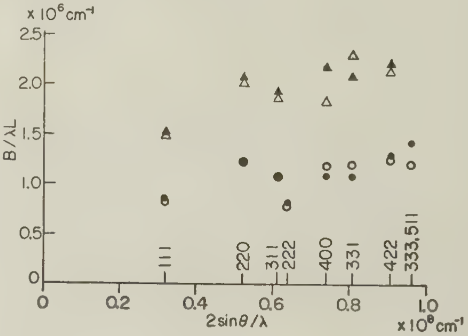

Fig. 5. Line breadth for two specimens.
● and ▲: 41.3 kV, ○ and △: 23.5 kV.

The observed points for the same reflection show fairly good agreements between two voltages, especially for low indeces, and are approximately in accordance with the relation (3). However, for simplicity, we adopt here the values of grain sizes obtained by applying the Scherrer formula, $B/\lambda L=1/D$, to the 111-reflection, as η is not so large and the estimation according to (3) is laborious.

In order to check the values estimated from Scherrer formula, a direct measurement of the grain size were made by electron microphotographs on a specimen for which the grain size estimated from the 111-reflection breadth was 120 A. Although, as seen in Fig. 6, the size of crystallites in the micrographs are widely distributed, the estimated mean size is about 120 A and in a agreement with the diffraction result.

ii) *Intensity of 222-Reflection*

Dependence of the intensity of 222-reflection on the crystal grain size can be observed from the comparison of Fig. 2 (a), and Fig. 7 (a) and

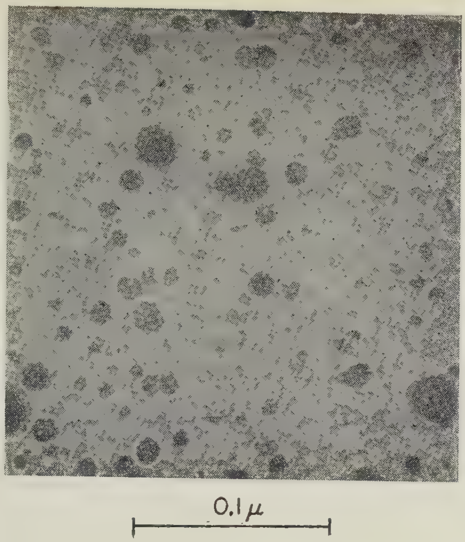

Fig. 6. Electron microphotograph of CuCl.

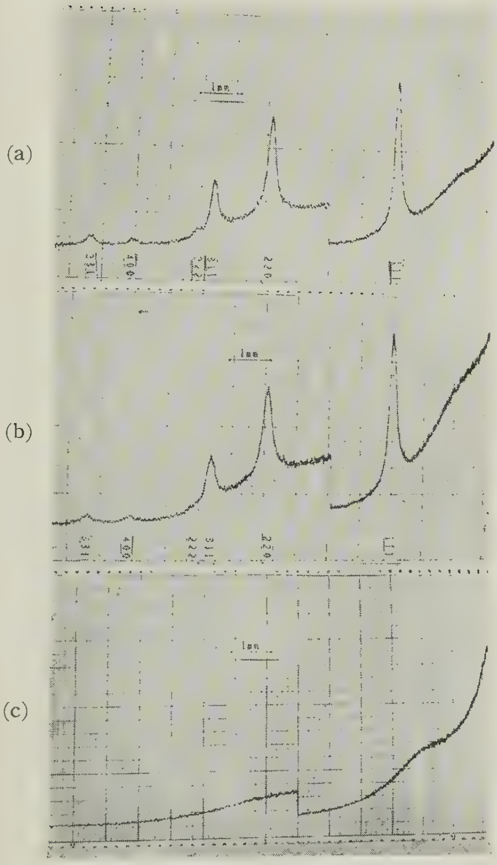

Fig. 7. Intensity curves from CuCl with (a) 100A and (b) 80A. (c) is the intensity curve from collodion. The outer parts are enlarged twice of the inner part.

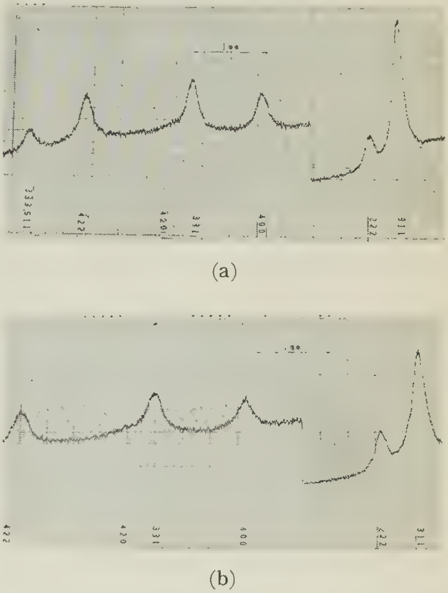
(b) in the case of 41.3 kV. These curves correspond to the grain sizes of about 120 A, 100 A and 80 A, respectively. Fig. 7 (c) shows the intensity curve for a collodion film as a reference.

Dependence of the intensity from the same specimen on the wave-length is seen in Fig. 2 (a) and Fig. 8 (a) for 41.3 kV and Fig. 2 (b) and Fig. 8 (b) for 23.5 kV. These observations reveal the fact that the change of the 222-reflection with grain size and wave-length is is clearly different from that of the ordinary reflections.



(a)

(b)

Fig. 8. Intensity curves from CuCl with grain size 120A. (a) 41.3 kV and (b) 23.5 kV.

In the comparison of the intensities of the 111- and 222-reflections, the peak areas may be estimated by the product of peak height and half breadth of the reflections. As seen in Fig. 5, the line breadths of 222-reflections agree with those of 111-reflections within the error of measurement. In cases the 222-reflection is weak, however, it is difficult to measure directly the breadth because of the bad separation from the intense 311-reflection. We, therefore, assumed that the breadth of the 222-reflection is always equal to that of the 111-reflection, and the integrated intensity was estimated only from the peak height.

The results are shown in Fig. 4, where the white and black circles correspond to 41.3 kV and 23.5 kV, respectively. The results for both the accelerating voltages agree sufficiently with each other. However, the experimental values are smaller than the theoretical ones, especially at small λD. Discussion about this discrepancy will be given in the next section. If we assume that the experimental results are proportional to $(\lambda D)^n$, the best fit is given by

$$n=2.08 .$$

In thicker specimens, the values of the intensity ratio larger than 0.15 were sometimes observed. However, in such cases, the intensity of background was large and the grain size estimated from the breadth of the 111-reflection was fairly small, probably as the results of plural scattering among crystallites[14]. Thus, these values were omitted from our results.

iii) *Intensity of 420-Reflection*

Fig. 8 (a) and (b) show the intensity curves obtained with strong incident beam from the specimen of the grain size 120 A at 41.3 kV, and 23.5 kV respectively. The driving speed of the detector in these measurements was a half of previous one. In each pattern, the weak 420-reflection appears at outside of the 331-reflection. We may easily notice that the dependence of the 420-reflection intensity on the wave-length is again different from that of ordinary reflections. The relative intensities of ring of the 420-, 222- and 331-reflections are tabulated in Table III, from which we can see that the dependence of the 420-reflection intensity on the wave-length is the same as that of 222, in spite of the difference that the appearance of 420 is caused by only the accidental interactions and that of 222 is mainly due to the systematic interactions. This relation has already been explained in the previous paper. In Ge, the same effect are found[15]. Detailed consideration will be given in the near future.

Table III. Relative intensities of each reflection

	420	222	331
41.3 kV	5	58	56
23.5 kV	5	60	37

§ 5. Discussion

As seen in Fig. 4, the experimental values are smaller than the theoretical values, especially at small λD. We consider now the probable causes for this discrepancy.

In the calculation of the theoretical curves of J_{222}/J_{111}, v's other than v_{111}, in particular v_{222}, are neglected. Although the more precise investigation on the influence of these neglected v's is necessary, it is conceivable that the influence of this approximation will be not appreciable.

As to the accuracy of the intensity measurement, it is probable that the error of the observed intensity of the 222-reflection may be appreciable for the specimen with small grain size for the reason of the bad separation from the intense 311-reflection. However, the same is not the case for the specimen with larger grain sizes, and the deviation of the observed points for larger D from the theorectical curves seems to be outside the experimental error.

The discrepancy may be caused by systematic errors in the estimation of the grain size. In the present experiment, the grain size was estimated from the breadth of the 111-reflection by assuming the Scherrer formula. If the more precise relation (3) is applied, a D-value larger than that deduced from the Scherrer formula is to be obtained, and as the result, the deviation of experimental points from the theoretical curves may become even greater. Therefore, the discrepancy shown in Fig. 4 seem to be not explained by the errors accompanying the measurement of the breadth, though the error of about 20% can not be avoided so long as the grain size is estimated from the line breadth.

In the calculation of the theoretical curves, we assumed that the crystal is perfect and is a parallel-sided plate with a definite thickness. Actually, however, the crystallites are generally granular with widely distributed grain sizes as seen in Fig. 6. Further, the crystallites may not be perfect crystals since the mean strain η estimated from (3) attains 0.5~1.0%. The deviation of the observed points from the linear relation also suggests that the lattice defects are present in crystallites. By taking accout of such circumstances, we can conclude qualitatively as follows:

i) When we assume that the crystal is spherical, the theoretical value of the integrated intensity ratio J_{222}/J_{111} decreases by the factor 3/5, since the integrated intensity of the 222- and 111-reflections are proportional to D^3 and D, respectively*.

ii) If we take account of the distribution of the grain size, the ratio J_{222}/J_{111} should increase for the same reason as mentioned in i)**.

iii) If the crystal is not perfect and contains many faults, the intensity of the 222-reflection will decreases more appreciably than that of 111, since the 222-reflection caused by the dynamical effect is sensitive for the crystal perfectness.

The discrepancy between experiment and theory can be reduced to some extent by the consideration i) and iii), but will be aggravated by the consideration ii).

As considered in the above discussion, there exist a number of complicating factors which may result in the discrepancy between theory and experiment, and it seems to be difficult to reach a satisfactory explanation for the discrepancy at the moment. However, so far as main features are concerned, the observed results in the present experiment may be considered to be in a considerable agreement with the theory.

The author would like to thank Prof. K. Kohra and S. Takagi for their encouragement. This work was partly supported by a research grant of the Minister of Education.

---

* When the crystallite is small and the shape is spherical, the integrated intensity of the 222-reflection J'_{222} is calculated by

$$J'_{222} \propto \int_0^{D/2} 2^3\{(D/2)^2 - x^2\}^{3/2} 2\pi x dx \, .$$

Applying the similar formula for J'_{111}, we get

$$\frac{J'_{222}}{J'_{111}} = \frac{3}{5} \frac{J_{222}}{J_{111}} \, .$$

** Assuming that the size distribution is Gaussian, the integrated intensity of the 222-reflection J''_{222} is calculated by

$$J''_{222} \propto \int_{-\infty}^{+\infty} D^3 \exp(-\alpha(D-D_0)^2) dD \, ,$$

and we get

$$\frac{J''_{222}}{J''_{111}} = \left(1 + \frac{3}{2\alpha D_0^2}\right) \frac{J_{222}}{J_{111}} \, .$$

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 16, No. 5, MAY, 1961

The Dipole Moment and End-to-End Length of the Isotactic Vinyl Polymer, III.
Convergence of Neumann Series

By Tsugio MORI

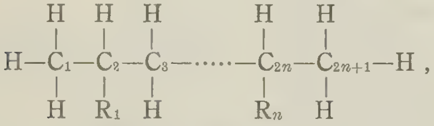
Ôtsu Senior High School, Ôtsu, Shiga-ken, Japan

(Received January 24, 1961)

The theory of dipole moment and end-to-end length of isotactic polymer is described. The problem of convergence of the infinite series in the matrix, which expresses a transformation of the bond vector, is studied in detail, a skeletal chain of linear polymer being regarded as a vector sum of many C–C bond vectors. The method of classifying the chain configurations is given on the basis of the convergence property of the series, which is an extension of the Neumann series. The polymer chain must be Gaussian, if the segments of polymer can rotate independently of each other. The hindrance potential for the internal rotation is assumed to be of the square-well type.

§ 1. Classification of Chain Configurations

We consider the dilute solution of the isotactic vinyl polymer



$$\begin{array}{ccccccccccccc} & & \mathrm{H} & & \mathrm{H} & & \mathrm{H} & & \mathrm{H} & & \mathrm{H} & & \\ & & | & & | & & | & & | & & | & & \\ \mathrm{H} & — & \mathrm{C}_1 & — & \mathrm{C}_2 & — & \mathrm{C}_3 & —\cdots\cdots— & \mathrm{C}_{2n} & — & \mathrm{C}_{2n+1} & — & \mathrm{H}\,, \\ & & | & & | & & | & & | & & | & & \\ & & \mathrm{H} & & \mathrm{R}_1 & & \mathrm{H} & & \mathrm{R}_n & & \mathrm{H} & & \end{array}$$

where the skeletal carbon atoms are numbered successively from one end of the skeletal chain, and the notations $\mathrm{R}_1, \cdots, \mathrm{R}_n$ are the numbered dipolar substituents. The mean square dipole moment $\langle\mu^2\rangle$ of this polymer is given by

$$\frac{\langle\mu^2\rangle}{n\mu_0^2}=1+\frac{2}{n}\sum_{i<j}^{n}\sum\langle\cos\omega_{ij}\rangle\,, \qquad (1)$$

where μ_0 is the absolute value of $\boldsymbol{\mu}_i$ which denotes the electric dipole moment vector of the side chain $\mathrm{C}_{2i}—\mathrm{R}_i$, and ω_{ij} is the angle between two vectors $\boldsymbol{\mu}_i$ and $\boldsymbol{\mu}_j$. The mean square end-to-end length $\langle R^2\rangle$ of this polymer is also written in a similar manner. If we put

$$N=2n+1\simeq 2n\,, \qquad (2)$$

we have

$$\frac{\langle R^2\rangle}{Nb_0^2}=1+\frac{1}{n}\sum_{i<j}^{2n}\sum\langle\cos\theta_{ij}\rangle\,, \qquad (3)$$

where b_0 is the absolute value of $\boldsymbol{b}_i$ which denotes the bond vector $\mathrm{C}_i—\mathrm{C}_{i+1}$, and θ_{ij} is the angle between two vectors $\boldsymbol{b}_i$ and $\boldsymbol{b}_j$.

Then the configurations of the polymer skeletal chain are classified as given in Table I which is based upon the order of infinity of the expression

$$\lim_{n\to\infty}\frac{1}{n}\sum_{i<j}^{2n}\sum\langle\cos\theta_{ij}\rangle\,.$$

Therefore, if we wish to calculate $\langle R^2\rangle$, the estimation of $\sum\sum\langle\cos\theta_{ij}\rangle$ is an important problem for us, and it is closely connected with the calculation of $\langle\mu^2\rangle$.

Table I. Classification of chain configurations.

Configuration		$\lim(\sum\sum\langle\cos\theta_{ij}\rangle/n)$
Gaussian chain	Random coil	0
	General Gaussian chain	A const. ($\neq 0$)
Interrupted configuration		The infinity of the order of n^{ν} (where $0<\nu<1$)
Rod configuration (including the crystalline one)		The infinity of the order of n

§ 2. Independent Segment Rotation and Neumann Series

We assume that the polymer skeletal chain in the dilute solution is the connection of many segments as the Markoff process. If the word "segment" signifies the C–C bond itself, and each bond rotates freely only subject to the condition that the bond angle $\pi-\gamma$ and the bond length b_0 are both constant, then (1) and (3) are reduced to

$$\left.\begin{aligned}\frac{\langle\mu^2\rangle}{n\mu_0{}^2}&\longrightarrow 1-\frac{2\alpha^3}{\beta^2}=0.92\\ \text{and}\qquad&\\ \frac{\langle R^2\rangle}{Nb_0{}^2}&\longrightarrow\frac{1+\alpha}{1-\alpha}=2\,,\end{aligned}\right\}\tag{4}$$

respectively. In evaluating this we use the values

$$\alpha=\cos\gamma=\frac{1}{3}\quad\text{and}\quad\beta=\sin\gamma=\frac{\sqrt{8}}{3}\,,\tag{5}$$

where γ is the supplement of the bond angle.

Next, if the segment signifies the monomer $CH_2—CHR$, and the rotations of segments and bonds are hindered by some causes, $\sum\sum\langle\cos\omega_{ij}\rangle$ and $\sum\sum\langle\cos\theta_{ij}\rangle$ are given by

$$\sum_{i<j}^{n}\sum\langle\cos\omega_{ij}\rangle=(001)\,\mathbf{Y}^T\mathbf{X}\left(\sum_{i<j}^{n}\sum\mathbf{X}^{j-i-1}\right)\mathbf{Y}\begin{pmatrix}0\\0\\1\end{pmatrix}\tag{6}$$

and

$$\sum_{i<j}^{2n}\sum\langle\cos\theta_{ij}\rangle=(001)\left\{(\mathbf{Z}+\mathbf{X})\left(\sum_{k<l}^{n}\sum\mathbf{X}^{l-k-1}\right)(\mathbf{1}+\mathbf{Z}')+n\mathbf{Z}'\right\}\begin{pmatrix}0\\0\\1\end{pmatrix},\tag{7}$$

respectively, where $\mathbf{1}$ is the unit matrix, and the notations $\mathbf{X}$, $\mathbf{Y}$, $\mathbf{Y}^T$, $\mathbf{Z}$, $\mathbf{Z}'$ are the matrices given in the preceding papers[1),2)]. The double summation in the right hand sides of these expressions should be read

$$\frac{1}{n}\sum_{i<j}^{n}\sum\mathbf{X}^{j-i-1}=(\mathbf{1}-\mathbf{X})^{-1}\left\{\mathbf{1}+\frac{1}{n}(\mathbf{1}-\mathbf{X})^{-1}(\mathbf{X}^n-\mathbf{1})\right\}\tag{8}$$

when $\mathbf{X}\neq\mathbf{1}$. Here n may be regarded as ∞, for $n=10^2\sim10^5$, and $\mathbf{X}$ is not the number, but the matrix. The infinite geometric series of matrix,

$$\mathbf{1}+\mathbf{X}+\mathbf{X}^2+\cdots\,,$$

is called the Neumann series[3)]. The left hand side of (8) may be regarded as an extension of the Neumann series. Hereupon the following principle can be stated.

Principle 1. The extended Neumann series appears in the calculations of $\langle\mu^2\rangle$ and $\langle R^2\rangle$ so far as we assume that the linear polymer is composed of segments whose rotations are independent of each other.

This principle undergoes no change whatever hindrance the segment rotation suffers. In this way, the convergence of the extended Neumann series becomes our subject.

§ 3. Convergence of Extended Neumann Series, I. General Theory

First we compare two series

$$\mathrm{S}_1=\lim_{n\to\infty}\sum_{i=1}^{n}\mathbf{X}^{i-1}\tag{9}$$

and

$$\mathrm{S}_2=\lim_{n\to\infty}\frac{1}{n}\sum_{i<j}^{n}\sum\mathbf{X}^{j-i-1}\,,\tag{10}$$

where the former is the ordinary Neumann series, and the latter is the extended one. If $\mathbf{X}\neq\mathbf{1}$, we have

$$\mathrm{S}_1=\lim_{n\to\infty}(\mathbf{1}-\mathbf{X})^{-1}(\mathbf{1}-\mathbf{X}^n)\,.$$

Therefore $\lim\mathbf{X}^n$ is a constant matrix if S_1 is convergent. Under this condition, we have

$$\lim_{n\to\infty}\frac{1}{n}\mathbf{X}^n=\mathbf{0}\,,$$

and this formula and (8) yield

$$\mathrm{S}_2=(\mathbf{1}-\mathbf{X})^{-1}\,.$$

In this way, we have the following theorem:

Theorem 1. If the Neumann series S_1 is convergent, then the series S_2 is also convergent.

Next, let us denote the nine elements of $\mathbf{X}$

by X_{kl}:

$$\mathbf{X}=(\mathrm{X}_{kl})=\begin{pmatrix} \mathrm{X}_{11} & \mathrm{X}_{12} & \mathrm{X}_{13} \\ \mathrm{X}_{21} & \mathrm{X}_{22} & \mathrm{X}_{23} \\ \mathrm{X}_{31} & \mathrm{X}_{32} & \mathrm{X}_{33} \end{pmatrix}, \tag{11}$$

and the maximum of the absolute values $|\mathrm{X}_{kl}|$ by X_m, namely,

$$\mathrm{X}_m=\max(|\mathrm{X}_{11}|, |\mathrm{X}_{12}|, \cdots, |\mathrm{X}_{33}|). \tag{12}$$

Then a dominant series of S_1 is

$$(1+\mathrm{X}_m+3\mathrm{X}_m^2+3^2\mathrm{X}_m^3+\cdots)\begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{pmatrix}. \tag{13}$$

This series is convergent when $\mathrm{X}_m<1/3$. Therefore, we conclude that:

Theorem 2. If $\mathrm{X}_m<1/3$, *the Neumann series* S_1 *is convergent.*

Theorem 3. If $\mathrm{X}_m<1/3$, *the series* S_2 *is convergent.*

On the other hand, the following theorem is verified after the diagonalization of S_1 and S_2:

Theorem 4. If all absolute values of eigenvalues of the matrix **X** *are smaller than* 1, *the series* S_1 *and* S_2 *are convergent.*

§ 4. Convergence of Extended Neumann Series, II. Square Well Potential

In the preceding paper[2)], we assumed that the internal rotation of skeletal chain of the polymer was governed by the square well potential,

$$\left.\begin{aligned} V&=0 && (\text{when } 0\leqq|\varphi|\leqq\mathcal{E}) \\ &=\infty && (\text{when } |\varphi|>\mathcal{E}), \end{aligned}\right\} \tag{14}$$

where φ is the rotation angle of the C–C bond, and $2\mathcal{E}$ the parameter which represents the width of the potential well. It was also assumed that the monomer is regarded as the segment, and the linear function

$$\varphi'=\lambda\varphi+\frac{2\pi}{3} \tag{15}$$

was introduced, where the independent variable φ and the dependent variable φ' are the rotation angles of the two adjoining C–C bonds which belong to the same segment. The coefficient λ in (15) is the parameter which signifies a kind of flexibility measure of the segment. In particular, the value $\lambda=0$ corresponds to the rigid segment, and the numerical calculations of $\langle\mu^2\rangle$ and $\langle R^2\rangle$ were carried out in the cases $\lambda=0, 1, -1$. But, in the preceding papers[1),2)], we neglected the discussion whether the extended Neumann series is convergent or not. Then it becomes the main subject of the present paper to verify the convergence of that series with use of the theorems described in § 3.

In the same manner as that of the preceding papers, we can obtain the expressions for nine elements of the matrix **X** under the assumptions (14) and (15), and the results are collected in Table II, where

Table II. X_{kl} expressed as the functions of ε.

	$\lambda=0$	$\lambda=1$	$\lambda=-1$
X_{11}	$-\frac{1}{18}(8+f_1)$	$\frac{1}{18}(1-8f_1-2f_2)$	$-\frac{1}{18}(2+8f_1-f_2)$
X_{12}	$-\frac{\sqrt{3}}{2}f_1$	$-\frac{\sqrt{3}}{6}(1+2f_2)$	$-\frac{\sqrt{3}}{6}(2+f_2)$
X_{13}	$-\frac{\sqrt{2}}{9}(1-f_1)$	$-\frac{\sqrt{2}}{9}(1+f_1-2f_2)$	$\frac{\sqrt{2}}{9}(2-f_1-f_2)$
X_{21}	$\frac{\sqrt{3}}{18}(8+f_1)$	$-\frac{\sqrt{3}}{18}(1-8f_1-2f_2)$	$\frac{\sqrt{3}}{18}(2+8f_1-f_2)$
X_{22}	$-\frac{1}{2}f_1$	$-\frac{1}{6}(1+2f_2)$	$-\frac{1}{6}(2+f_2)$
X_{23}	$\frac{\sqrt{6}}{9}(1-f_1)$	$\frac{\sqrt{6}}{9}(1+f_1-2f_2)$	$-\frac{\sqrt{6}}{9}(2-f_1-f_2)$
X_{31}	$\frac{2\sqrt{2}}{9}(1-f_1)$	$\frac{2\sqrt{2}}{9}(1-f_1)$	$\frac{2\sqrt{2}}{9}(1-f_1)$
X_{32}	0	0	0
X_{33}	$\frac{1}{9}(1+8f_1)$	$\frac{1}{9}(1+8f_1)$	$\frac{1}{9}(1+8f_1)$

$$f_1=\frac{\sin \varepsilon}{\varepsilon} \quad \text{and} \quad f_2=\frac{\sin 2\varepsilon}{2\varepsilon} . \tag{16}$$

According to Table II, we can calculate the values of X_{kl} as the functions of ε within the interval $0\leqq\varepsilon\leqq\pi$, and plot X_{kl} against ε. Corresponding to $\lambda=0, 1, -1$, these plots are illustrated in Figs. 1, 2 and 3, respectively, where the insertion of numerical tables is neglected.

Let us discuss the case $\lambda=1$ as an example in the problem of convergence. It is shown by Fig. 2 that the premise of Theorem 3 is satisfied in the small domain $2.9<\varepsilon\leqq\pi$. However, if we wish to confirm the convergence of the series $\mathbf{S}_2$ in the whole domain $0<\varepsilon\leqq\pi$, we cannot help depending upon Theorem 4, although a further numerical calculation is needed.

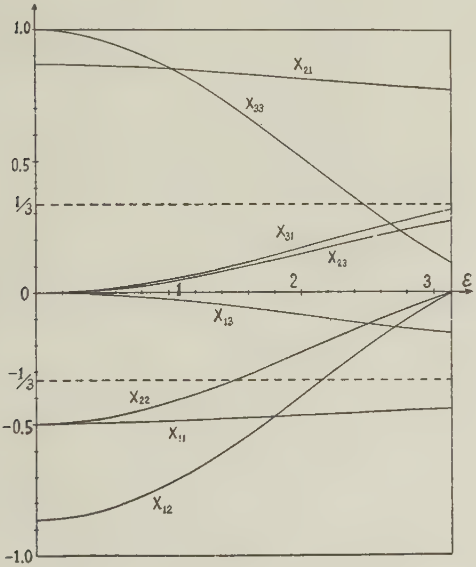


Fig. 1. Plots of X_{kl} against ε in the case $\lambda=0$.

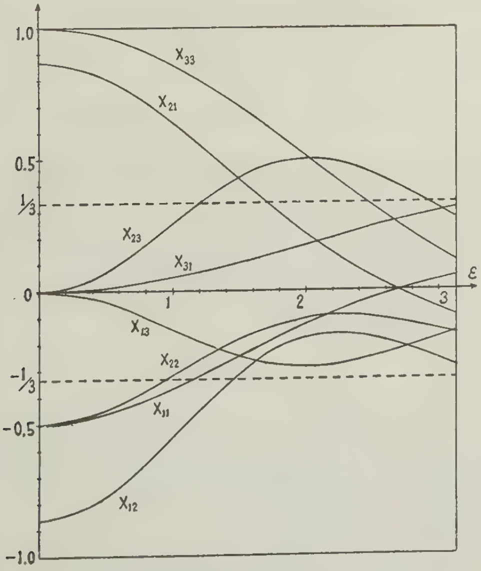

Fig. 2. Plots of X_{kl} against ε in the case $\lambda=1$.

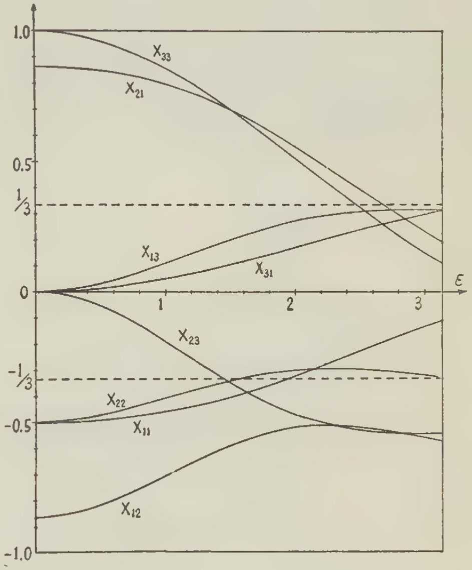

Fig. 3. Plots of X_{kl} against ε in the case $\lambda=-1$.

In this way, we must solve the secular equation of $\mathbf{X}$,

$$|x\mathbf{1}-\mathbf{X}|=\mathbf{0} , \tag{17}$$

and obtain the eigenvalues x_1, x_2 and x_3. If $\lambda=1$ and $\varepsilon=0$, then (17) is reduced to

$$x^3-1=0 ,$$

and the eigenvalues are

$$\left.\begin{matrix} x_1 \\ x_2 \end{matrix}\right\}=\frac{-1\pm\sqrt{3}\,i}{2} \quad \text{and} \quad x_3=1 .$$

If $\lambda=1$ and $\varepsilon=\pi$, then (17) is reduced to

$$x^3+\left(\frac{1}{3}\right)^3=0 ,$$

and the eigenvalues are

$$\left.\begin{matrix} x_1 \\ x_2 \end{matrix}\right\}=\frac{1\pm\sqrt{3}\,i}{6} \quad \text{and} \quad x_3=-\frac{1}{3} .$$

In such a manner, we can obtain various eigenvalues corresponding to values of ε which runs from 0 to π. If these eigenvalues are plotted on the Gaussian plane, then two curves and two straight intervals which are shown in Fig. 4 are generated.

The Gaussian plot thus afforded tells us the solution of our convergence problem. If $\varepsilon=0$, the representative points of the eigenvalues lie on the circumference of the unit circle, and the series S_2 is divergent. However, if $0<\mathcal{E}\leqq\pi$, the representative points of the eigenvalues lie in the unit circle, and the series S_2 is convergent. This result is common to the cases $\lambda=0, 1, -1$. Therefore, if $n\rightarrow\infty$, then $\sum\sum\langle\cos\omega_{ij}\rangle/n$ and $\sum\sum\langle\cos\theta_{ij}\rangle/n$ are convergent in the domain $0<\mathcal{E}\leqq\pi$, but divergent at $\mathcal{E}=0$ which corresponds to the crystalline configuration. Accordingly, we can state the following principle:

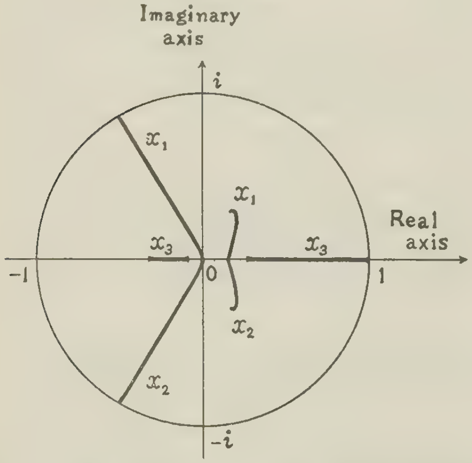

Fig. 4. The Gaussian plot of the eigenvalues of $\mathbf{X}$ in the case $\lambda=1$.

Principle 2. If the linear polymer is composed of segments whose rotations are independent of each other, it must be the Gaussian chain.

This principle has been known in Eyring's case in which the C–C bonds rotate freely and independently of each other[4], and, in this paper, it has been verified that this principle undergoes no change through the replacement of the C–C bonds by the segments which have some flexibility and make the hindered rotation.

§ 5. Discussion

Up to the present, we have used only the square well potential in the treatment of the internal rotation of the polymer chain. Besides it, however, several kinds of potentials may be conceived, e.g., the phonodisk groove potential as given by

$$\left.\begin{aligned} V&=-a\varphi && (\text{when}\quad -\mathcal{E}\leqq\varphi<0) \\ &=a\varphi && (\text{when}\quad 0\leqq\varphi\leqq\mathcal{E}) \\ &=\infty && (\text{when}\quad |\varphi|>\mathcal{E}) \\ &(\text{where}\quad a>0) \end{aligned}\right\}, \quad (18)$$

the harmonic oscillator potential $V=a\varphi^2$, etc. Although these potentials are not studied in this paper, it seems that Principle 2 need not be altered whatever potential we use. On the other hand, so far as we consider $n\rightarrow\infty$, our Principle 2 may undergo no change even if the segment is composed of three or four C–C bonds. Therefore, such a treatment may not be able to afford the interrupted configuration of Table I. However, the Gaussian chain, or the unperturbed configuration, cannot explain the experimental values of $\langle\mu^2\rangle$ and $\langle R^2\rangle$ [2], and hence an actual linear polymer in the solution must take the interrupted configuration. In this way, we are led up to the following imaginations; that is, the segment is composed of many C–C bonds, and sometimes the segment itself contains the crystalline part even in the solution, and the process $n\rightarrow\infty$ is often unadoptable.

If we adopt the above imaginations in the treatments of $\langle\mu^2\rangle$ and $\langle R^2\rangle$, the calculations may be very difficult. Therefore, we keep somewhat the concept of the segment composed of two C–C bonds, and make an attempt to obtain what expressions for $\langle\mu^2\rangle$ and $\langle R^2\rangle$ may represent the interrupted configuration. According to § 3 and § 4, it is evident that

$$\lim_{n\rightarrow\infty}\frac{1}{n}\mathbf{X}^n=\mathbf{0} \qquad (0\leqq\mathcal{E}\leqq\pi) \tag{19}$$

and

$$\lim_{n\rightarrow\infty}\frac{1}{n}(\mathbf{1}-\mathbf{X})^{-1}(\mathbf{X}^n-\mathbf{1})=\mathbf{0} \quad (0<\mathcal{E}\leqq\pi)\,. \tag{20}$$

The formula (20) may be regarded as a mathematical representation of Principle 2, for it reduces S_2 to $(\mathbf{1}-\mathbf{X})^{-1}$ which is independent of n. If we wish to be free from the influence of Principle 2, we must replace the convergent term

$$\frac{1}{n}(\mathbf{1}-\mathbf{X})^{-1}(\mathbf{X}^n-\mathbf{1})$$

by a divergent term $g(n)\mathbf{1}$, where $g(n)$ is a function of n, and is introduced in order to bring the interrupted configuration. Thus we adopt the replacement

$$\frac{1}{n}\sum_{i<j}^{n}\sum\mathbf{X}^{j-i-1}\longrightarrow\{1+g(n)\}(\mathbf{1}-\mathbf{X})^{-1}\,. \tag{21}$$

In the preceding paper¹⁾,

$$g(n)=K(n^{\nu}-1) \tag{22}$$

was attempted as the $g(n)$ term, where the notation ν is the parameter which is also used in Table I. Of course, the three cases $\nu=0$, $0<\nu<1$ and $\nu=1$ correspond to the Gaussian, interrupted and rod configurations, respectively.

In conclusion, some statements which must be corrected are found in the preceding paper¹⁾ after the above discussion, where the correction has already been published as a short note in this Journal⁵⁾.

Mathematical Considerations on Chemical Kinetics of Radiation-Induced Polymerization

By Ayao AMEMIYA and Mitio INOKUTI

Department of Applied Physics, Faculty of Engineering,
University of Tokyo, Tokyo, Japan

(Received January 24, 1961)

The chemical kinetics of radiation-induced polymerization is mathematically investigated. The implication of the "stationary state" hypothesis, currently employed in kinetic treatments, is carefully examined. It is shown that the hypothesis is valid only in a certain time interval. Qualitative behaviors of the total number of polymer radicals as well as of polymer molecules as a function of time are derived without resorting to the stationary state hypothesis. In particular, the asymptotic behavior of the total number of radicals proves to be sensitive to the mode of termination reaction. It is also confirmed that the molecular size distribution approaches to the Poisson type asymptotically.

§ 1. Introduction

Recently, experimental researches are carried out on the radiation-induced polymerization of various organic monomers, in which the experimental data are usually analysed in terms of chemical kinetics involving the so-called "stationary state hypothesis". The hypothesis implies, as is well known, that the concentration of radicals or reaction intermediates can be regarded as constant during the over-all process. We have, however, reasons to doubt the validity of the hypothesis in some of radiation-induced polymerization reactions. Firstly, some of the radicals formed during irradiation are quite long-lived, as is shown, for instance, by the decay of radical concentration after irradiation observed by means of electron spin resonance absorption.¹⁾ Secondly, we may sometimes have a very high dose rate, for instance, using charged particle accelerators, and then the substance under irradiation may contain radicals in extremely high concentrations.

In view of the just mentioned situation, we believe that mathematical considerations are necessary concerning the chemical kinetics of radiation-induced polymerizations, and, in particular, the validity of the stationary state hypothesis.

It is well known that the radiation-induced polymerization has many features common to the thermal or catalyst-induced polymerization reaction and that the set of differential equations describing the former is to some extent similar to that appearing in the latter. The only difference consists in the initiation. For, in the case of the radiation-induced polymerization, it is not only a monomer but also a polymer which can be excited, while, only a monomer plays a part in the initiation of the thermal or catalyst-induced polymerization. The difference naturally modifies the set of differential equations we consider, but from mathematical viewpoint, it never introduces an essential difference, but rather brings about a convenience in the formalism.

In our treatment we assume that the rate constant of each of the reactions we consider is independent of time during the over-all process. It may be noted that radical diffusion sometimes modifies rate constants of termination which are known to depend on the spatial distribution of polymer molecules formed (Trommsdorff effect[2]). But our assumption is plausible in the case of the polymerization in a dilute solution.* Anyway, we believe it will never affect essential points of our discussion. Even under the just mentioned assumption, mathematical treatment of the set of differential equations is so difficult on account of the non-linearity that we have not succeeded in obtaining the exact solution.

For this reason, the "stationary state hypothesis", introduced by Bodenstein et al[3], is customarily employed and has proved to be very convenient in many cases. We will examine consequences of this hypothesis in our model reaction scheme and derive some results concerning the behavior of the exact solution without resorting to this hypothesis.**

§ 2. The Model Reaction Scheme

Our reaction scheme is given as follows:

$$\begin{array}{ll} \text{initiation} & \mathrm{M}_s \rightsquigarrow \mathrm{R}_s, \\ \text{propagation} & \mathrm{R}_s+\mathrm{M}_t \rightarrow \mathrm{R}_{s+t}, \\ \text{disproportionation} & \mathrm{R}_s+\mathrm{R}_t \rightarrow \mathrm{M}_s+\mathrm{M}_t, \\ \text{radical transfer} & \mathrm{R}_s+\mathrm{M}_t \rightarrow \mathrm{M}_s+\mathrm{R}_t, \\ \text{recombination} & \mathrm{R}_s+\mathrm{R}_t \rightarrow \mathrm{M}_{s+t}, \end{array} \tag{1}$$

where M_s and R_s stand for the polymer molecule and the polymer radical with degree of polymerization s, respectively. Here we list the symbols we use in the following:

τ: time measured from the beginning of irradiation,
I: dose rate,
k_i: rate constant of initiation per unit dose rate***,
k_p: rate constant of propagation***,
k_d: rate constant of disproportionation***,
k_x: rate constant of radical transfer***,
k_c: rate constant of recombination***,
M_s: ratio of the number of polymer molecules with degree of polymerization s to the total number of monomers at $\tau=0$,
R_s: ratio of the number of polymer radicals with degree of polymerization s to the total number of monomers at $\tau=0$.

Then our set of differential equation reads:

$$\begin{aligned} \frac{dM_s}{d\tau} = & -k_i I M_s - k_p M_s \sum_{t=1}^{\infty} R_t + k_d R_s \sum_{t=1}^{\infty} R_t + \underline{k_d R_s{}^2} + k_x R_s \sum_{t=1}^{\infty} M_t \\ & -k_x M_s \sum_{t=1}^{\infty} R_t + \frac{1}{2} k_c \left[\sum_{h=1}^{s-1} R_h R_{s-h} \right], \end{aligned} \tag{2}$$

---

* In a dilute solution, the possibility of some solvent effect cannot be excluded, but we will not deal with it in the present work.

** Recently, Kyner et al[4] published a work on a subject apparently similar to ours, but it should be noted that non-linear terms, in which the very difficulty consists, do not appear in their scheme and in this respect their problem is quite different from ours.

*** Rigorously speaking, these rate constants may depend on the degree of polymerization, but we regard them as constant here.

$$\begin{aligned}\frac{dR_s}{d\tau} &= k_i I M_s - k_p R_s \sum_{t=1}^{\infty} M_t + k_p \sum_{h=1}^{s-1} M_h R_{s-h} - k_d R_s \sum_{t=1}^{\infty} R_t - \underline{k_d R_s^2} \\ &\quad - k_x R_s \sum_{t=1}^{\infty} M_t + k_x M_s \sum_{t=1}^{\infty} R_t - k_c R_s \sum_{t=1}^{\infty} R_t - \underline{k_c R_s^2}\end{aligned}$$

where

$$\left[\sum_{h=1}^{s-1} R_h R_{s-h}\right] = \begin{cases} \displaystyle\sum_{h=1}^{s-1} R_h R_{s-h} & \text{for odd } s, \\ \displaystyle\sum_{h=1}^{s-1} R_h R_{s-h} + \underline{R_{s/2}^2} & \text{for even } s. \end{cases} \tag{3}$$

It is convenient to regard the degree of polymerization as a continuous rather than discrete variable, and to rewrite $M_s(\tau)$ and $R_s(\tau)$ as $M(s, \tau)ds$ and $R(s, \tau)ds$ respectively, so that we can replace summation by integration.*

Then we have

$$\begin{aligned}\frac{dM(s, \tau)}{d\tau} &= -k_i I M(s, \tau) - \{(k_p + k_x) M(s, \tau) - k_d R(s, \tau)\} \int_1^{\infty} R(t, \tau) dt \\ &\quad + k_x R(s, \tau) \int_1^{\infty} M(t, \tau) dt + \frac{k_c}{2} \int_1^{s} R(h, \tau) R(s-h, \tau) dh\,, \\ \frac{dR(s, \tau)}{d\tau} &= k_i I M(s, \tau) - (k_c + k_d) R(s, \tau) \int_1^{\infty} R(t, \tau) dt \\ &\quad - (k_x + k_p) R(s, \tau) \int_1^{\infty} M(t, \tau) dt + k_p \int_1^{\infty} M(h, \tau) R(s-h, \tau) dh \\ &\quad + k_x M(s, \tau) \int_1^{\infty} R(t, \tau) dt\,.\end{aligned} \tag{4}$$

Further we define the n-th moments of the degree of polymerization with respect to the distributions $M(s, \tau)$ and $R(s, \tau)$ as

$$m_n(\tau) = \int_1^{\infty} s^n M(s, \tau) ds\,, \qquad r_n(\tau) = \int_1^{\infty} s^n R(s, \tau) ds\,. \tag{5}$$

It is easy to derive from (4) the following equation for the moments:

$$\begin{aligned} dr_0/d\tau &= k_i I m_0 - (k_c + k_d) r_0^2 \\ dm_0/d\tau &= -k_i I m_0 - k_p m_0 r_0 + [(k_c/2) + k_d] r_0^2\,. \end{aligned} \tag{6}$$

$$\begin{aligned} dr_1/d\tau &= k_i I m_1 - (k_c + k_d) r_0 r_1 - k_x m_0 r_1 + (k_p + k_x) r_0 m_1\,, \\ dm_1/d\tau &= -k_i I m_1 - (k_p + k_x) r_0 m_1 + k_x m_0 r_1 + (k_c + k_d) r_0 r_1\,. \end{aligned} \tag{7}$$

$$\begin{aligned} dr_2/d\tau &= k_i I m_2 - (k_c + k_d) r_0 r_2 - k_x m_0 r_2 + (k_p + k_x) r_0 m_2 + 2 k_p m_1 r_1\,, \\ dm_2/d\tau &= -k_i I m_2 - (k_p + k_x) r_0 m_2 + (k_c + k_d) r_0 r_2 + k_x m_0 r_2 + k_c r_1^2\,. \end{aligned} \tag{8}$$

We have by (7)

$$d(r_1 + m_1)/d\tau = 0\,, \qquad r_1 + m_1 = 1\,. \tag{9}$$

This assures the conservation of total number of monomers.** Thus (7) can be rewritten as

---

* When we regard s as continuous, the underlined terms in Eqs. (2) and (3) are higher infinitesimals and may be neglected.

** This conservation law also holds even when we regard s as discrete. In other words, it holds exactly.

$$dm_1/d\tau=-[k_iI+(k_p+k_x+k_c+k_a)r_0+k_xm_0]m_1+k_xm_0 \\ +(k_c+k_a)r_0\ , \qquad r_1=1-m_1\ . \tag{7'}$$

We observe by (6), (7′), and (8) that m_1, r_1, r_2, and m_2 can be obtained as a solution of linear differential equation, once the non-linear equations are solved to give $r_0(\tau)$ and $m_0(\tau)$ and this non-linearity is the very subject of our discussion.

In what follows (except in Section 9), we will work with the case where no radical exists at $\tau=0$, or with the initial condition $R(s,\ 0)=0$.

§ 3. The Meaning of the Stationary State

The stationary state hypothesis is generally interpreted in either of the following two ways. The first interpretation implies that we can assume that $dr_0/d\tau=0$ for $\tau_1<\tau<\tau_2$ or that there exist such τ_1 and τ_2 that $r_0=$const. for $\tau_1<\tau<\tau_2$.[5]

The second interpretation is more general, implying that

$$|dr_0/d\tau|\ll|dm_0/d\tau|$$

for $\tau_1<\tau<\tau_2$.[6]

The first interpretation requires that $r_0=r_{00}=$const. Therefore, we have

$$m_0(\tau)=[m_{00}+(k_cr_{00}/2k_p)]\exp[-k_pr_{00}(\tau-\tau_1)]-(k_cr_{00}/2k_p)$$

by (6) under the condition that $m_0=m_{00}$ at $\tau=\tau_1$.

Since $m_0>0$ for any τ, we have

$$\tau_2-\tau_1\leqq(k_pr_{00})^{-1}\log[1+(2m_{00}k_p/k_cr_{00})]\ .$$

This gives the range where the stationary state hypothesis is possible.

On the other hand, using $dr_0/d\tau=0$ and (6), we have

$$k_iI=\frac{(k_c+k_a)r_{00}^2}{[m_{00}+(k_cr_{00}/2k_p)]\exp[-k_pr_{00}(\tau-\tau_1)]-(k_cr_{00}/2k_p)}\ .$$

Thus, if we adopt the first interpretation, we have a definite functional dependence of k_iI in time τ, which is evidently unphysical. Consequently, the first interpretation is unreasonable so that we will adopt the second one.[5]

§ 4. The Expansion with Respect to Time

In order to examine the initial stage, we expand r_0 etc. with respect to τ. For simplicity, we regard k_iI as constant hereafter and put $k_iI\tau=t$, $k_p/k_iI=a$, $(k_c+k_a)/k_iI=b$, $(k_c/2+k_a)/k_iI=c$, $k_x/k_iI=e$. Further, we adopt the initial condition that $r_0=r_1=r_2=0$, $m_0=m_1=m_2=1$ at $t=0$.

$$\begin{aligned} r_0&=t-(t^2/2!)+[t^3(1-a-2b)/3!]+\cdots\cdots\cdots\ , \\ m_0&=1-t+[t^2(1-a)/2!]+[t^3(-1+4a+2c)/3!]+\cdots\cdots\cdots\ , \\ m_1&=1-r_1=1-t+[t^2(1-a)/2!]+[t^3(-1+4a+2b+ae)/3!]+\cdots\cdots\cdots\ , \\ r_2&=t-[t^2(1-3a)/2!]+[t^3(1-2b-10a-3ae+2a^2)/3!]+\cdots\cdots\cdots\ , \\ m_2&=1-t+[t^2(1-a)2/!]+[t^3(-1+4a+6b-4c+3ae)3!]+\cdots\cdots\cdots\ . \end{aligned} \tag{10}$$

Therefore

$$\begin{aligned} m_1/m_0&=1+[t^3(2b-2c+ae)/6]+\cdots\cdots\cdots\ , \\ m_2/m_1&=1+[t^3(2b-2c+ae)/3]+\cdots\cdots\cdots\ , \\ (m_1+r_1)/(m_0+r_0)&=1+(t^2a/2)-[t^3(3a-2b+2c)/6]+\cdots\cdots\cdots\ , \\ (m_2+r_2)/(m_1+r_1)&=1+at^2+[t^3(-3a+2b-2c+a^2)/3]+\cdots\cdots\cdots\ , \end{aligned} \tag{10'}$$

where the last two quantities correspond to the number-average and the weight-average degree of polymerization, respectively.

It should be noted here that the above expansion with respect to t converges for any finite value of t. This fact can be proved by a general theorem concerning the differential equation of the first order.[7]

In each of the above expansion, the constant a begins to appear in the second order term, and the other rate constants in the third order. In particular, e does not appear in $(m_1+r_1)/(m_0+r_0)$ or $(m_2+r_2)/(m_1+r_1)$. This fact means that the effect of radical transfer presents itself only after a considerable time interval. In Fig. 1, the behaviors of $m_0=1-x$, $m_1=u$, $r_0=y$, $m_2=v$, and $r_2=w$ near $t=0$, are schematically shown.

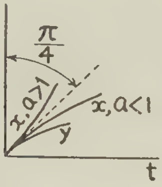

Fig. 1 a.

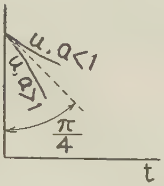

Fig. 1 b.

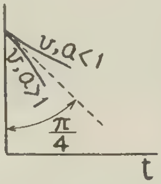

Fig. 1 c.

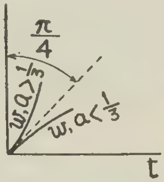

Fig. 1 d.

§ 5. Relation between the Total Number of Radicals and that of Molecules

For convenience, we put $r_0=y$, $m_0=1-x$ and rewrite (6) as*

$$\dot{x}=(1-x)(1+ay)-cy^2\,, \qquad \dot{y}=1-x-by^2\,, \tag{11}$$

where $x(t)$ and $y(t)$ are to satisfy the initial condition $x(0)=y(0)=0$.

If we regard y as a function of x, we obtain by (11) the differential equation.*

$$y'(x)=P(x,\ y)/Q(x,\ y)\,, \qquad P(x,\ y)=1-x-by^2\,, \qquad Q(x,\ y)=(1-x)(1+ay)-cy^2\,, \tag{12}$$

with the initial condition that $y=0$ for $x=0$. According to Painlevé's theorem,[8] the immovable singularities of $y(x)$ are $x=1$, $y=0$ and $x=1-[(b-c)^2/a^2b]$, $y=-(b-c)/ab$, and the movable singularities are algebraic branch points. A little calculation shows that the value of y'' at a point where $y'=0$ is negative in the region where $y>0$, that if $y(x)$ has an extremum, it must be a maximum.

In order to trace the curve for $y=y(x)$, it is convenient to use the curves $P=0$ and $Q=0$. In Fig. 2, we see $P>0$, $Q>0$ in region I. $P<0$, $Q>0$ in region II, and $P<0$, $Q<0$ in region III. Further $dy/dx=\infty$ on the boundary between II and III. Since $y=y(x)$ is a differentiable function, it passes the origin $x=y=0$, increases monotonically to reach a maximum on the boundary between I and II and then decreases monotonically in II to approach the point $x=1$, $y=0$. It never enters the interior of region III. Otherwise, $y(x)$ or $y'(x)$ would be discontinuous on the boundary between II and III.

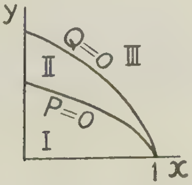

Fig. 2.

In order to determine the behavior of $y=y(x)$, we consider a function $Y_u(x)$ such that

$$Y_u'=(1+aY_u)^{-1}\,, \quad Y_u(0)=0\,,$$

namely,

$$x=Y_u+(aY_u^2/2)\,. \tag{13}$$

Evidently, $Y_u(x)>y(x)$ in the regions I and II. On the other hand, if we define $Y_l(x)$ as

---

* We will hereafter denote differentiation with respect to t and x by dot and prime, respectively. For example, $\dot{x}=dx/dt$, $y'=dy/dx$, $y''=d^2y/dx^2$.

$$Y_l'=(1-x-bY_l^2)/[(1+a/\sqrt{b})(1-x)]\,, \qquad Y_l(0)=0\,, \tag{14}$$

then $y(x)>Y_l(x)$ in the region I. For, since the maximum of $y(x)$ is given by $P=0$, we get $y<1/\sqrt{b}$, and the maximum of $Y_l(x)$ also lies on the curve $P=0$ as is easily seen. If $Y_l(x)$ and $y(x)$ interesects with each other in II, we shall have $y(x)<Y_l(x)$ on the right side of the point of intersection.

To solve Eq. (14), we put

$$X=\sigma(1-x)^{1/2}\,, \qquad \sigma=2b/(a+\sqrt{b})\,,$$

so that the initial condition is written as $Y=0$ for $X=\sigma$. Further the transformation

$$Y_l=-\frac{X}{\sigma\sqrt{b}}\frac{d}{dX}[\log w(X)]$$

yeilds the following equation for $w(X)$:

$$X(d^2w/dX^2)+(dw/dX)-Xw=0\,.$$

Therefore, by making use of the initial condition, we have

$$Y_l=-\frac{X}{\sigma\sqrt{b}}\cdot\frac{I_1(X)K_1(\sigma)-K_1(X)I_1(\sigma)}{I_0(X)K_1(\sigma)+K_0(X)I_1(\sigma)}\,, \tag{15}$$

where $I_n(X)$ and $K_n(X)$ are the modified Bessel functions of the nth order.

For $|X|\ll 1$, Y_l is approximated as

$$Y_l\cong-\frac{1}{\sigma\sqrt{b}}\left\{(\log X)^{-1}+\frac{K_1(\sigma)+CI_1(\sigma)}{I_1(\sigma)}(\log X)^{-2}\right\},$$

where C is the Euler constant. Since $Y_l(\sigma)=0$, there exists an extremum in the interval $0<X<\sigma$ according to Weierstrass' theorem. It is clear that this extremum is a maximum given by $Y_l=X/\sigma\sqrt{b}$ and it is just at the point where $y=Y_l(X)$ and $P=0$ intersect with each other. The value of X corresponding to the maximum is given as the root of the equation.

$$[I_0(X)+I_1(X)]/I_1(\sigma)=[K_1(X)-K_0(X)]/K_1(\sigma)\,,$$

The uniqueness of the root follows from the fact that the left-hand side of the above equation is a monotonically increasing function of X and the right-hand side a monotonically decreasing function.

Next we examine the behaviours of $P=0$. $Q=0$, $Y_l=Y_l(x)$ and the solution $y=y(x)$ of (12) in the neighborhood of $x=1$, or $X=0$. From $P=0$, we have

$$y=X/\sqrt{b}\,\sigma\,,$$

and from $Q=0$,

$$y=(X/\sigma\sqrt{c})+(X^2a/2c\sigma^2)+\cdots\cdots\cdots\,.$$

As seen in Section 7, the solution $y(x)$ of (12) in the neighborhood of $y=1$ satisfies

$$cy^2(1+ay)^{-1}<1-x<by^2\,,$$

so that it can be expanded as

$$1-x=cy^2+L_1y^3+\cdots\cdots\cdots\,,$$

where L_1 is a constant. This equation can be solved with respect to $y(X)$ to give

$$y(X)=\frac{X}{\sigma\sqrt{c}}-\frac{2(b-c)-a}{2\sigma^2 c}X^2+\cdots\cdots\cdots,$$

comparing this result with the behaviors of $P=0$, $Q=0$, $y=Y_u(x)$ and $y=Y_l(x)$ near $x=1$, we have the graph in Fig. 3.

Consequently, we can conclude from the above results that the curve $y=y(x)$ will behave as shown in Fig. 4.

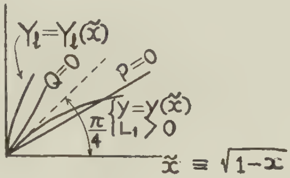

Fig. 3.

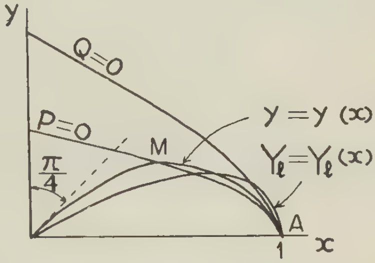

Fig. 4.

§ 6. The Validity of the Stationary State Hypothesis

The second interpretation of the stationary state hypothesis leads to the assumption that $y(x)$ should be approximately given by $P=0$, and therefore it will be possible only between the maximum M and the zero A. (Fig. 4)

Putting

$$bz^2=1-x\,, \qquad y=z(x)+\xi(x)$$

in (12) and neglecting ξ^2 under the assumption $|z(x)|\gg|\xi(x)|$, we have

$$\xi'=(2bz)^{-1}-[2b/z(abz+b-c)]\xi\ .$$

This equation can be solved under the condition

$$\xi=0 \qquad \text{for} \quad x=x_0$$

to give

$$\xi=\frac{\eta_0}{b(a-4b)}\left[\left(\frac{\eta}{\eta_0}\right)^{4b/a}-\frac{\eta}{\eta_0}\right],$$

where $abz+b-c=\eta$, $abz_0+b-c=\eta_0$. The function $\xi(\eta)$ proves to be zero at $\eta=0$ and $\eta=\eta_0$, and to have a maximum

$$\begin{array}{ll} \left(\dfrac{\eta_0}{4b^2}\right)\left(\dfrac{a}{4b}\right)^{a/(4b-a)} & \text{for } b-c=\eta_0[a/4b]^{a/(4b-a)} \\ \dfrac{\eta_0}{b(a-4b)}\left[\left(\dfrac{b-c}{\eta_0}\right)^{4b/a}-\dfrac{b-c}{\eta_0}\right] & \text{for } b-c>\eta_0[a/4b]^{a/(4b-a)} \end{array}$$

This estimation is permissible only if the term proportional to ξ^2 is negligibly small as compared with that proportional to ξ in the equation determining ξ and $|\xi/z|<\varepsilon$ where ε is a sufficiently small positive number, since $z\to 0$ for $x\to 1$. Introducing the notation $\eta/\eta_0=\lambda$, $4b/a=\nu$ and $(b-c)/\eta_0=\theta$, ξ/z is written as

$$\xi/z=(\lambda^\nu-\lambda)(1-\nu)^{-1}(\lambda-\theta)^{-1}\ .$$

Thus ξ/z is a monotonically decreasing function of λ between $\lambda=\theta$ and $\lambda=1$, $\xi/z\to\infty$ for $\lambda\to\theta$ and $\xi/z=0$ for $\lambda=1$ (for any value of ν). If we define λ_ε as the value of λ satisfying

$$(\lambda^\nu-\lambda)(1-\nu)^{-1}(\lambda-\nu)^{-1}=\varepsilon\ ,$$

it is nearly unity for sufficiently small ε and can be expanded as

$$\lambda_\varepsilon=1-(1-\theta)\varepsilon+(1-\theta)[1-\nu(1-\theta)/2]\varepsilon^2+\cdots\cdots\cdots\cdots .$$

The second equation of (11) is written as

$$\dot{\lambda}(t)=-[\eta_0/2b(1-\nu)][(1-\nu)(\lambda-\theta)\lambda+(\lambda-\varphi)(\lambda^\nu-\lambda)] .$$

where $\varphi=(b+c)/\eta_0$. Putting $t=t_1$ for $\lambda=1$ and $t=t_2$ for $\lambda=\lambda_\varepsilon$, we integrate the above equation and obtain

$$t_2-t_1=[2b(1-\nu)/\eta_0]\int_{\lambda_\varepsilon}^{1}[(1-\nu)(\lambda-\theta)\lambda+(\lambda-\varphi)(\lambda^\nu-\lambda)]^{-1}d\lambda .$$

This expression can be simplified for small ε, by making use of the above expansion of λ_ε, in the following form:

$$t_2-t_1=[2b/\eta_0][\varepsilon-\{1+\theta-\varphi-\nu(1-\theta)\}\varepsilon^2/2+\cdots\cdots\cdots\cdots] .$$

The effect of the term proportional to ξ^2 can be estimated as follows. First we note that the equation for $\xi(\lambda)$ is written as

$$\frac{d\xi}{d\lambda}=-\frac{\eta_0}{ab}+\frac{\nu\xi}{\lambda}\left\{1+\frac{ab(2\varphi-\lambda)}{2\eta_0\lambda(\lambda-\theta)}\xi\right\}+O(\xi^3) ,$$

where the second term proportional to ξ in the curly bracket may be written, replacing ξ by the approximate value $\eta_0[(\lambda^\nu-\lambda)/ab(1-\nu)]$, as

$$\frac{1}{2(1-\nu)}\cdot\frac{(\lambda^\nu-\lambda)(2\varphi-\lambda)}{\lambda(\lambda-\theta)}\leqq\frac{1}{2(1-\nu)}\cdot\frac{(\lambda_\varepsilon{}^\nu-\lambda_\varepsilon)(2\varphi-\lambda_\varepsilon)}{\lambda_\varepsilon(\lambda_\varepsilon-\theta)}\cong[(2\varphi-1)\cdot\varepsilon/2] .$$

Consequently, the range of applicability of the stationary state hypothesis is established by calculating t_2-t_1 or λ_ε, where λ_ε is determined in the following way. Given a sufficiently small positive number ε_0. We first determine ε so as to satisfy

$$|(2\varphi-1)\cdot\varepsilon/2|=\varepsilon_0 , \tag{18}$$

and then find λ_ε using this value of ε.

§ 7. The Estimation of the Numbers of Molecules and Radicals

The number of radicals is given by $r_0=y(t)$, the variation of which is described by the following differential equation of the second order deduced by eliminating x in (11)

$$\ddot{y}+(1+2\alpha y)\dot{y}+\beta y^3+\gamma y^2=0 ,$$

where $2\alpha-2b+a$, $\beta=ab$, $\gamma=b-c$. We impose on $y(t)$ the initial conduction that $y=0$, $dy/dt=1$ at $t=0$.

According to investigations of Painlevé and others,8) the equation (11) is known to have movable algebraic singularities, but does not belong to the so-called "canonical type" of their classification, so that it is very difficult to discuss the nature of the solution of (12) in a straightforward manner. Here we will discuss it in a somewhat different way from Painlevé and others'.

In the previous section, we proved that

$$1>y\geqq 0 , \qquad \lim_{x\to 1-0} y(x)=0 .$$

Further it can be shown by (11) that, if $y(t)$ has an extremum, it must be a maximum so that $y(t)$ cannot be a oscillatory function.

We rewrite (11) by making use of the initial condition as

$$y=t-\int_0^t y\,dt-\alpha\int_0^t y^2dt-\int_0^t dt\int_0^t(\beta y^3+\gamma y^2)dt\,.$$

Now we assume that the total number of radicals $y(t)$ reaches a finite saturation value L, or that $y(t)=L>0$ for $t>G$ where G is sufficiently large positive number. Then, for $t>G$,

$$y\cong t-\int_0^G\left[y+\alpha y^2+\int_0^t(\beta y^3+\gamma y^2)dt\right]dt-\int_G^t[L+\alpha L^2-t(\beta L^3+\gamma L^2)]dt$$
$$-\left[t\int_0^t(\beta y^3+\gamma y^2)dt\right]_{t=G}^{t=t}\equiv\Phi_0(G)+\Phi_1(G)t-[(\beta L^3+\gamma L^2)/2]t^2\,.$$

According to this equation, $y(t)$ decreases parabolically for sufficiently large t. This is inconsistent with the assumption $y(t)\cong L>0$. Thus we see that the assumption was false and that no positive saturation value exists. Since on the other hand y cannot be negative as seen in Fig 4, we conclude that

$$\lim_{t\to+\infty} y(t)=+0\,.$$

Further, since the curve $y=y(x)$ lies in the region II in the neighborhood of $x=1$, we have

$$by^2>1-x>cy^2(1+ay)^{-1}\,.$$

Therefore, we may substitute

$$1-x=\sum_{s=0}^{\infty}L_sy^s$$

into (11) and obtain

$$L_0=c\,,\qquad L_1=2c\gamma-ac\,.$$

Using this result, we have, by (2),

$$t=(\gamma y)^{-1}-L_1\gamma^{-2}(\log y)+O(1)\,,$$

where we have assumed that $\gamma>0$. We can solve this equation with respect to y to obtain

$$r_0=y=(\gamma t)^{-1}[1+L_1\gamma^{-2}(\log t)/t]+\cdots\cdots\cdots\,. \tag{20}$$

Thus x is also found as

$$m_0=1-x=c(\gamma t)^{-2}[1+2L_1\gamma^{-2}(\log t)/t]+\cdots\cdots\cdots\,. \tag{21}$$

In particular, if $\gamma=0$ or $b=c$ ($k_c=0$), we have different expressions:

$$\begin{aligned} r_0=y&=(2\beta t)^{-1/2}+(\alpha/\beta t)-(3/4\sqrt{2\bar{\beta}})(\log t)/t^{3/2}+\cdots\cdots\cdots\,,\\ m_0=1-x&=(2at)^{-1}+[(4b+a)/2a(2\beta)^{1/2}]t^{-3/2}-(3/4a)(\log t)/t^2+\cdots\cdots\cdots\,. \end{aligned} \tag{20'}$$

It is easily shown that we have $x\geqq y$ for any finite value of t and x at a point where $x=0$ is positive. Further, $x_l(t)$ and $x_u(t)$ are an upper and lower bounds of $x(t)$, which are defined as follows:

$$\dot{x}_l=1-x_l-cx_l^2\,,\quad x_l(0)=0\,,\qquad \dot{x}_u=(1-x_u)(1+ax_u)\,,\quad x_u(0)=0\,. \tag{22}$$

Again, we can also find such $y_l(t)$ and $y_u(t)$ that

$$y_l(t)<y<y_u(t)\,.$$

The functions $y_l(t)$ and $y_u(t)$ are defined by

$$\dot{y}_l=1-x_u-by_l^2\,,\quad y_l(0)=0\,,\qquad \dot{y}_u=1-by_u^2\,,\quad y_u(0)=0\,. \tag{23}$$

These informations tell us that the behavior of $x=x(t)$ and $y=y(t)$ will be as shown in Fig. 5, and Fig. 6.

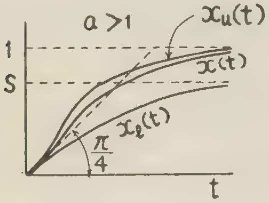

Fig. 5a.

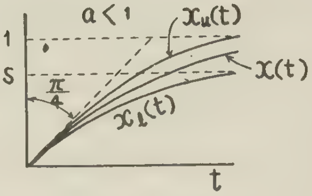

Fig. 5b.

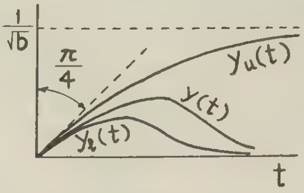

Fig. 6.

§ 8. The Estimation of Higher Moments

The equations (7), (8) for m_1, r_2 and m_2 read:

$$m_1=-(F+G)m_1+G\,, \quad r_2=Fm_2-Gr_2+2am_1(1-m_1)\,, \quad m_2=-Fm_2+Gr_2+2(b-c)(1-m_1)^2\,, \tag{24}$$

where

$$F=1+(a+e)y\,, \quad G=by+e(1-x); \qquad m_1=m_2=1\,, \quad r_2=0 \text{ for } t=0\,. \tag{25}$$

Once the t-dependence of F and G is determined, these equations can be easily integrated. But, since analytic expressions for $x(t)$ and $y(t)$ have not yet been obtained, it is impossible to express m_1, r_2 and m_2 as explicit functions of t. It is also difficult to find these functions by the method used in Section 7. We can only determine an upper and a lower bound of m_1:

$$\begin{aligned} &u_1>m_1>u_2\,, \\ &u_1=(1+a+b+2e)^{-1}\{a+b+2e+\exp[-(1+a+b+ae)t]\}\,, \\ &u_2=\exp[-(a+e+1)t]\,. \end{aligned} \tag{26}$$

The behaviors of the function m_1, r_2 and m_2 for large t are given by putting (20), (21) or (20′), (21′) into (24) and (25). Here we give only the final result:
For $\gamma>0$,

$$\begin{aligned} m_1&=b(\gamma t)^{-1}[1+L_1\gamma^{-2}(\log t)/t]+\cdots\cdots\cdots\,, \\ m_2&=2(b+\gamma)-(2bL_1/c\gamma)(\log t)/t+\cdots\cdots\cdots\,, \\ r_2&=2\gamma t-(2bL_1/c\gamma)\log t+\cdots\cdots\cdots\,. \end{aligned} \tag{27}$$

For $\gamma=0$,

$$\begin{aligned} m_1&=b(2\beta t)^{-1/2}+b(2at)^{-1}-[3b/4(2\beta)^{1/2}](\log t)/t^{3/2}+\cdots\cdots\cdots\,, \\ m_2&=2b+\cdots\cdots\cdots\,, \\ r_2&=2(\beta t)^{1/2}+\cdots\cdots\cdots\,. \end{aligned} \tag{27′}$$

The number-average degree of polymerization $(m_1+r_1)/(m_0+r_0)=1/(1-x+y)$ is a monotonically increasing function of t with the asymptotic form for large t

$$\begin{aligned} 1/(1-x+y)&=\gamma t-L_1\gamma^{-1}\log t+\cdots\cdots\cdots && (\gamma>0)\,, \\ &=(2\beta t)^{1/2}-(a+3b)+\cdots\cdots\cdots && (\gamma=0)\,. \end{aligned} \tag{28}$$

The weight-average degree of polymerization $(m_2+r_2)/(m_1+r_1)=m_2+r_2$ is also a monotonically increasing function of t with the asymptotic form for large t

$$\begin{aligned} m_2+r_2&=2\gamma t-(2bL_1/c\gamma)\log t+\cdots\cdots\cdots && (\gamma>0)\,, \\ &=2(2\beta t)^{1/2}+\cdots\cdots\cdots && (\gamma=0)\,. \end{aligned} \tag{29}$$

The fact that the ratio of the weight-average to the number-average degree of polymerization tends to 2 for large t tells us that the distribution in a sufficiently polymerized system approaches to the Poisson type, as reasonably expected. In Fig. 7, we give schematic curves for the average degrees of polymerization.

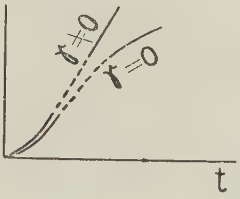

Fig. 7.

It should be noted that the average degrees of polymerization are independent of the recombination rate k_c in the initial stage (see Eqs. (10) and (10′)), but that, for large total dose or after sufficient time interval, they exhibit different dose dependence according as $\gamma>0$ or $\gamma=0$. Namely, the average degrees of polymerization tend to be proportional to D/I for $\gamma>0$ and to $D^{1/2}/k_t I$ for $\gamma=0$, where D means the total dose $D=I\tau$.

§ 9. Solution with a Different Initial Condition

So far we have dealt with the case where only monomer molecules are present at $t=0$. In this section we consider a more general initial condition that that $x=x_i$, $y=y_i$ at $t=0$, which implies that some monomer radicals exist at $t=0$. Analysis similar to that in Section 5 give informations about the behavior of r_0 and m_0. The resulting curves* are shown in Fig. 8 and Fig. 9.

Under the initial condition considered in this section we cannot use the method in Section 6 in order to examine the validity of the stationary state hypothesis. In what follows, we describe a different approach to somewhat rough estimation which gives a sufficient condition for the validity.

Denoting the ordinate for any x of the $P=0$ and the curve $Q=0$ by y_p and y_q, respectively, the quantity

$$l=(y_q-y_p)/y_p$$

can be interpreted as measure of validity, because in the stationary state $y_q=y_p$. By definition l satisfies

$$(c/b)(1+l)^2-ab^{\;1/2}(1-x)^{1/2}(1+l)-1=0\ .$$

When we regard l as a function of $(1-x)^{1/2}$ we have a curve as shown in Fig. 10.

Now we may define the precision ε of the stationary state approximation by

$$|(y-y_p)/y_q|<\varepsilon\ . \tag{30}$$

Thus, provided that $\varepsilon>l_1=(b/c)^{1/2}-1$, the stationary state approximation is reasonable in the sense that by (30) holds in the interval $0<x<x_\varepsilon$, where x_ε is given by

$$(c/b)(1+\varepsilon)^2-ab^{-1/2}(1-x_\varepsilon)^{1/2}(1+\varepsilon)-1=0\ . \tag{31}$$

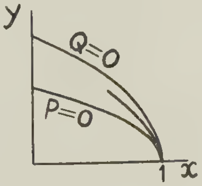

Fig. 8 a.

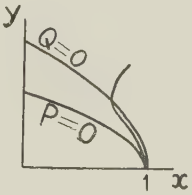

Fig. 8 c.

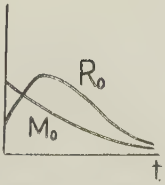

Fig. 9 a.

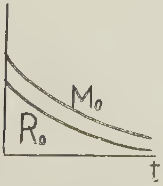

Fig. 9 b.

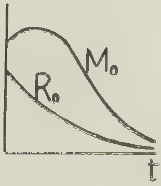

Fig. 9 c.

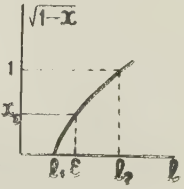

Fig. 10.

---

* When we analyse a very simple model of kinetics treated by Hirschfelder[10] according to our method, the resulting curve are very similar to those shown in Fig. 9. (Unpublished)

This result can be as a criterion for the validity of the stationary state approximation.

§ 10. Concluding Remarks

In conclusion, we will summarize our results.

(I) The stationary state hypothesis leads to mathematical contradiction if it is interpreted to require that the number of radicals should remain constant for a finite time interval.

(II) If we interpret the stationary state hypothesis from a wider standpoint, we find the restricted range of its validity. We have derived an expression by which the range is estimated.

(III) Without resorting to the rather ambigous hypothesis, we can classify various possible behaviors of the number of radicals as well as of molecules as a function of time. In particular, we have given a lower and an upper bound of the number of radicals as well as of molecules at any time.

(IV) It can be shown that the number of radicals generally increases at the beginning, then reaches a maximum and decreases finally, vanishing asymptotically after an infinite lapse of time.

(V) We have discussed the asymptotic behavior of the total number of radicals as well as of molecules to find out that there is a marked distinction in the asymptotic behavior for the case that the recombination between radicals does not occur from that when it does occur. It is also shown that the molecular size distribution approaches the the Poisson type asymptotically. So far our discussions have been formally confined to radiation-induced polymerization described by our model reaction scheme. However, this scheme is also applicable to other cases such as conventional radical polymerization and ionic polymerization, if we adopt properly modified interpretation of the rate constant and regard $R_s(\tau)$ as the fraction of appropriate reaction intermediates having degree of polymerization s. Thus these cases can be also studied by our present method to give similar results although some modifications will be necessary.

Acknowledgement

Finally the authors should like to express thanks to Dr. M. Matsumoto, Kurashiki Rayon Co., for his interests and valuable comments. The authors are also indebted to the Ministry of Education for Scientific Research Fund.

The Rheological Behavior and Thixotropy of a Fatty Plastic Body

By Toshimaro SONE

Research Laboratory, Snow Brand Milk Products Co., Ltd.,
Shinagawa, Tokyo

(Received January 31, 1961)

The fatty plastic body such as butter or margarine possesses the remarkable non-Newtonian character in its rheological properties. The quantitative study of the viscosity, elasticity and yield value of butter has been performed under various conditions of temperature and shearing stress. The apparatus employed in the measurements involve an oscillating plate viscometer, a cone-plate viscometer and a parallel plate plastometer.

The viscosity, elasticity and yield value decrease remarkably when the specimen is subjected to the kneading on the roll mill, but they recover gradually to their original values after setting the specimen for a long time. The phenomenon can be called as a kind of thixotropy.

The volume dilatometry of the specimen has been also carried out continuously for a setting period of two months. From the comparison of results, the magnitude of viscosity or yield value of butter could be successfully connected to the degree of crystallization of fat in butter which had been evaluated from the specific volume of the specimen. The origin of the thixotropic softening and hardening of butter should be sought for, therefore, in the mechanism of rupture and formation of the three dimensional network of fat crystal in the specimen.

§ 1. Introduction

The fatty plastic body such as butter, margarine and confectioner's fat consists of many small crystals of the order of a few micron or less, enmeshing a considerable proportion of liquid oil within their texture. Consequently its rheological properties are highly dependent upon temperature and pressure. Especially, butter is a typical fatty plastic body which has been widely used as eatables by spreading on bread, and its rheological properties are most important in the practical process as carrying, storage, moulding, and spreading. Many investigations on the rheological properties of butter so far carried out[1)-8)] indicate that the viscosity of butter varies with time during working or setting. Scott Blair et al.[2)-4)] have pointed out that the decrease of viscosity during working and the recovery during setting are a kind of thixotropic phenomena.

In this paper, using butter as an example of plastic bodies, a more quantitative study of the rheological properties of plastic body has been undertaken. In connection with the thixotropic phenomena the variation of crystallinity during working and setting has been also investigated in detail.

§ 2. Experimental Methods

2.1 *Specimen*

The butter employed in our experiment was storaged for about one month before measurements in a constant temperature room at +5°C, so that the tempering of specimen had been completed. Its chemical components are 16% water, 2% salts, 0.8% protein, and 81.0 % fat approximately. The liquid components are being dispersed into the solid fat in the shape of spherical droplets ranging from about one to ten micron in diameter.

2.2 *Procedure and method of kneading*

The duplicate roller used for kneading of butter has the size of 7.5 cm diameter and 17.5 cm length, and the clearance between rollers is varied in four steps of 0.55, 1.65, 3.00 and 4.05 mm respectively. The speed of rotation of roller is 18 r.p.m. and the amount of sample used for kneading at one time is about 500 g. The temperature of working was kept at 25°C or 20°C, but the temperature of sample rose up about 2°C during kneading.

2.3 *Vibrating plate viscometer*

During working at 25°C, about 50 g of worked butter were taken out into a glass beaker at intervals of a few to ten minutes. Immediately, the dynamic viscosity and rigidity modulus were measured using a vibration-plate viscometer.[9),10)] The vibrating porting of this viscometer was a small cylindrical rod of brass which had the size of 3 mm diameter and 30 mm length.

The resonance angular frequency and mechanical loss of this viscometer are connected with the viscosity η and rigidity G of the specimen by the following equations:

$$\eta = K(\tan\delta - \tan\delta_0) \qquad \text{(poise)} \qquad (1)$$

$$G = \frac{K}{\omega_0}(\omega^2 - \omega_0^2) \qquad (\text{dyne/cm}^2), \qquad (2)$$

where K is a constant of apparatus, ω_0, ω the resonance angular frequency in air and in sample respectively and $\tan\delta_0$, $\tan\delta$ the mechanical loss in air and in sample respectively. The constant K was determined by using silicone oils of known coefficients of viscosity.

2.4 *Cone-plate viscometer*

Static viscosity and yield value of butter immediately after working was measured using a cone-plate viscometer which was the same type as developed by Markovitz et al.[11)] A small quantity of viscous butter was taken up from the roller and filled into the wedge-like space between cone and plate. The upper cone was fixed and the lower plate was rotated around its axis at a given torque, and then the rotational velocity of the plate was measured.

The viscosity η is represented by the following equation;

$$\eta = \frac{\tau}{(\Omega/\theta)}, \qquad (3)$$

where τ is the torque of rotation, Ω is the angular velocity and θ is the angle between cone and plate. Thus, Ω/θ represents the rate of shear. In this experiment, the angle θ was 2° and Ω/θ was ranged from 1 to 10^2 sec^{-1}.

Although the worked butter is very fluid, it has still a low yield value and when the rotational torque becomes larger than the yield value, the rotational angular velocity of the plate increases rapidly. The yield value can be determined by extrapolating this flow curve to the zero shear rate.

2.5 *Parallel plate plastometer*

At intervals during working, a batch of viscous butter was taken from the roller and was poured into a metal mould and the cylindrical specimen of 6 cm diameter and 1.4 cm height was made. The viscosity of the specimen was measured by means of a parallel plate plastometer and its change was investigated during setting for a period of 60 days at temperature 16°C, and 20°C and 25°C respectively.

The parallel plate plastometer is the one generally used for measuring the plasticity of rubber. The specimen with cylindrical form is placed between two parallel plates and a constant force F is applied perpendicularly to the plate. The displacement of the upper plate, or the change of the height of specimen, is measured continuously. The viscosity of the specimen can be determined from the time variation of the height of the specimen.

The equation developed by Dienes and Klemm[12)] has been employed in the preliminary experiments. In the present case, the volume of the specimen is constant. Assuming Newtonian flow of the specimen, the reciprocal of the fourth power of the height h is connected with time t by the following equation:

$$\frac{3\mathrm{V}^2}{8\pi}\left(\frac{1}{h^4} - \frac{1}{h_0^4}\right) = \frac{\mathrm{F}}{\eta}t, \qquad (4)$$

where F is the force applied to the specimen, V the constant volume of the specimen, and η the viscosity. The mean shear rate of the specimen can be calculated by the following equation derived by Longworth[13)]:

$$\bar{\dot{\gamma}} = \frac{2}{\pi R^2 h}\int_{r=0}^{r=R}\int_{z=0}^{z=(h/2)} 2\pi r\frac{\partial v}{\partial z}\,dr\,dz$$
$$= \frac{2\pi^{1/2}h_0^{5/2}\mathrm{F}}{3\mathrm{V}^{3/2}\eta}\ (\text{sec}^{-1}), \qquad (5)$$

where R is the radius of the specimen, $\bar{\dot{\gamma}}$ the mean velocity gradient in the direction parallel to the plate, and h_0 the initial height.

When the pressure is removed from the specimen compressed to the height $h_{\min}$, the recovery of the height Δx is observed. The corresponding strain γ is expressed by

$$\gamma = \frac{\Delta x}{h_{\min}}, \qquad (6)$$

Then the Young's modulus E is calculated from the equation

$$E=\frac{F_R}{r}\,,\qquad (\text{dyne/cm}^2) \tag{7}$$

where F_R is the pressure before unloading.

As the above described Dienes' equation has been derived for the Newtonian liquid, the viscosity η calculated from this equation is only apparent for the non-Newtonian material such as butter. Recently, Oka, et al.[14] have developed a new theory which can be applied to the Bingham body with a yield value. According to their theory, when the volume of the specimen is kept constant, the time variation of the distance between parallel plate is expressed by

$$-\dot{h}=\left(F-\frac{fV^{3/2}}{3\pi^{1/2}h^{5/2}}\right)\frac{2\pi h^5}{3\eta V^2}\,, \tag{8}$$

where f is the yield value. Denoting by h_l the limiting height of the specimen for $\dot{h}=0$, one gets from equation (8),

$$h_l=\left(\frac{V^{3/2}f}{3\pi^{1/2}F}\right)^{2/5}. \tag{9}$$

From equation (9) the yield value f is obtained from the height of the specimen when the velocity of decrease of height approaches zero.

From the equation (8) one gets also:

$$\log\left(-\frac{\dot{h}}{h^5}\right)=\log\left(F-\frac{fV^{3/2}}{3\pi^{1/2}h^{5/2}}\right)+\log\frac{2\pi}{3\eta V^2}\,. \tag{10}$$

Thus the plot of $\log(-\dot{h}/h^5)$ against $\log(F-fV^{3/2}/3\pi^{1/2}h^{5/2})$ is linear. From the point where the straight line intersects with the ordinate, the viscosity of the specimen is determined. An example of the experimental data of butter plotted according to equation (10) is represented in Fig. 1, which shows the linear relation over a certain range of $\dot{h}/h^5$.

2.6 *Volume dilatometry of butter, fat and liquid component*

The relation between specific volume and temperature in butter, butter fat, and liquid component were measured by a dilatometric method. The dilatometer consisted of a capillary and a valve, made of Pyrex glass, the volume of the valve being 5.0 c.c. and the diameter of the capillary 1.5 mm. After inserting the specimen, the glass tube was evacuated for one hour, and then purified mercury was filled in the capillary.

The butter fat was obtained by the following procedure. After melting butter of 200 g at 90°C for about one hour, butter fat was separated using a filter paper. The filtered fat was washed three or four times by hot distilled water at 80°C. After confirming no salt reaction by 0.1 N. $AgNO_3$, the filtered warm butter fat was dried in a vacuum oven. In the dilatometry, about 3 g. of molten liquid butter fat was used.

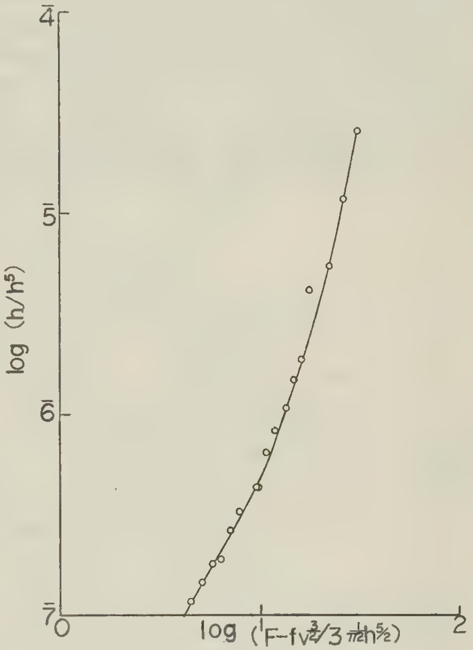

Fig. 1. The plot of experimental data by the equation (10).

The liquid components were separated from butter by mechanical working at +5°C. The most part of the liquid was water, but contained 10.9% salt and 2.9% protein and the very small amount of water soluble inorganic components.

The dilatometer filled with the worked butter was kept at 20°C in a constant temperature room and the height of mercury head was measured every day for about two months. The degree of crystallinity was determined from the specific volume using the correlation curve between specific volume and crystallinity of standard butter. Specific volume—temperature curve corresponding to the solid state was corrected for the deviation by freezing of the liquid components.

§ 3. Experimental results and discussions

3.1 *Temperature dependence of viscosity and elasticity*

A preliminary test was first made for virgin butter at various temperatures, shear rate and pressures. The viscosity and the elasticity of virgin butter was measured at several temperature from 11°C to 25°C, by means of a parallel plate plastometer. The viscosity was calculated by Dienes and Klemm's equation.

Fig. 2 illustrates the relation between the viscosity and the mean shear rate in the logarithmic scales. The change of viscosity with the shear rate or the temperature is not so large in a range from 11°C to 14°C. But when the temperature rose to 20°C, the viscosity of butter decreases rapidly and $\log \eta$ decrease linearly with the increase of $\log \overline{\dot{\gamma}}$. At the temperature over 20°C, the viscosity of butter becomes greatly dependent on the temperature and the shear rate, that is, the rheological behavior is non-Newtonian.

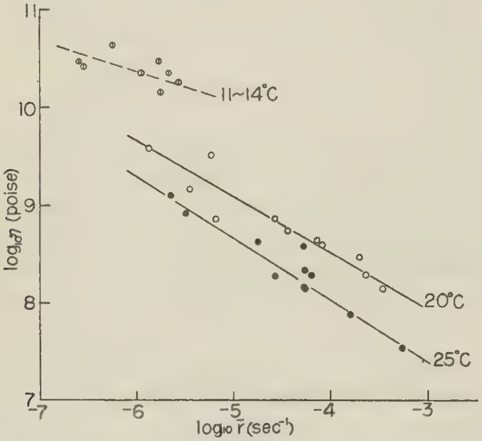

Fig. 2. The variation of the viscosity η with the shear rate $\overline{\dot{\gamma}}$ at the various temperature from 11°C to 25°C.

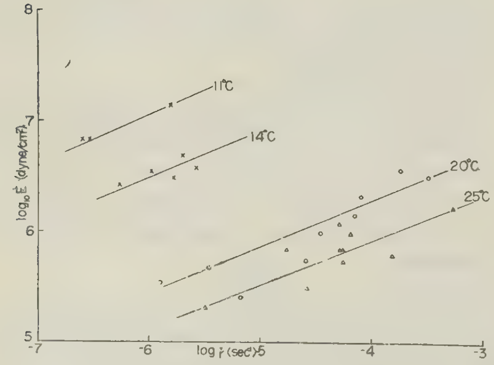

Fig. 3. The variation of the elasticity E with the shear rate $\overline{\dot{\gamma}}$ at the various temperature from 11°C to 25°C.

Fig. 3 depicts the variation of Young's modulus E of virgin butter with the mean shear rate $\overline{\dot{\gamma}}$ for the various temperatures. It is seen that $\log E$ increases linearly with $\log \overline{\dot{\gamma}}$ and that E decreases rapidly with the rise of temperature. The value of Young's modulus obtained is of the same order as the results by Davis[3], 10^5–10^6 dyne/cm^2 at 16°C. The behavior of elastic modulus also indicates the non-Newtonian character in the mechanical property of butter.

3.2 *The variation of viscosity and rigidity during working*

The results described in the previous section has shown that the mechanical properties of butter is largely affected with temperature variation. In order to see the effects of the mechanical processes, it is necessary to investigate the variation of the mechanical properties during kneading. For this purpose, about 500 g. butter was kneaded by a duplicate roller at 25°C and the viscosity and rigidity during kneading were measured by a vibrating plate viscometer with the lapse of time. The temperature rise of butter during rolling was only about 2°C and did not affect the viscosity and the rigidity.

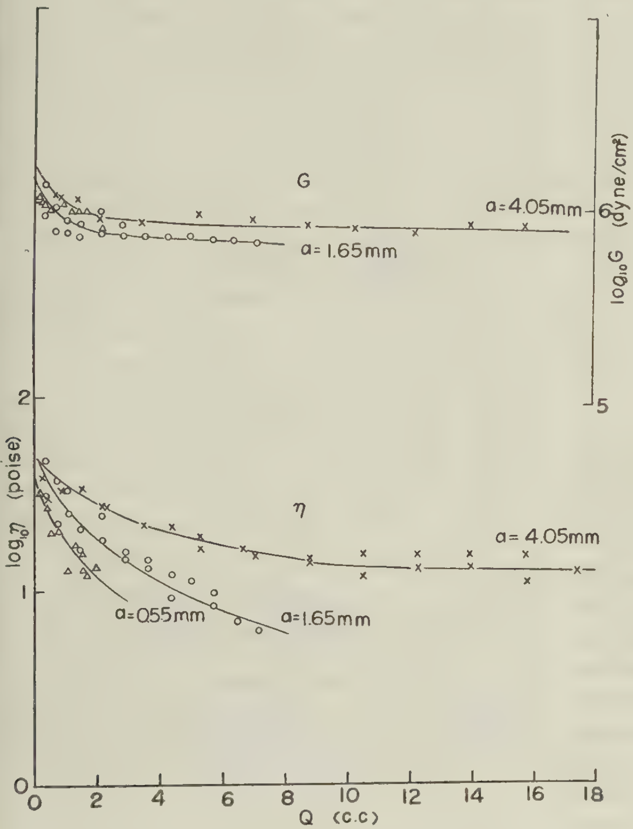
Now denoting by a the clearance of the roller, by v the pheripheral velocity of the two cylinders which have equal velocity, and assuming that the butter does not slip at the surfaces of the rollers, the amount of flow Q through the clearance of the rollers per unit length parallel to roller shaft is roughly calculated by

$$Q = vat_w\,, \tag{11}$$

where t_w is the time of working.

Fig. 4 shows the variation of the viscosity and the rigidity during working with the lapse of time at 25°C. In the abscissa the amount of flow Q is taken instead of time. The decrease in the viscosity and the rigidity of butter is most rapid initially and each values gradually reach to an equilibrium one which varies with the clearance of the rollers.

Intuitively, one sees that the narrowing of the clearance between the two rollers increases the shearing stress and the destruction of the rolled medium continue until the lower viscosity is accomplished.



Nig. 4. The variation of the viscosity η and the rigidity G of butter with the amount of working measured at about 500 cps.

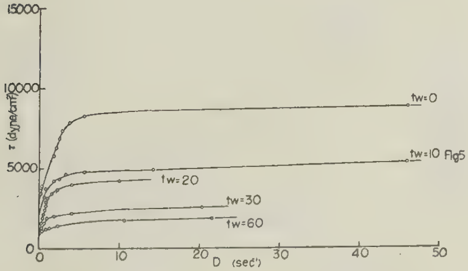


Fig. 5. The flow curve of kneaded butter.

Using a cone-plate viscometer the yield value in addition to the flow curve was measured at 21°C. Through these experiments, the butter was kneaded by the clearance of the rollers which is fixed at 3 mm and the kneading temperature was kept at 20°C. The curves in Fig. 5 show the relation between shear stress τ and shear rate D for different working time in the linear scale. Each flow curve can be separated into two parts, one is over the range 0–10 sec^{-1} being non-linear and the other over the upper range of the rate of shear (10–50 sec^{-1}) being approximately linear. Upper linear parts of each curve have an identical gradient. The lower part is strongly curved, but the yield value is obtained by extrapolation of the lower linear portion. It is remarkable that the butter has a yield value even after working for 60 minutes.

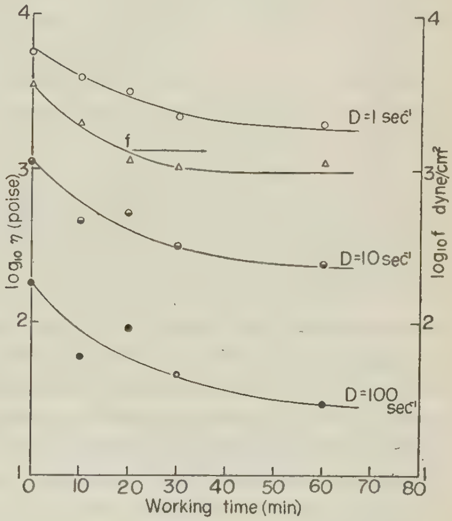

Fig. 6. The variation of viscosity η and the yield value f of butter with working time. Kneading of butter and measurement of viscosity and yield value were carried out at 21°C±1°C.

Fig. 6 shows the variation of yield value and viscosity with the working time. The tendency that the yield value and the viscosity rapidly decrease in the initial period of working, about 30 minutes, and thereafter approaches to the constant value, is similar to the variation of the dynamic rigidity and viscosity during working, which has been already described.

The apparent viscosity η was defined as the ratio of the shear stress to the shear rate τ/D and the relation between the apparent viscosity η and the shear rate D is shown in Fig. 7. The curve of each working time are nearly straight with an almost equal slope.

Recently Tempel[15] has observed the decrease of the viscosity and the rigidity with the increase of shear stress in the fatty gels of 15%-25% glycerol-tristearate suspension in paraffin oil. He assumes that the three dimensional network of tristearate crystals is ruptured by the shearing stress. The reduction of the viscosity, rigidity and the yield value of butter during working seems to involve similar mechanism. Namely, being subjected to the strong shearing stress by compression through the clearance of the roller, the crystal network constituting the body of butter is broken and molten by the mechanical friction between the crystals. These consideration will be further discussed and confirmed in a later section from the dilatometric study.

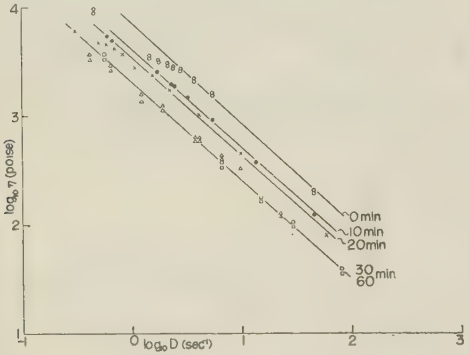

Fig. 7. The variation of the viscosity of butter with the rate of shear at various working time from 0 to 60 minutes.

3.3 *The recovery of viscosity and yield value during setting*

The previous investigators[16),17)] have already reported that the viscosity of butter which had been reduced by working recovered to the original viscosity after a certain time of setting. The variation of viscosity and yield value due to the setting of butter was measured by means of a parallel plate plastometer at 25°C. The butter was kneaded by the roller whose clearance was fixed at 1.65 mm and the temperature of setting after working was kept at 16°C for from one day to ten days. Using the equation of Oka, et al. both the yield value and the viscosity have been determined.

From Fig. 8 and 9, one sees that the relations between the viscosity and the working time and between the yield value and the working time are similar to the results which were obtained by a cone-plate viscometer (Fig. 6), although the present data were obtained at one day after each working time.

However, because the present viscosity measurements were carried out at the different temperature and under much lower shear rate than the case by the cone-plate viscometer, both results can not be quantitatively compared with each other.

The closed points indicate the recovery of

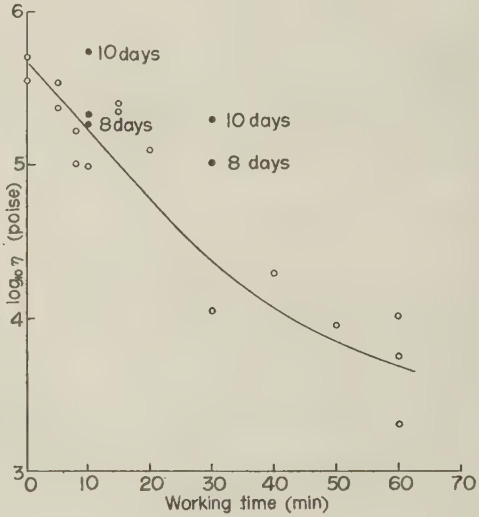

Fig. 8. The variation with working time of the viscosity of butter measured at 25°C after setting for 20 hours at 16°C. Closed points show data after setting 8 days and 10 days at 16°C.

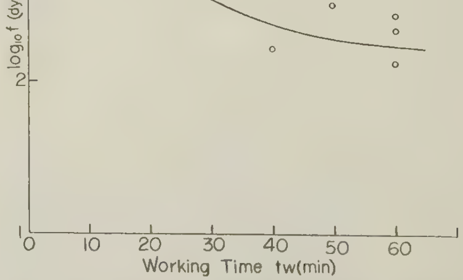

Fig. 9. The variation with working time of the yield value of butter measured at 25°C after setting for 20 hours at 16°C. Closed points show data after 8 days and 10 days at 16°C.

the viscosity and the yield value after eight or ten days setting. It is seen that the thixotropic recovery of the viscosity and the yield value is progressively performed as the lapse of setting days.

Scott Blair[2)], Davis[3)], and Dolby[4)] have previously discussed the recovery of viscosity in connection with the recrystallization of fat which is the mixture of a solid phase and a liquid phase. From the reduction of recovery of the viscosity after the repetition of working, it was concluded that the body or texture of fat could not be completely reproduced to the original state. However, provided that their setting time were long enough as the author's, the recovery of the viscosity might be more perfect.

From the fact that the yield value of butter does not disappear after such long working time and that it gradually recovers by setting as well as the viscosity, the butter can be defined to be a thixotropic plastic substance, as denominated by Burger and Scott Blair[18)].

3.4 *Volume dilatometry of butter, fat and other liquid component*

The relation between temperature and specific volume of butter, butter fat and dispersed dropets were determined by dilatometric measurements (Fig. 10). The temperature range of observation was from −38°C up to 50°C and the rising rate was very slow, about 6°C/hour so that the retardation of phase transition would be perfectly eliminated.

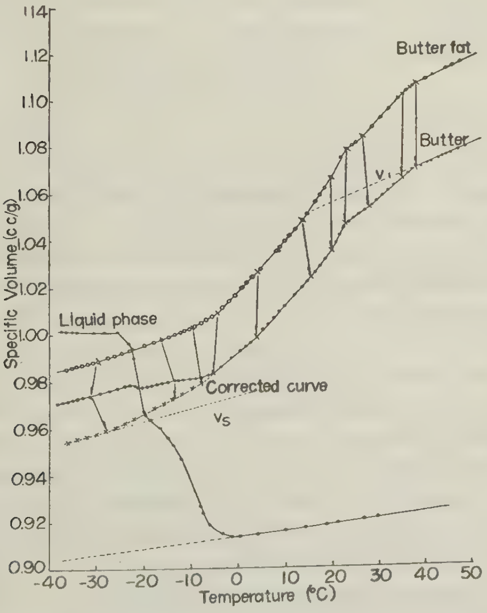

Fig. 10. Specific volume of butter fat, butter and liquid component versus temperature.

Volume-temperature relation of butter fat shows distinctly many breaks at the respective specified temperature. The lower (under −32°C) and upper (over 40°C) linear portion is the specific volume of solid state and liquid state of fat respectively varying with temperature. The breaks between these two parts should correspond to the phase transition temperature of many ingredients (glyceride of fatty acids) involved in the specimen. The specification of each glycerides of fatty acid corresponding to each breaks, however, could not be performed.

The thermal expansion coefficient of butter fat evaluated by Demann, et al.[19)] was 0.58×10^{-3} c.c./g.°C for the solid state and 0.58×10^{-3} c.c./g.°C for the liquid state. From the present experiment the thermal expansion coefficient of butter fat was obtained to be 0.48×10^{-3} c.c./g.°C for the solid state and 1.00×10^{-3} c.c./g.°C for the liquid state. The values obtained in both measurements agree approximately with each other.

In the case of whole butter, a depression of dilation curve occurs around −22°C, which is not observed in the case of butter fat. From the thermal dilation curve of liquid component, however, it is recognized that the above depression is caused by the freezing of liquid droplets contained in the butter. Consequently, in order to obtain the relation between the crystallinity of fat and temperature, the dilation curve of whole butter must be corrected by substituting the extrapolated values which are obtained by extending of the linear portion of the liquid component curve. The corrected curve is shown by the dotted line in Fig. 10. Each transition points of butter are in fairly good agreement with those of butter fat (see Table I).

The degree of crystallization θ is calculated by the following relation,

$$\theta=\frac{v_l-v_t}{v_l-v_s}, \qquad (12)$$

where v_l, v_s is the specific volume of the liquid and solid state of butter respectively. The value v_l and v_s at the measuring temperature t were obtained by the extrapolation of the straight lines at both ends in the dilation curve.

Table I. Thermal transition points of Butter and Butter fat.

Butter fat, $t_{B.F}$ (°C)	Butter, t_B (°C)	Δt ($t_B - t_{B.F}$)
−30.8	−31.0	−0.2
−16.5	−13.8	+2.7
−10.0	− 8.0	+2.0
− 4.8	− 5.5	−0.7
3.8	3.6	−0.2
13.2	16.0	+1.8
19.2	19.5	+0.3
22.6	22.4	−0.2
26.1	27.5	+1.4
35.3	34.5	−0.8
37.6	37.5	−0.1

The degree of crystallization of butter and butter fat obtained from the above calculation is plotted against temperature in Fig. 11. Both curves are very similar with each other. Especially, the fact that the curves fall off in the range from 19°C to 27°C suggests that the large amount of crystallized fat melts at these temperatures, causing the sudden decrease of the viscosity of butter as mentioned previously.

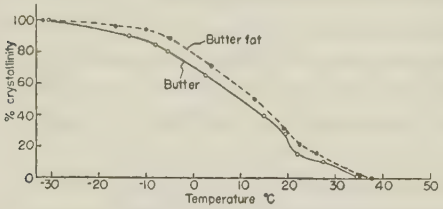

Fig. 11. Crystallinity of butter fat and butter versus temperature.

3.5 *The crystallization of worked butter during setting*

The soft butter which was worked for 30 minutes at 20°C, was filled in a dilatometer and placed in a room regulated to the constant temperature of 20°C. Then the decrease of specific volume was measured for the period of 60 days. The degree of crystallization corresponding to each specific volume can be calculated using the correlation curve which was given in Fig. 10.

Immediately after working of the butter, as is seen in Fig. 12, the degree of crystallization is only about 3%, but it gradually increases through many steps.

Each jumping from step to step probably corresponds to the transformation from the metastable state to crystallized state of each di- or tri-glyceride.

Avrami has theoretically found that the kinetics of phase change is expressed by the following equation[20)]-

$$1-\frac{v_0-v_t}{v_0-v_\infty}=\exp(-kt^n)\,, \qquad (13)$$

where v_t is the specific volume at time t, v_0 and v_∞ the specific volume at the initial and the final state respectively, and k, n are constants. The constant k is proportional to the rate of nucleation and also to the rate of growth, while the constant n is defined by the mechanism of nucleation (see Table II). When the logarithm of $\log(v_\infty-v_t)/(v_\infty-v_0)$ is plotted against the logarithm of time, n is obtained from the slope of line and changes from 1 to 4.

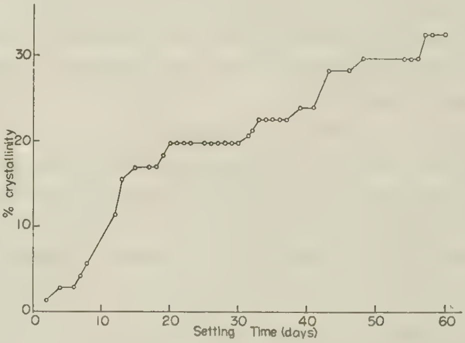

Fig. 12. Crystallization curve of worked butter during setting at 20°C.

Table II.

Value of n.	Shape of crystal	Mechanism of genesis of nuclei
1	needle like	predetermined
2	needle like	sporadic
3	polyhedral like	predetermined
4	polyhedral like	sporadic

According to the equation (13), the results of Fig. 12 were reproduced in Fig. 13. The relation between $\log\log(v_\infty-v_t)/(v_\infty-v_0)$ and $\log t$ is linear and its slope is about 1.1. Thus, it can be said that the crystals in worked butter grow up in the needle-like shape and their nuclei generate predeterminately.

The experimental results obtained at −5°C are also plotted in Fig. 13 in which the slope is about 2.0. Therefore, although the shape of crystals is needle-like, the genesis of nuclei is sporadic.

Few observations have been published on the crystal growth of butter and other fat during isothermal setting. Microscopic observations by Mohr, et al.[17),21)] can only be referred.

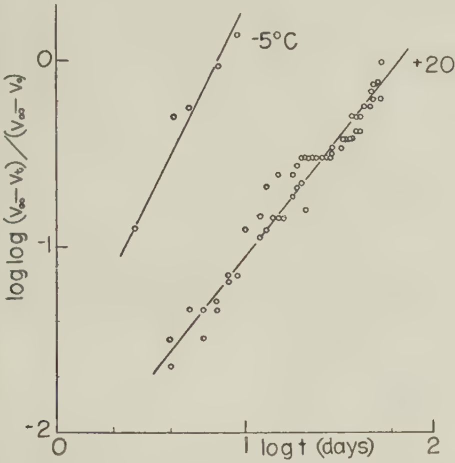

Fig. 13. The analysis of the change of specific volume during setting by Avrami's theory.

Recently, the author and his co-worker[22)] have found with the electron microscope that the shape of the crystal in butter is plate-like at low temperature of −40°C. This fact indicates that the value of constant n should become larger at lower temperatures.

3·6 *The recovery of viscosity, yield value and crystallinity during setting*

As described in the previous section 3.3, the viscosity and the yield value of worked butter recover approximately to their original unworked values after sufficient time of setting. In order to investigate further the relation between the degree of crystallization and the rheological properties of butter, the measurements of the viscosity and the yield value during setting was carried out in parallel with the volume dilatometry.

In Fig. 14, the recoveries of the viscosity and the yield value with the lapse of setting days are represented by the logarithmic scales. The rate of recovery of the viscosity is rapid during the initial ten days and then becomes slower. The recover of the yield value is more rapid than the viscosity and the recovered value after setting of ten days approaches nearly to the yield value of unworked butter.

Assuming that the increase of viscosity during setting is proportional to the decrease of specific volume, the values of viscosity can be replaced for the specific volume in the Avrami's equation as follows,

$$1-\frac{\eta_t-\eta_0}{\eta_\infty-\eta_0}=\exp(-kt^n)\,, \qquad (14)$$

where η_t is the viscosity at time t, η_0 and η_∞ the viscosity at the initial and final state respectively. Using equation (14), the results in Fig. 14, were reproduced in Fig. 15.

It is seen there that the plots are slightly

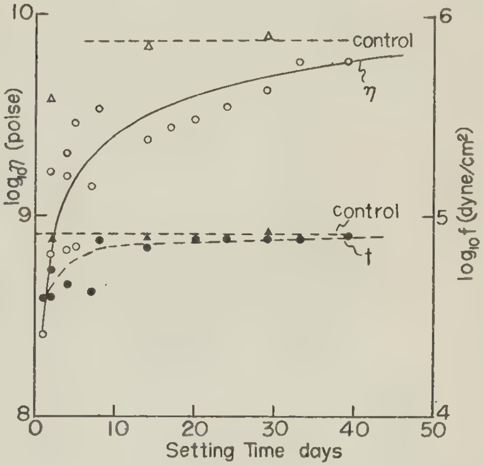

Fig. 14. The recovery of the viscosity η and yield value f of worked butter during setting at 20°C.

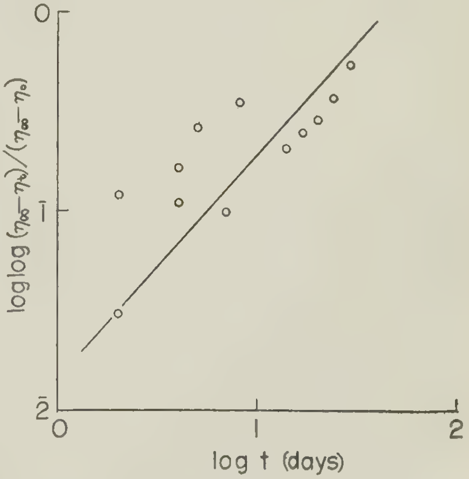

Fig. 15. The analysis of the recovery of viscosity during setting by Avrami's theory. The viscosity was substituted for the specific volume in the Avrami's equation.

disordered but the linear relationship between $\log\log(\eta_\infty-\eta_t)/(\eta_\infty-\eta_0)$ and $\log t$ holds fairly well. The slope of straight line is about 1.2 and agrees with the value of the slope of the straight line in Fig. 13 which expresses the relation between $\log\log(v_\infty-v_t)/(v_\infty-v_0)$ and $\log t$.

From the results mentioned above, it must be admitted that the thixotropic recovery of the viscosity and the yield value is entirely associated with the growth of fat crystals.

§ 4. Conclusion

From all the above described experimental results we may draw some conclusions about the fine structure and the rheological properties of butter which was taken as an example of a soft plastic body. The large temperature dependence, especially around 20°C., is attributed to the melting of fat crystals. The rheological properties are largely dependent on the shear rate and the shear stress and exhibit the non-Newtonian character.

The authors has described in the previous work that the crystals in butter have the dendrical or plate-like shape at low temperatures and their main constituents are the fatty acids of stearin, palmitin and olein. As suggested by Tempel, the fat crystals in butter from a three dimensional network structure, which is deformed under the external force.

Under the low shear stress the breaking of the mechanical interlinks between fat crystals is negligible, but when subjected to higher shear stress as in the case of strong kneading, the junctions between crystals are completely ruptured and causes the softening of the material. Besides, as is seen from dilatometric study, butter includes many kinds of fat which has comparatively low melting temperature. Therefore, the fat crystals are easily melted by the mechanical friction between them during strong kneading.

On the other hand, it is remarkable that the definite yield value is still observed after quite a long working, which suggests the remaining of the crystal network.

It is also noticeable that both the viscosity and the yield value can recover to the original values after setting, which manifests the complete recrystallization of fat crystals.

Phenomenologically butter can be called as a thixotropic substance, or more strictly a plasto-thixotropic substance as defined by Burger, et al.

The isothermal growth of fat crystals during setting can be interpreted by the Avrami's theory. In the fat of kneaded soft butter the needle-like crystals grow during setting and these crystals form a kind of network which occludes liquid oil of low melting temperatures. It has been revealed by the present experiments that the recovery of viscosity during setting is closely related to the crystal growth of butter fat and the formation of crystal network.

A more extended study in the viscoelastic properties of plastic body is now being undertaken. The electron microscope observation would be also helpful in analyzing the microstructure of fat crystals in the texture.

§ 5. Acknowledgements

The author wishes to express his sincere thanks to Dr. Eiichi Fukada, Kobayashi Institute of Physical Research, for his continual guidance and encouragement throughout this work. His particular thanks are due to Prof. Dr. Syoten Oka, Tokyo Metropolitan University, and to Prof. Dr. Jiro Furuichi, Hokkaido University, for their many helpful discussions and advices. He is also indebted to Mr. Masayoshi Fukushima of the Research Laboratory of Snow Brand Milk Products Co. for his contribution in getting the experimental data of this work.

Scattering of Microwaves from a Cylindrical Plasma in the Born Approximation. I

By Yukio MIDZUNO

Department of Physics, Faculty of Science, University of Tokyo

The scattering of a plane microwave incident upon a cylindrically symmetric non-uniform plasma is treated in the Born approximation. When the electric vector is parallel to the axis of the cylinder, the angular distribution function of the cylindrical wave scattered from a cylindrical collisionless plasma is given by

$$f(\theta)=\sqrt{\frac{\pi}{2}}e^{(3/4)\pi j}\int_0^\infty k^2\eta(\rho')J_0\left(2k\rho'\sin\frac{\theta}{2}\right)\rho'd\rho' .$$

Here θ is the scattering angle, $\eta=(\omega_p/\omega)^2$ with the plasma frequency ω_p, and the incident wave is assumed to be proportional to $e^{j(\omega t-kx)}$. The angular distributions for other cases, e.g. waves with the electric vector perpendicular to the axis and/or plasmas with collision loss in a magnetic field, are simply related to $f(\theta)$. For some special density distributions such as that of J_0-type, the integration in $f(\theta)$ can be performed analytically. Finally the same formulas are rederived by summing the radiations from electrons which are forced to oscillate by the incident wave.

§ 1. Introduction

Recently many experiments on the propagation of microwaves in cylindrical discharge tubes have been carried out with the purpose of measuring the density or the density distribution of plasma in the tubes$^{1)}$. Most of them measured the phase shift of the waves effected by the plasma and derived the density using a formula appropriate to the one-dimensional arrangements. In other words, they treated the plasma as if it had the form of an infinite plane slab, upon which a plane microwave is incident normally. But in some of these experiments, the wavelength of the microwaves was comparable with the dimension of the discharge tubes and in such cases the scattering of a plane wave from a cylindrical plasma would be a better approximation to the reality than the arrangements above. Furthermore if we wish to know the density distribution, we must carry out some experiments varying at least one parameter such as the frequency of the microwaves$^{2)}$. In the case of the scattering from a cylindrical plasma, there is a possibility that the angular distribution of the scattered waves can be used for that purpose.

Plasma behaves as a dielectric medium for the propagation of microwaves, and the scattering of microwaves from a cylindrical plasma is nothing but that from a dielectric rod. The effective dielectric constant of a plasma depends on the frequency of the waves and the density of the plasma. It is anisotropic in a magnetic field. Thus we have in general the problem of the scattering from a non-uniform anisotropic dielectric rod[3].

The scatterings of microwaves from a uniform isotropic dielectric rod have been investigated by several authors from both the theoretical and the experimental sides[4),5)]. The same problem from an anisotropic rod was only recently dealt with by Platzman and Ozaki[6], who treated the normal incidence of a plane microwave upon a circular cylinder of a uniform plasma in a uniform magnetic field parallel to the axis of the cylinder. Then the resultant wave equations can be solved in terms of a series of Bessel functions and they got the angular distributions of the scattered waves using an electronic computor. Although their method is rigorous and can be used no matter how dense the plasma is, it would be extremely laborious, were it not prohibitive, to apply this method to a non-uniform cylindrical plasma.

In this paper, we treat the scattering of microwaves from a non-uniform cylindrical plasma in the Born approximation. Although this can be applied only to a plasma of relatively low density, it has such an advantage that the final results are very simple for any cylindrically symmetric density distribution of plasma, especially simple for some realistic distributions. We formulate in section 2 the basic equations of our problem, and in section 3 derive the angular distribution of the wave scattered from a non-uniform cylindrical plasma. Section 4 presents the integrated forms of the angular distributions for some realistic density distributions. Finally in section 5 the same formulas as in section 3 are rederived from another point of view, which will help us to grasp the nature of the scatterings from a plasma.

§ 2. Basic Equations

We start with the Maxwellian equations for the electromagnetic field (in Gaussian units)

$$\mathrm{rot}\, \boldsymbol{E}+\frac{1}{c}\frac{\partial \boldsymbol{B}}{\partial t}=0\,, \tag{2.1}$$

$$\mathrm{rot}\, \boldsymbol{B}-\frac{1}{c}\frac{\partial \boldsymbol{E}}{\partial t}=\frac{4\pi}{c}\boldsymbol{J}\,. \tag{2.2}$$

Let a plasma be at rest. Then the current $\boldsymbol{J}$ in the plasma is determined by the following equation[7]:

$$\frac{m}{ne^2}\frac{\partial \boldsymbol{J}}{\partial t}=\boldsymbol{E}+\frac{1}{ne}\,\mathrm{grad}\, p_e-\frac{1}{nec}\boldsymbol{J}\times\boldsymbol{B}-\frac{m\nu}{ne^2}\boldsymbol{J}\,, \tag{2.3}$$

where m, $-e$, ν are the mass, charge and collision frequency of an electron and n and p_e are the number density and the partial pressure of the electron gas respectively. When the wave-length of the incident wave is much larger than the Debye length, as usually the case, $(ne)^{-1}\,\mathrm{grad}\, p_e$ is much smaller than $\boldsymbol{E}$ induced by the density variations of electrons and can be neglected. Furthermore since we shall treat $\boldsymbol{J}$ as a small quantity induced by the incident waves, $\boldsymbol{B}$ in the right hand side of (2.3) can be replaced by the external uniform static field $\boldsymbol{B}_0$. Then under the assumption that no external electrostatic field exists and that all small oscillating quantities are proportional to $e^{j\omega t}$, where ω is the frequency of the incident wave, (2.3) reduces to

$$(1-j\beta)\boldsymbol{J}-j\gamma\boldsymbol{J}\times\boldsymbol{b}=-j\frac{\omega}{4\pi}\eta\boldsymbol{E}\,. \tag{2.4}$$

Here $\beta=\nu/\omega$, $\gamma=\omega_c/\omega$, $\eta=(\omega_p/\omega)^2$; ω_c and ω_p are the electron cyclotron frequency and the plasma frequency respectively,

$$\omega_c=\frac{e|\boldsymbol{B}_0|}{mc}\,,\qquad \omega_p{}^2=\frac{4\pi e^2 n}{m}\,, \tag{2.5}$$

and $\boldsymbol{b}$ is the unit vector parallel to $\boldsymbol{B}_0$. The solution of (2.4) is expressed as

$$\boldsymbol{J}=\sigma\cdot\boldsymbol{E}\,, \tag{2.6}$$

where σ is the conductivity tensor and given by (with z axis along $\boldsymbol{b}$)

$$\sigma=\frac{\omega\eta}{4\pi j}\begin{pmatrix} L & jM & 0\\ -jM & L & 0\\ 0 & 0 & N\end{pmatrix}, \tag{2.7}$$

$$L=\frac{1-j\beta}{(1-j\beta)^2-\gamma^2}\,,\quad M=\frac{\gamma}{(1-j\beta)^2-\gamma^2}\,,\quad N=\frac{1}{1-j\beta}\,. \tag{2.8}$$

The substitution of (2.6) into (2.2) shows that the plasma is equivalent to a medium whose effective dielectric constant is given by

$$\mathcal{E}=\begin{pmatrix}1-L\eta & -jM\eta & 0\\ jM\eta & 1-L\eta & 0\\ 0 & 0 & 1-N\eta\end{pmatrix}. \tag{2.9}$$

Let us derive the equation for $\boldsymbol{E}$. On eliminating $\boldsymbol{B}$ from (2.1) and (2.2) and using (2.6) we get

$$-\operatorname{rot}\operatorname{rot}\boldsymbol{E}+k^2\boldsymbol{E}=\frac{1}{c}4\pi jk\sigma\cdot\boldsymbol{E}\,, \tag{2.10}$$

where $k=\omega/c$. If we introduce the cylindrical coordinates (ρ, θ, z) with z axis along $\boldsymbol{b}$ and assume all the quantities to be independent of z, (2.10) reduces to

$$\frac{1}{\rho}\frac{\partial}{\partial\rho}\left(\rho\frac{\partial E_z}{\partial\rho}\right)+\frac{1}{\rho^2}\frac{\partial^2 E_z}{\partial\theta^2}+k^2E_z=k^2N\eta E_z \tag{2.11}$$

and other two equations which contain E_ρ and E_θ simultaneously.

The equation for $\boldsymbol{B}$ are derived in a similar manner from (2.1), (2.2) and (2.6) to be

$$\operatorname{rot}\operatorname{rot}\boldsymbol{B}-k^2\boldsymbol{B}=\frac{4\pi}{c}\operatorname{rot}(\sigma\cdot\boldsymbol{E})\,, \tag{2.12}$$

which reduces, under the same assumption as above, to

$$\begin{aligned}&\frac{1}{\rho}\frac{\partial}{\partial\rho}\left(\rho\frac{\partial B_z}{\partial\rho}\right)+\frac{1}{\rho^2}\frac{\partial^2 B_z}{\partial\theta^2}+k^2B_z\\ &\qquad=jk\left\{\frac{1}{\rho}\frac{\partial}{\partial\rho}[\rho(-jM\eta E_\rho+L\eta E_\theta)]-\frac{1}{\rho}\frac{\partial}{\partial\theta}[L\eta E_\rho+jM\eta E_\theta]\right\}\end{aligned} \tag{2.13}$$

and other two equations for B_ρ and B_θ. $\boldsymbol{E}$ is given in terms of $\boldsymbol{B}$ to be

$$\boldsymbol{E}=\frac{1}{jk}\mathcal{E}^{-1}\operatorname{rot}\boldsymbol{B}\,, \tag{2.14}$$

where $\mathcal{E}^{-1}$ means the inverse tensor of $\mathcal{E}$. It is written in components as follows:

$$\left.\begin{aligned}E_\rho&=\frac{1}{jk}\frac{1}{(1-L\eta)^2+(M\eta)^2}\left[(1-L\eta)\frac{1}{\rho}\frac{\partial B_z}{\partial\theta}-jM\eta\frac{\partial B_z}{\partial\rho}\right],\\ E_\theta&=-\frac{1}{jk}\frac{1}{(1-L\eta)^2+(M\eta)^2}\left[jM\eta\frac{1}{\rho}\frac{\partial B_z}{\partial\theta}+(1-L\eta)\frac{\partial B_z}{\partial\rho}\right],\\ E_z&=\frac{1}{jk}\frac{1}{1-N\eta}\left[\frac{1}{\rho}\frac{\partial}{\partial\rho}(\rho B_\theta)-\frac{1}{\rho}\frac{\partial B_\rho}{\partial\theta}\right].\end{aligned}\right\} \tag{2.15}$$

Substitution of (2.15) into (2.13) gives us the desired equation for B_z. In the following throughout this paper we make an assumption that the density distributions of plasmas are independent of θ. Then (2.13) can be reduced to a little more convenient form:

$$\begin{aligned}&\frac{1}{\rho}\frac{\partial}{\partial\rho}\left(\rho\frac{\partial B_z}{\partial\rho}\right)+\frac{1}{\rho^2}\frac{\partial^2 B_z}{\partial\theta^2}+k^2B_z=k^2L\eta B_z\\ &\qquad+jk\left\{-jM\eta\left[\frac{1}{\rho}\frac{\partial}{\partial\rho}(\rho E_\rho)+\frac{1}{\rho}\frac{\partial}{\partial\theta}E_\theta\right]-jE_\rho\frac{\partial}{\partial\rho}(M\eta)+E_\theta\frac{\partial}{\partial\rho}(L\eta)\right\}.\end{aligned} \tag{2.16}$$

From these equations it follows that two modes of waves exist independently each other, one of which has only E_z, H_ρ, H_θ as non-zero components and the other has only H_z, E_ρ and E_θ, and that every normally incident wave can be expressed as a superposition of these waves[3)]. We shall call the former as waves of E-type and the latter as waves of H-type. Then the basic equation for the waves of E-type is (2.11) and that for H-type is given by (2.16) and (2.15).

§ 3. The Scattering Formulas in the Born Approximation

First we discuss the scattering of the waves of E-type. It is shown in Appendix that by means of the two-dimensional Fourier transforms the equation (2.11) is transformed to

$$E_z(\boldsymbol{\rho})=\text{incident wave}+\frac{j}{4}k^2\int H_0^{(2)}(k|\boldsymbol{\rho}-\boldsymbol{\rho}'|)N\eta(\rho')E_z(\boldsymbol{\rho}')d\boldsymbol{\rho}'\,. \tag{3.1}$$

Here $H_0^{(2)}(x)$ is the Hankel function of the second kind; $\boldsymbol{\rho}$ and $\boldsymbol{\rho}'$ are two-dimensional vectors; the integration should be carried out over all the plane, and we have used the boundary condition that at infinity the scattered waves should have only the outgoing components. The expression (3.1) enables us to get $E_z(\boldsymbol{\rho})$ in a power series of η by the successive substitutions. But here we adopt the Born approximation and make the substitution only once. Then $E_z(\boldsymbol{\rho}')$ in the integrand of (3.1) may be replaced by $E_z(\boldsymbol{\rho}')$ of the incident wave itself.

Let the incident wave to be a plane wave*:

$$E_{0z}(\boldsymbol{\rho})=E_0e^{-j\boldsymbol{k}\cdot\boldsymbol{\rho}}\,, \tag{3.2}$$

where $\boldsymbol{k}$ is a wave vector normal to the axis of the cylinder and $|\boldsymbol{k}|=k$. Now we are interested in the field at a remote point, i.e. the case for $\rho\gg\rho_0$ and $k\rho\gg1$, where ρ_0 denotes the radius of the cylindrical plasma. Accordingly we can replace $H_0^{(2)}(k|\boldsymbol{\rho}-\boldsymbol{\rho}'|)$ in the integrand of (3.1) by its asymptotic expression:

$$H_0^{(2)}(k|\boldsymbol{\rho}-\boldsymbol{\rho}'|)=\sqrt{\frac{2}{\pi}}\frac{1}{\sqrt{k\rho}}e^{-jk\rho+jk\rho'\cos\varphi+(\pi/4)j}+O\left(\frac{1}{(k\rho)^{3/2}}\right) \tag{3.3}$$

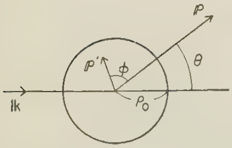

Fig. 1.

where φ is the angle between $\boldsymbol{\rho}$ and $\boldsymbol{\rho}'$ (Fig. 1), and thus we get the following final result:

$$E_z(\boldsymbol{\rho})=E_0e^{-j\boldsymbol{k}\cdot\boldsymbol{\rho}}+E_0f_{\parallel}(\theta)\frac{1}{\sqrt{k\rho}}e^{-jk\rho}+O\left(\frac{1}{(k\rho)^{3/2}}\right) \tag{3.4}$$

with

$$f_{\parallel}(\theta)=\frac{1}{4}\sqrt{\frac{2}{\pi}}e^{(3/4)\pi j}\int k^2N\eta(\rho')e^{jk\rho'(\cos\varphi-\cos(\theta+\varphi))}d\boldsymbol{\rho}'\,, \tag{3.5}$$

or, when the integration with respect to φ is carried out

$$f_{\parallel}(\theta)=\sqrt{\frac{\pi}{2}}e^{(3/4)\pi j}\int_0^\infty k^2N\eta(\rho')J_0\left(2k\rho'\sin\frac{\theta}{2}\right)\rho'd\rho'\,. \tag{3.6}$$

The magnetic field of the scattered wave at a remote place is derived from equation (2.1) to be

$$B_{s\rho}(\boldsymbol{\rho})=O\left(\frac{1}{(k\rho)^{3/2}}\right), \qquad B_{s\theta}(\boldsymbol{\rho})=E_0f_{\parallel}(\theta)\frac{1}{\sqrt{k\rho}}e^{-jk\rho}+O\left(\frac{1}{(k\rho)^{3/2}}\right). \tag{3.7}$$

The waves of H-type can be treated just in the same way as above. We get the following equation corresponding to (3.1):

$$B_z(\boldsymbol{\rho})=\text{incident wave}+\frac{j}{4}k^2\int H_0^{(2)}(k|\boldsymbol{\rho}-\boldsymbol{\rho}'|)[\text{r.h.s. of (2.16) }(\boldsymbol{\rho}')]d\boldsymbol{\rho}'\,. \tag{3.8}$$

In the Born approximation, $\boldsymbol{E}$ and $\boldsymbol{B}$ in the integrand of (3.8) are again replaced by those of the incident wave. Here we note that for the incident wave

$$\frac{1}{\rho}\frac{\partial}{\partial\rho}(\rho E_\rho)+\frac{1}{\rho}\frac{\partial}{\partial\theta}E_\theta$$

vanishes identically because the field must satisfy the Maxwell equations in vacuum. Let the incident wave be a plane wave

$$B_{0z}(\rho)=B_0e^{-j\boldsymbol{k}\cdot\boldsymbol{\rho}} \tag{3.9}$$

$$E_{0\rho}(\boldsymbol{\rho})=B_0\sin\theta e^{-j\boldsymbol{k}\cdot\boldsymbol{\rho}}\,, \qquad E_{0\theta}(\rho)=B_0\cos\theta e^{-j\boldsymbol{k}\cdot\boldsymbol{\rho}}\,. \tag{3.10}$$

---

* In this section we omit the time factor $e^{j\omega t}$.

Then we have

$$B_z(\boldsymbol{\rho})=B_0e^{-j\boldsymbol{k}\cdot\boldsymbol{\rho}}+\frac{j}{4}\int H_0^{(2)}(k|\boldsymbol{\rho}-\boldsymbol{\rho}'|)$$
$$\times\left\{k^2L\eta(\rho')e^{-j\boldsymbol{k}\cdot\boldsymbol{\rho}'}+k\sin\theta' e^{-j\boldsymbol{k}\cdot\boldsymbol{\rho}'}\frac{\partial}{\partial\rho'}(M\eta(\rho'))+jk\cos\theta' e^{-j\boldsymbol{k}\cdot\boldsymbol{\rho}'}\frac{\partial}{\partial\rho'}(L\eta(\rho'))\right\}d\boldsymbol{\rho}'$$

where (ρ', θ') is the components of $\boldsymbol{\rho}'$ in the two-dimensional polar coordinate system. On carrying out the integration with respect to θ', we get the final result

$$B_z(\boldsymbol{\rho})=B_0e^{-j\boldsymbol{k}\cdot\boldsymbol{\rho}}+B_0f_\perp(\theta)\frac{1}{\sqrt{k\rho}}e^{-jk\rho}+\mathrm{O}\left(\frac{1}{(k\rho)^{3/2}}\right), \tag{3.11}$$

$$f_\perp(\theta)=\sqrt{\frac{\pi}{2}}e^{(3/4)\pi j}\left\{\int_0^\infty k^2L\eta(\rho')J_0\left(2k\rho'\sin\frac{\theta}{2}\right)\rho'd\rho'\right.$$
$$+j\cos\frac{\theta}{2}\int_0^\infty k\frac{\partial}{\partial\rho'}(M\eta(\rho'))J_1\left(2k\rho'\sin\frac{\theta}{2}\right)\rho'd\rho'$$
$$\left.+\sin\frac{\theta}{2}\int_0^\infty k\frac{\partial}{\partial\rho'}(L\eta(\rho'))J_1\left(2k\rho'\sin\frac{\theta}{2}\right)\rho'd\rho'\right\}$$
$$=\sqrt{\frac{\pi}{2}}e^{(3/4)\pi j}\int_0^\infty k^2(L\cos\theta-jM\sin\theta)\eta(\rho')J_0\left(2k\rho'\sin\frac{\theta}{2}\right)\rho'd\rho'. \tag{3.12}$$

The electric field of the scattered wave is given by

$$E_{s\rho}(\rho)=\mathrm{O}\left(\frac{1}{(k\rho)^{3/2}}\right),\qquad E_{s\theta}(\rho)=B_0f_\perp(\theta)\frac{1}{\sqrt{k\rho}}e^{-jk\rho}+\mathrm{O}\left(\frac{1}{(k\rho)^{3/2}}\right). \tag{3.13}$$

It should be noted that a resonance phenomenon will occur at $\gamma\ (=\omega_c/\omega)=1$, as easily seen from (2.8). But since one of our basic assumptions is that the scattered wave should be weak compared with the incident wave, (3.12) ought not to be used under the condition $\gamma\approx 1$ and $\beta\ (=\nu/\omega)\ll 1$.

§ 4. Density Distributions of Some Special Types

In fully ionized gases β is proportional to n, but in slightly ionized gases it is independent of n. Accordingly under uniform external magnetic fields, L, M and N can be regarded as constants independent of the density distribution of the plasma in a slightly ionized gas or under the condition $\beta\ll 1$. Then it is convenient to express $f_\parallel(\theta)$ and $f_\perp(\theta)$ in terms of $f_\parallel(\theta)$ for the collisionless plasma, which we denote by $f(\theta)$ in the following.

$$f_\parallel(\theta)=Nf(\theta), \tag{4.1}$$

$$f_\perp(\theta)=(L\cos\theta-jM\sin\theta)f(\theta), \tag{4.2}$$

$$f(\theta)=\sqrt{\frac{\pi}{2}}e^{(3/4)\pi j}\int_0^\infty k^2\eta(\rho')J_0\left(2k\rho'\sin\frac{\theta}{2}\right)\rho'd\rho'. \tag{4.3}$$

For some types of density distributions, the integration in (4.3) can be performed analytically. In this section we shall show some useful examples.

Hereafter we assume $\eta(\rho)=0$ for $\rho>\rho_0$, and give explicitly the dependency of η on ρ only for $\rho<\rho_0$.

1. *The Uniform Distribution*

When

$$\eta=\eta_0\qquad\text{for}\quad\rho<\rho_0, \tag{4.4}$$

$$f(\theta)=\frac{1}{2}\sqrt{\frac{\pi}{2}}e^{(3/4)\pi j}\frac{k\rho_0J_1(2k\rho_0\sin(\theta/2))}{\sin(\theta/2)}\eta_0. \tag{4.5}$$

2. *The Parabolic Distribution*

The distributions of the type ρ^{2n} ($n=0, 1, 2, \cdots$) enable us to perform the integration in $f(\eta)$ analytically by using the formula

$$\int z^{m+1}J_0(z)dz=-m^2\int z^{m-1}J_0(z)dz+z^{m+1}J_1(z)+mz^mJ_0(z)\,. \tag{4.6}$$

The uniform distribution is a special case of them. Another interesting case would be the parabolic distribution:

$$\eta(\rho)=\eta_0[1-(\rho/\rho_0)^2] \qquad \text{for} \quad \rho<\rho_0\,, \tag{4.7}$$

$$f(\theta)=\sqrt{\frac{\pi}{2}}\,e^{(3/4)\pi j}\frac{J_2(2k\rho_0\sin(\theta/2))}{2\sin^2(\theta/2)}\eta_0\,. \tag{4.8}$$

3. *The Distribution of J_0-type*

In a positive column the most plausible density distribution is that of J_0-type[8]:

$$\eta(\rho)=\eta_0J_0(\zeta_1\rho/\rho_0) \qquad \text{for} \quad \rho<\rho_0\,, \tag{4.9}$$

where $\zeta_1=2.4048\cdots$ is the least zero-point of $J_0(x)$. For this distribution also the integration can be performed giving

$$f(\theta)=\sqrt{\frac{\pi}{2}}\,e^{(3/4)\pi j}\zeta_1J_1(\zeta_1)\frac{(k\rho_0)^2J_0(2k\rho_0\sin(\theta/2))}{\zeta_1^2-(2k\rho_0\sin(\theta/2))^2}\eta_0\,. \tag{4.10}$$

§ 5. An Alternative Derivation of the Scattering Formulas

Scattering of microwaves by a plasma is effected by the following mechanism. Electrons in the plasma are forced to oscillate by the field of the incident wave and emit radiations, which in turn perturb the motion of other electrons. In the Born approximation the motion of electrons is assumed to be determined solely by the incident wave and the effect of the scattered waves are neglected. Then it is possible to get the scattering formulas by discussing the motion of each electron directly and summing the radiations from all the electrons in the plasma. Although this procedure gives of course the same formulas as before, it would considerably help us to grasp the very nature of the scattering.

Let us consider the motion of an electron. We neglect the thermal motion of the electron and let the electron oscillate about a point Q($\boldsymbol r'$) under the influence of the incident wave. The equation of motion for the electron is

$$m\frac{d^2}{dt^2}\tilde{\boldsymbol r}=-e\boldsymbol E(\tilde{\boldsymbol r},t)-\frac{e}{c}\frac{d\tilde{\boldsymbol r}}{dt}\times\boldsymbol B(\tilde{\boldsymbol r},t)-m\nu\frac{d\tilde{\boldsymbol r}}{dt}\,. \tag{5.1}$$

Here we can replace $\boldsymbol B(\tilde{\boldsymbol r},t)$ by $\boldsymbol B_0$; and under the assumption that the amplitude of the oscillation is far smaller than the wave length of the incident wave, $\boldsymbol E(\tilde{\boldsymbol r},t)$ can be replaced by $\boldsymbol E_0(\boldsymbol r',t)$. Assuming all the varying quantities are proportional to $e^{j\omega t}$, we can easily solve (5.1) and get the electric dipole moment $\boldsymbol p(t)$ about Q due to this electron.

First we shall consider the case of waves of the E-type. The incident wave is given by

$$E_{0z}(\boldsymbol\rho,t)=E_0e^{j(\omega t-\boldsymbol k\cdot\boldsymbol\rho)}\,, \qquad E_{0x}=E_{0y}=0\,. \tag{5.2}$$

Then from the solution of (5.1) we get

$$\boldsymbol p(t)=-\frac{e^2E_0}{m\omega^2}Ne^{j(\omega t-\boldsymbol k\cdot\boldsymbol\rho')}\boldsymbol e_z\,, \tag{5.3}$$

where $\boldsymbol e_z$ is the unit vector along z axis ($=\boldsymbol b$). Let us take a remote point P($\boldsymbol r$) (Fig. 2). The electromagnetic field at P is[9]

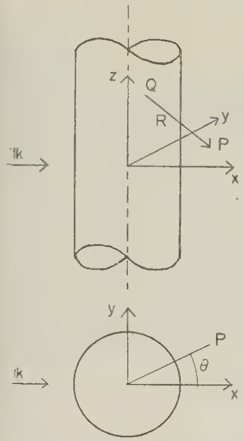

Fig. 2.

$$\boldsymbol{E}(\boldsymbol{r},t)=-\frac{\ddot{\boldsymbol{p}}}{c^2R}+\frac{\boldsymbol{R}(\ddot{\boldsymbol{p}}\cdot\boldsymbol{R})}{c^2R^3}\,, \tag{5.4}$$

$$\boldsymbol{B}(\boldsymbol{r},t)=-\frac{\boldsymbol{R}\times\ddot{\boldsymbol{p}}}{c^2R^2}\,, \tag{5.5}$$

where $\boldsymbol{R}$ is the vector from Q to P, $R=|\boldsymbol{R}|$ and

$$\ddot{\boldsymbol{p}}=\frac{\partial^2}{\partial t^2}\,\boldsymbol{p}\left(t-\frac{R}{c}\right)=-\omega^2\boldsymbol{p}\left(t-\frac{R}{c}\right). \tag{5.6}$$

Thus denoting the cylindrical coordinate of P by $(\rho,\theta,0)$ and that of Q by (ρ',θ',z'), we have the contribution of the electron at Q to the scattered field E_{sz} at P as follows:

$$\begin{aligned}(E_{sz}(\boldsymbol{r},t))_{\mathrm{Q}}&=\frac{\omega^2p_z(t-(R/c))}{c^2R}-\frac{z'(\omega^2\boldsymbol{p}(t-(R/c))\cdot\boldsymbol{R})}{c^2R^3}\\&=-\frac{e^2E_0}{c^2m}N\frac{1}{R}\left(1-\frac{z'^2}{R^2}\right)e^{j(\omega t-kR-k\rho'\cos\theta')}\,.\end{aligned}$$

Then summing the contributions from all the electrons in the plasma, we get

$$E_{sz}(\boldsymbol{r},t)=-\frac{k^2E_0}{4\pi}e^{j\omega t}\int\frac{1}{R}\left(1-\frac{z'^2}{R^2}\right)e^{-j(kR+k\rho'\cos\theta')}N\eta(\rho')d\boldsymbol{r}'\,, \tag{5.7}$$

where the integration should be carried out over the entire space.

In the course of the integration with respect to z', we meet the following type of integral.

$$\begin{aligned}I&\equiv\int_{-\infty}^{\infty}\frac{1}{R^3}e^{-jkR}dz'\\&=\int_{-\infty}^{\infty}\frac{1}{(\xi^2+z'^2)^{3/2}}\exp\{-jk(\xi^2+z'^2)^{1/2}\}dz'\end{aligned} \tag{5.8}$$

where

$$\xi^2=\rho^2+\rho'^2-2\rho\rho'\cos(\theta-\theta')\,. \tag{5.9}$$

Since in our problem $\rho\gg\rho'$ and $k\rho\gg1$, there holds $k\xi\gg1$. Accordingly we need only the asymptotic expression of I for $k\xi\gg1$. When we introduce a new variable $u=k(R-\xi)=k((\xi^2+z'^2)^{1/2}-\xi)$, the integral I reduces to

$$I=2k^2e^{-jk\xi}\int_0^{\infty}\frac{e^{-ju}du}{(u+k\xi)^2\sqrt{u+2k\xi}\sqrt{u}}$$

from which the asymtotic expression can be shown without difficulty to be

$$I=\sqrt{2\pi}k^2\frac{1}{(k\xi)^{5/2}}e^{-jk\xi-(\pi/4)j}\left[1+\mathrm{O}\left(\frac{1}{k\xi}\right)\right]. \tag{5.10}$$

Then the integration over θ' can be carried out as in §3 and we get the final result:

$$E_{sz}(\boldsymbol{r},t)=E_0\sqrt{\frac{\pi}{2}}e^{(3/4)\pi j}\frac{1}{\sqrt{k\rho}}e^{j(\omega t-k\rho)}\int_0^{\infty}k^2N\eta(\rho')J_0\left(2k\rho'\sin\frac{\theta}{2}\right)\rho'd\rho'\,. \tag{5.11}$$

This is just the same expression as (3.6). E_{sx} and E_{sy} are easily shown to vanish in the course of the integration with respect to z'.

When the incident wave is of H-type

$$E_{0y}(\boldsymbol{\rho},t)=B_0e^{j(\omega t-kx)}\,,\qquad E_{0x}=E_{0z}=0\,, \tag{5.12}$$

we have

$$p(t)=-(jMe_x+Le_y)\frac{e^2B_0}{m\omega^2}e^{j(\omega t-kx')}\,, \tag{5.13}$$

where e_x and e_y are unit vectors along x axis and y axis respectively. The contribution to the scattered field B_{sz} at P from an electron at Q is

$$\begin{aligned}(B_{sz}(\boldsymbol{r},t))_Q&=-\frac{1}{c^2R^2}(\boldsymbol{R}\times\ddot{\boldsymbol{p}})_z\\ &\approx\frac{\omega^2\rho}{c^2R^2}\left[\cos\theta p_y\left(t-\frac{R}{c}\right)-\sin\theta p_x\left(t-\frac{R}{c}\right)\right]\\ &=-\frac{e^2B_0}{c^2m}\frac{\rho}{R^2}(L\cos\theta-jM\sin\theta)e^{j(\omega t-kR-kx')}\,,\end{aligned} \tag{5.14}$$

and the scattered field ot P is given by

$$B_{sz}(\mathbf{r},t)=-\frac{k^2B_0}{4\pi}e^{j\omega t}\int\frac{\rho}{R^2}e^{-j(kR+kx')}(L\cos\theta-jM\sin\theta)\eta(\rho')d\mathbf{r}'\,. \tag{5.15}$$

Here the integral,

$$\int_{-\infty}^{\infty}\frac{1}{R^2}e^{-jkR}dz'$$

is evaluated for $k\xi\gg1$ to be

$$\sqrt{2\pi}\,k\frac{1}{(k\xi)^{3/2}}e^{-jk\xi-(\pi/4)j}\left(1+O\left(\frac{1}{k\xi}\right)\right). \tag{5.16}$$

After the integration with respect to θ', we get the final result:

$$\begin{aligned}B_{sz}(\boldsymbol{r},t)=B_0\sqrt{\frac{\pi}{2}}e^{(3/4)\pi j}\frac{1}{\sqrt{k\rho}}e^{j(\omega t-k\rho)}\\ \times\int_0^\infty k^2(L\cos\theta-jM\sin\theta)\eta(\rho')J_0\left(2k\rho'\sin\frac{\theta}{2}\right)\rho'd\rho'\,,\end{aligned} \tag{5.17}$$

which is again equivalent to (3.12). B_{sx} and B_{sy} vanish in the course of the integration with respect to z'.

§ 6. Concluding Remarks

We have derived the formulas for the angular distribution of the microwaves scattered by a cylindrical plasma when a plane wave is incident normally upon the cylinder. Consulting the derivations, we find that our formulas are valid under the following conditions.

1) The scattered wave is very weak compared with the incident wave within the cylindrical plasma.

2) The amplitude of the forced oscillation of electrons in plasma is much smaller than the wavelength of the incident wave.

3) The distance between the electron and the point of observation is much larger than both the wavelength of the incident electromagnetic field and the radius of the cylinder.

The expression for $f(\theta)$ has the form of the Hankel transform[10]:

$$f^*(x)=\sqrt{\frac{\pi}{2}}e^{(3/4)\pi j}(k\rho_0)^2\int_0^\infty\eta^*(y)J_0(xy)ydy\,, \tag{6.1}$$

where we have introduced the dimensionless variables $x=2k\rho_0\sin(\theta/2)$ and $y=\rho/\rho_0$ and the functions $f^*(x)\equiv f(\theta)$ and $\eta^*(y)\equiv\eta(\rho)$. The inversion formula of the Hankel transforms gives

$$\eta^*(y)=\sqrt{\frac{2}{\pi}}e^{-(3/4)\pi j}\frac{1}{(k\rho_0)^2}\int_0^\infty f^*(x)J_0(xy)xdx\,. \tag{6.2}$$

But since x can increase only up to $2k\rho_0$, our knowledge is incomplete to determine $\eta^*(y)$ even if we could measure the angular distribution of the scattered wave completely. And (6.2) shows that the larger $k\rho_0$ is, the more precisely we can determine $\eta^*(y)$, as expected. Although our formula is thus not sufficient to determine the density distribution completely, it would be very useful when we wish to analyse experimental results assuming some reasonable distributions.

The author wishes to express his sincere thanks to Prof. T. Kihara for his continual guidance and his kindness in reading the original manuscript. His thanks are also due to Drs. Y. Sakamoto and S. Miyoshi at the Institute of Physical and Chemical Research, who suggested him this problem and gave kind discussions from the experimental side.

Appendix Derivation of (3.1)

We start with the equation (2.11):

$$\nabla^2 E_z+k^2E_z=k^2N\eta(\boldsymbol{\rho})E_z\,. \tag{A.1}$$

On assuming that E_z is independent of z and introducing the two-dimensional Fourier transform $\tilde{E}_z(\boldsymbol{p})$ of $E_z(\boldsymbol{\rho})$ by

$$\int E_z(\boldsymbol{\rho})e^{j\boldsymbol{p}\cdot\boldsymbol{\rho}}d\boldsymbol{\rho}=\tilde{E}_z(\boldsymbol{p})\,, \tag{A.2}$$

we get from (A.1)

$$\tilde{E}_z(\boldsymbol{p})=G(\boldsymbol{p})+\frac{k^2}{k^2-p^2}\int N\eta(\boldsymbol{\rho})E_z(\boldsymbol{\rho})e^{j\boldsymbol{p}\cdot\boldsymbol{\rho}}d\boldsymbol{\rho} \tag{A.3}$$

where $G(\boldsymbol{p})$ is a function of $\boldsymbol{p}$ corresponding to the incident wave and must satisfy $(k^2-p^2)G(\boldsymbol{p})=0$. On inversing (A.3), we have

$$E_z(\boldsymbol{\rho})=\text{incident wave}+\frac{1}{(2\pi)^2}\iint\frac{k^2}{k^2-p^2}N\eta(\boldsymbol{\rho}')E_z(\boldsymbol{\rho}')e^{j\boldsymbol{p}\cdot(\boldsymbol{\rho}-\boldsymbol{\rho}')}d\boldsymbol{\rho}'d\boldsymbol{p} \tag{A.4}$$

or integrating with respect to the angular component φ of $\boldsymbol{p}$, where $j\boldsymbol{p}\cdot(\boldsymbol{\rho}-\boldsymbol{\rho}')=jp|\boldsymbol{\rho}-\boldsymbol{\rho}'|\cos\varphi$, we get

$$E_z(\rho)=\text{incident wave}+\frac{1}{2\pi}\int k^2N\eta(\boldsymbol{\rho}')E_z(\boldsymbol{\rho}')d\boldsymbol{\rho}'\int_0^\infty\frac{J_0(|\boldsymbol{\rho}-\boldsymbol{\rho}'|p)}{k^2-p^2}pdp\,. \tag{A.5}$$

The integration with respect to p must be carried out in such a manner that the result should express the outgoing cylindrical wave at infinity. For this purpose we consider the following integral[11]:

$$I=\frac{1}{2\pi j}\int_C\frac{zH_0^{(2)}(az)}{r^2-z^2}dz\,, \tag{A.6}$$

where a is a real positive number, r is a complex number with a negative imaginary part and C is the integration path shown in Fig. 3. Then

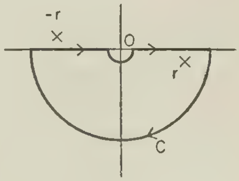

Fig. 3.

$$I=\frac{1}{2\pi j}\int_{-\infty}^{\infty}\frac{zH_0^{(2)}(az)}{r^2-z^2}dz$$
$$=\frac{1}{2\pi j}\left\{\int_0^{\infty}\frac{zH_0^{(2)}(az)}{r^2-z^2}dz-\int_0^{\infty}\frac{zH_0^{(2)}(aze^{-\pi j})}{r^2-z^2}dz\right\}$$
$$=\frac{1}{2\pi j}\int_0^{\infty}\frac{2zJ_0(az)}{r^2-z^2}dz\,. \tag{A.7}$$

On the other hand, the integral I is easily evaluated by means of the residue at the pole. Equating these expressions we get

$$\int_0^{\infty}\frac{zJ_0(az)}{r^2-z^2}dz=\frac{\pi j}{2}H_0^{(2)}(ar)\,. \tag{A.8}$$

Inserting the equation, which is obtained from (A.8) by letting the imaginary part of r tend to zero, into (A.5), we get the desired resut (3.1).

Photoconductive Hall Effect in Potassium Bromide

By Masami ONUKI

Department of Applied Physics, Osaka City University, Osaka

(Received December 9, 1960)

A.C. method was employed to investigate the mobility of the conduction electron in KBr under space charge free condition at temperatures between 80°K and room temperature. In this experiment white light was used to illuminate the specimen to enhance the conductivity. The mobility which depends on temperature was found to be inversely proportional to the mean density of phonons excited in the crystal. This fact suggests that the mobility is determined mainly by the scattering of the optical mode of lattice vibration. Using the Low and Pines formula, the following values were obtained:

Effective mass of the bare conduction electron, $m^*=0.23\,m$
Effective mass of the polaron, $m_p=0.33\,m$
Strength of interaction between the electron and the polarization, $\alpha=2.56$,

where m is the free electron mass.

§1. Introduction

Experimental studies of electron mobility in polar crystals provide means to check theories of polarons developed by a number of authors.[1-4]

The Hall mobilities of electrons (or holes) in CdS, PbS, PbTe, and ZnO which are polar in nature and have comparatively low specific resistance due to presence of impurities, were measured by several workers.[5-7] The mobilities of carriers in these materials were explained by the combination of the scattering mechanisms of both the optical and acoustic modes of lattice vibration even at room temperature, and therefore it was difficult to separate the mobility due to the optical scattering from the other. The strength of interaction between the electron and the polarization produced by the former was estimated to be less than that in the case of alkali halides. Thus the polaron theories were not necessary to be essential to describe the mobility of above materials.

Recently, Brown and his co-workers made accurate measurements of the drift and Hall mobilities of electrons in silver halide.[8-10] According to their results, the drift mobility (μ_D) was much smaller than the Hall mobility (μ_H) around 80°K and below. This fact is due to the apparent large drift time affected by the trapping of electrons in some shallow traps in the crystals observed in the measurement of the drift time. The Hall mobility measured by them was the mobility which was not affected by the trapping, and thus their results were able to be compared with one predicted by the theory. They concluded that reasonable agreement between the experimental results of the Hall mobility and the polaron theories was observed in the temperature region from about 100°K to 30°K. Further, they estimated that $m^*=0.3\,m$, $m_p=0.4\,m$, and $\alpha=2.2$ for AgCl, where m^* and m_p are the effective masses of the bare conduction electron and the polaron, respectively, and α is the strength of interaction of the electron with the polarization. However, studies of electron mobility in alkali halide, which is the most typical material in ionic crystals, have rather been sluggish in development because of the following difficulties; (1) very high resistivity of the crystal even in the photoconducting state, due to extremely short lifetime of the conduction electron ($10^8\sim10^9\ \Omega$ cm at room temperature), (2) non-uniformity of electic field in the crystal due to the formation of space charge field, resulting difficulty to obtain accurate Hall voltage, (3) slow change of the photoconductivity of the crystal due to bleaching of F centers by the irradiation of light, (4) the flicker noise due to trapping and releasing of electrons by various trapping centers produced by the irradiation.

Redfield has measured the Hall mobilities of electrons in KCl, and NaCl at room and liquid nitrogen temperature by the use of pulsed light.[11] However, the observed results are considerably scattered, and it seems difficult to compare them with theory. Macdonald and Robinson have measured the Hall mobility of electron in KBr only at room temperature by the a. c. method.[12] At present, experimental informations about the mobility of polaron are extremely limited. This fact is due to the difficulties mentioned above and is probably to the uncontrolled impurities in the specimens which might decrease the photoconductivity and increase the noise. Accordingly reliable temperature dependence of polaron mobility has been sought for.

We made experiment with KBr of high purity prepared by recrystallization technique. The conductivity was enhanced by illuminating the additively colored crystal with white light. The Hall voltage was measured by a.c. method at 330 cps in the temperature region between −190°C and room temperature. The crystal impedance between the Hall electrodes was measured at each temperature to correct the apparent Hall voltage into the true Hall voltage, because the crystal impedance was much larger than the input impedance of the amplifier used in this experiment. The Hall mobility of the electron was able to be obtained in the above temperature region under the condition of space charge free and small disturbance noise.

§ 2. Experimental Method and Procedure

Irradiation with strong light results in the decrease of photoconductivity of colored alkali halides due to photo-chemical reaction in them. For this reason, a colored KBr crystal which is the most stable against illumination among alkali halides was adopted. Further, the crystals used were purified by the recrystallization process to avoid the flicker noise inherent to the above reaction and to enhance the photoconductivity in the measurement. KBr crystals were additively colored and the concentration of the F center was estimated to be $1\sim2\times10^{16}/\mathrm{cm}^3$. The dimension of specimens was about $4\times1.5\times1.2\,\mathrm{mm}^3$. The electrodes were made of silver paint.

The photoconductivity of colored KBr decays with time if d. c. electric field is applied, because of the formation of space charge.[13–14] This undesirable effect, however, can be eliminated by the use of a. c. field and steady illumination.[15] A. c. 330 cps was adopted for the measurement of the Hall voltage, in consideration of the results of frequency-dependence of a. c. photoconductivity, and to avoid the 60 cps hum noise and flicker noise, the latter of which is inversely proportional to frequency.

The measuring apparatus is shown in Fig. 1. A 330 cps oscillator (A), whose push-pulled outputs are 100 volts maximum with respect to the ground, is connected to the current electrodes (***a*** and ***b***). This oscillator is

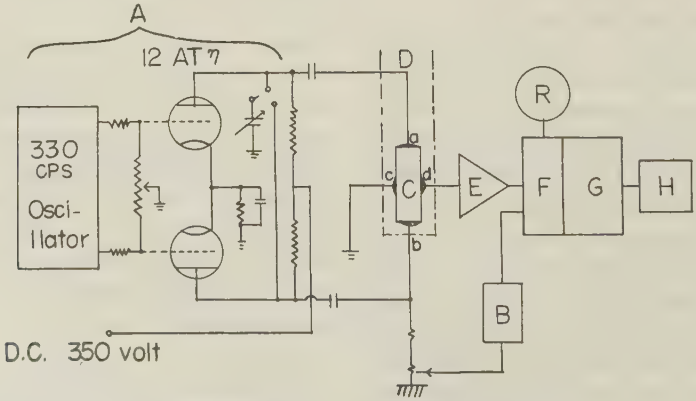

Fig. 1. Apparatus to measure the Hall voltage and the crystal impedance.
(A): 330 cps oscillator; (E): pre-amplifier; (F): differential amplifier; (G): tuned amplifier for 330 cps; (H): d.c. detector; (B): phase-shifter; (C): specimen; (D): cryostat.
For the measurement of crystal impedance, one of the Hall electrodes (c) is connected to the output of the oscillator and the other (d) to the input of the amplifier.

stabilized so that the voltages of the push-pulled outputs are constant and the output wave form has very little distortion. This push-pull driver was devised so that both the voltage and the phase of either output can be changed independently. The background input voltage of the pre-amplifier (***E***) due to the non-uniform illumination over the surface of the specimen and the unbalance-setting of the Hall electrodes could be eliminated to nearly zero by adjusting the voltage and phase of each output of the oscillator.

The input system of the pre-amplifier consists of a cascode circuit after Macdonald, where the input impedance was as large as 80 $M\Omega$ at 330 cps, the input capacitance formed between shielding being eliminated by the feed back device.[16] This pre-amplifier contains also an *RC* tuned amplifier whose pass band is made comparatively wide so as to ensure good phase characteristics vs. frequency. The main amplifier (***F***, ***G***) consists of a differential (***F***) and an *RC* tuned (***G***) amplifier for 330 cps. The d. c. detector (***H***) is set next to the above device. One of the input of the differential amplifier is connected to the output of the oscillator through an attenuator and phase-shifter (***B***). The differential amplifier serves to avoid the effect of induced current through the capacity between the Hall electrodes in the measurement of the crystal impedance and also to adjust the unbalanced voltage between the two Hall electrodes in the measurement of the Hall voltage. A cathode ray oscilloscope (***R***) is attached to the output of the differential amplifier to observe the balancing of the input and to detect the phase of the Hall voltage. The total maximum sensitivity of the device was 3×10^{-3} volt/mA.

A 500 watt projection lamp was used as the light source. The light was filtered with water to eliminate the flicker noise caused by long wave irradiation. Using a focusing lens and mirror, the light was projected uniformly upon the specimen (***C***) in the cryostat (***D***). The gap width of the magnet was 43 mm and the maximum field was 4500 oersteds.

Since the impedance between the Hall electrodes (***c*** and ***d***) which is about $1\sim3\times10^{9}\ \Omega$ at room temperature under illumination, is much higher than the input impedance ($\simeq 80\ M\Omega$), the true Hall voltage V_H is calculated from the apparent Hall voltage V_H' by the use of the following formula,

$$V_H'/V_H = Z_{in}/(Z_{in}+Z_{cry}) \simeq Z_{in}/Z_{cry}\ , \qquad (1)$$

where Z_{in} and Z_{cry} are and the input and the crystal impedance, respectively. Hence, in this work it is necessary to measure Z_{cry} as well as V_H' in order to get V_H.

The Hall mobility μ_H is expressed as follows:

$$\theta = \mu_H H\times10^{-8} = (V_H/t)/(KV_l/l)\ , \qquad (2)$$

(in practical units),

where θ is the Hall angle, H the magnetic field, V_l the applied electric field, t the width, l the length of the specimen, and K the numerical factor due to the non-uniformity of the electric field near the Hall electrodes.

The temperature-dependence of μ_H can be obtained by measuring Z_{cry} and V_H' at each temperature, if we use formula (1), (2), and the measured sensitivity of the detector, where Z_{in}, V_l, t, l, and H are constant and independent of temperature for a given specimen.

The value of K was determined to be 0.83 by the following method. A conducting carbon sheet similar to the specimen in shape, upon which silver-paint electrodes were attached on the same position as that of the specimen, was prepared.[17] A pattern of equipotential lines of the sheet was obtained by a simple experimental procedure. The ratio of the effective electric field estimated from the equipotential line between the Hall electrodes to the average applied field between the two current electrodes was calculated to be 0.83 in the present case.

§ 3. Results and Discussion

(1) *A. c. method of measurement of photoconductivity*

The space charge effect in the measurement of photocurrent is eliminated by adopting the a. c. field and steady illumination. Electrons that approach the anode surface in a half cycle of the a. c. field may fill the ionized F centers (negative ion vacancies) which were formed near the surface in the previous half cycle, thereby the surface regions of the specimen tend to be neutralized.[13]

It has been known that there are non-photoconducting layers between the electrodes and the specimen. These layers behave as constant capacities in series with the true crystal impedance. Fig. 2 shows the equivalent circuit of the specimen in the photoconducting state. If the frequency of the applied a. c. field is comparatively low, almost all of the applied a. c. voltage is fed in these charge-free layers, resulting in small photoconductivity. This effect should cause small Hall voltage, because the longitudinal voltage V_l is not applied uniformly through the specimen. Further, inaccuracy in estimating Z_{cry} should result from this effect.

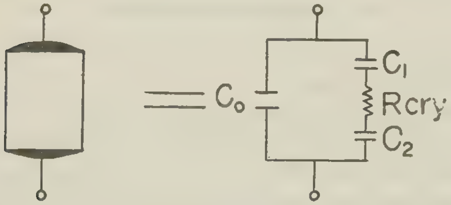

Fig. 2. The equivalent circuit of the specimen in the photoconducting state.
In the circuit diagram, C_0 represents the capacity between the electrodes, R_{cry} the resistance of the photoconducting region in the specimen, and C_1 and C_2 the capacities of the charge-free regions near the electrodes.

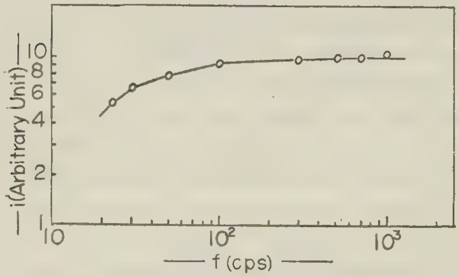

Fig. 3. The frequency-dependence of photocurrent at room temperature.

Frequency-dependence of photocurrent was measured in order to have informations about this surface effect. In this measurement the RC tuned systems contained in the detector were omitted. The frequency of the applied voltage was varied from 20 cps to 1000 cps, the applied voltage being kept at 5 volts throughout this frequency range. The results are shown in Fig. 3. As is seen in the figure, the photocurrent under illumination increases with frequency up to 200 cps and then saturates thereafter. The frequency at which saturation starts shifted to the lower frequency side as the intensity of illumination was decreased. Using this characteristics and the saturated value of the crystal impedance, the capacity of the charge-free layer per unit area may be estimated to be $1.5\times10^2\ \mu\mu F/\text{cm}^2$. If equal charge-free regions about on each electrode, that is, $C_1=C_2$ in Fig. 2, the thickness of the regions may be calculated to be 1.4×10^{-3} cm. At present the cause of the formation of these charge-free layers is not clear.[15] In the measurement of the Hall voltage, the impedance between the two Hall electrodes and that between the two current electrodes under illumination of white light were $1\sim3\times10^9\ \Omega$, and $8\sim25\times10^9\ \Omega$, respectively, which were much larger than the capacitive impedance of the charge-free layers of $2\times10^8\ \Omega$ at 330 cps. For this reason it should be concluded that the undesirable effect of the charge-free layers becomes negligible by adopting 330 cps as the measuring frequency.

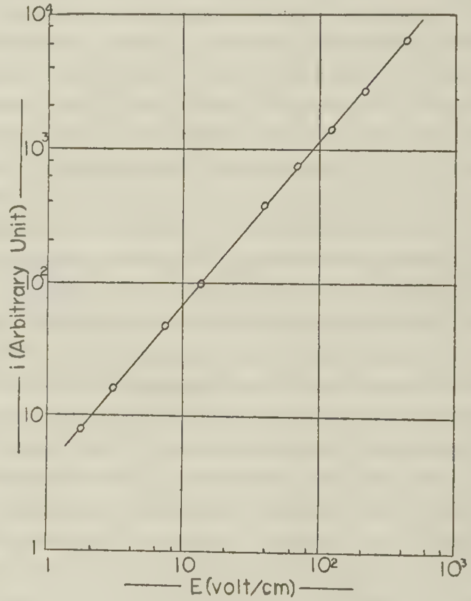

Fig. 4. The field-dependence of photocurrent at 330 cps.

As for the dependence of photocurrent on the applied electric field, results shown in Fig. 4 were obtained. The measuring frequency was 330 cps. The photocurrent was linearly dependent on the field strength from 1.8 volts/cm up to 4×10^2 volts/cm in this measurement. The saturation effect of the photocurrent could not be observed for low fields used in the present work. This fact suggests that the space charge free condition is realized in this experiment.

F centers in KBr are known to behave as trapping centers for conduction electrons at low temperatures below −100°C. In other words, the electrons released from *F* centers are capable of being trapped by other *F* centers which are not ionized, and consequently, *F′* centers may be formed at low temperatures. The *F′* center bleaches thermally to two *F* centers in several seconds at about −100°C. The decay current due to this thermally releasing effect after the turn-off of illumination was observed by the authors.[13] For the reason mentioned above, the temperature-dependence of photocurrent under illumination with white light differed from that under illumination with *F*-band light, as seen in Fig. 5. In the figure the solid line corresponds to the case of the steady white light illumination and the dotted line to the case of the steady *F*-band illumination, the measuring frequency being 330 cps in both cases. In the former case the photocurrent was more enhanced than in the latter case at low temperatures, because of the optical excitation of *F′* electrons by the *F′*-band light contained in white light. As the thermal excitation of *F′* electrons becomes effective at higher temperatures, the curves in Fig. 5 corresponding to the above two cases show identical inclination. To avoid the complicated trapping effect and to enhance the photoconductivity of the specimen, it is desirable to adopt white illumination for the measurement of the Hall voltage.

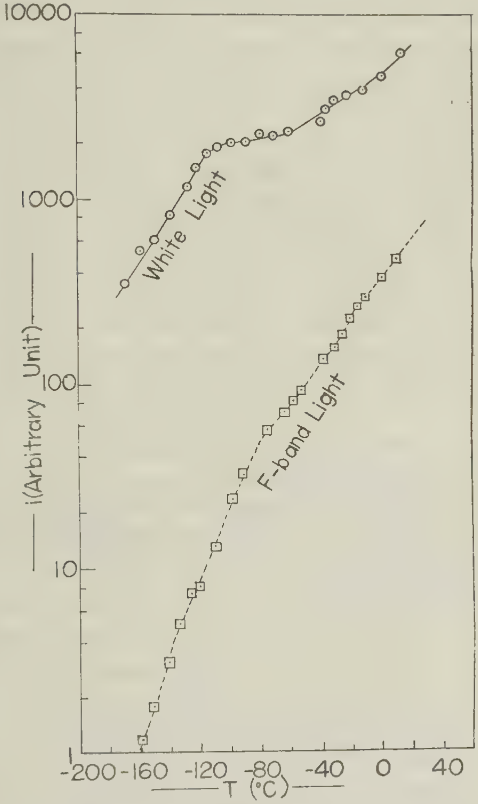

Fig. 5. The temperature-dependence of photocurrents due to white light and F-band light.
———: In the case of white light.
…………: In the case of F-band light.

(2) *The Hall mobility*

The apparent Hall voltage V_H' was found to depend linearly on the applied magnetic field. Fig. 6 shows these results. At low magnetic fields it was difficult to detect V_H' on account of disturbance noise. Noise became smaller as the temperature was decreased. As is seen in Fig. 6, V_H' is linearly dependent on H, $\mu_H H/c$ being much smaller than unity in this case. Further, the signal of V_H' was ascertained to change by 180° in its phase relative to the applied electric field by mean of varying the polarity of the magnetic field H.

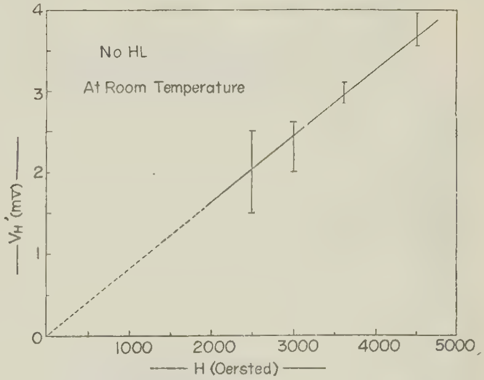

Fig. 6. V_H' as a function of the applied magnetic field.

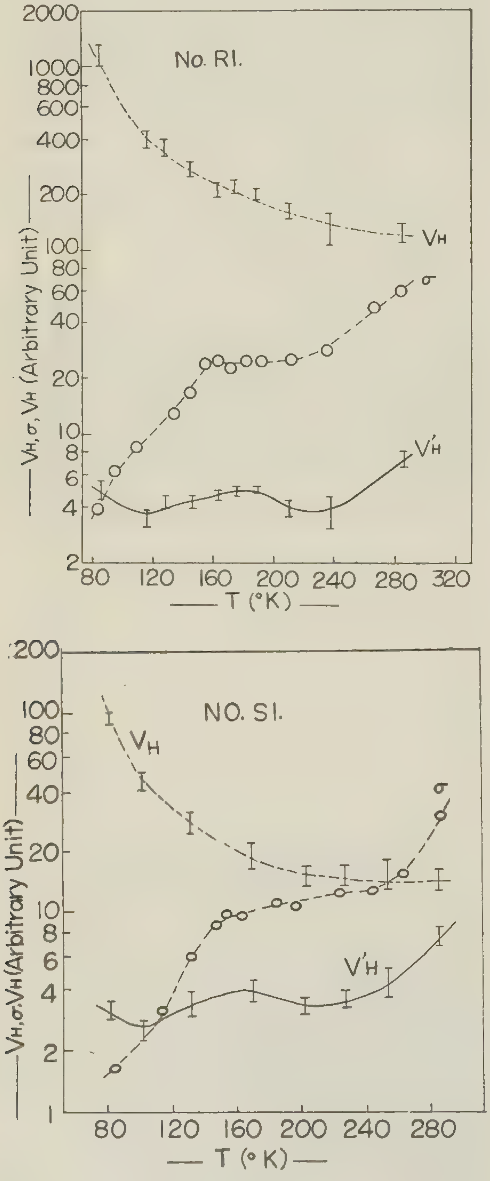
Fig. 7 and 8 show the photoconductivity σ which is the reciprocal of Z_{cry}, V_H', and V_H in arbitrary scale as functions of temperature for *NO. R1* and *NO. S1* specimens, respectively. The values of μ_H at room temperature were calculated to be 31±6 cm²/volt-sec and 27±5 cm²/volt-sec, respectively, from the analysis mentioned in § 2. These values may be compared with ~30 cm²/volt-sec, the mobility estimated indirectly from the photocapacitive effect by Kahn.[18] Macdonald has given the value as 7.5~12.5 cm²/volt-sec, and it seems to be far smaller. The small value of Macdonald might be due to the neglect of the correction for Z_{cry}.



Figs. 7 and 8. V_H', σ and V_H vs. temperature, the ordinate being in arbitrary scale.

Average values of μ_H for more than ten specimens are plotted as a function of temperature in Fig. 9. These points fit better to $\mu_H=A(exp\,\Theta/T-1)$ rather than to $\mu_H=BT^{-n}$. If we fit the data to $\mu_H=BT^{-n}$, the value of n varies from 1 to 2.2 and is not constant over the experimental temperature range. In conclusion, the temperature-dependence of μ_H obtained in this experiment shows clearly exponential type behavior of conduction electrons in ionic crystals. Further, μ_H should be equal to the microscopic mobility μ, because the relaxation time of collision by the optical mode of lattice vibration is independent of mean velocity of electrons.[16),19)] The best fit for the low temperature region was obtained with $A=16.4$ cm²/volt-sec and $\Theta=255$°K.

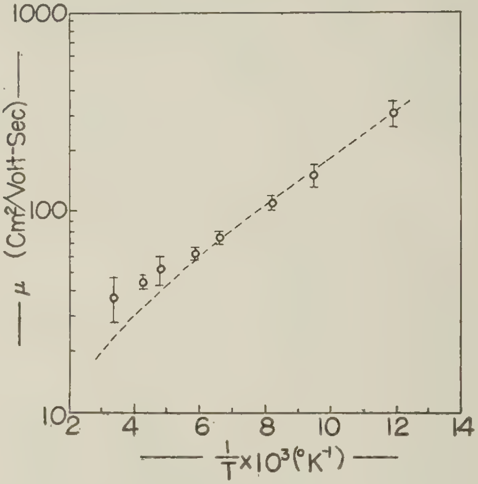


Fig. 9. Mobility of conduction electrons in KBr as a function of temperature.

The dotted line shows the theoretical curve calculated from the Low and Pines formula, $\mu_H=A(\exp\Theta/T-1)$, with $A=16.4$ cm²/volt-sec and $\Theta=255$°K.

According to the polaron theory of Low and Pines, the mobility of the polaron is given as follows in the temperature region $T<\Theta$:

$$\mu=\frac{1}{2\alpha\omega}\cdot\frac{e}{m^*}\left(\frac{m^*}{m_p}\right)^3\cdot f(\alpha)\cdot(exp\,\Theta/T-1), \quad (3)$$

$$m_p=m^*\left(1+\frac{\alpha}{6}\right), \quad (4)$$

$$\alpha=\frac{e^2}{\hbar}\left(\frac{m}{2\hbar\omega}\right)^{1/2}\frac{\mathcal{E}_s-\mathcal{E}_0}{\mathcal{E}_s\mathcal{E}_0}\left(\frac{m^*}{m}\right)^{1/2}, \quad (5)$$

where m^* and m_p are the effective masses of the bare conduction electron and the polaron respectively, $f(\alpha)$ the slowly varying function nearly equal to 1.2 for $\alpha=2\sim5$. ω and Θ are the logitudinal frequency and its associated Debye temperature which are related to the reststrahl frequency ω_t in the following formulas:

$$\omega=\sqrt{\frac{\varepsilon_s}{\varepsilon_0}}\,\omega_t,\ \hbar\omega=k_0\Theta \tag{6}$$

For KBr, values, $\varepsilon_s=4.78$, $\varepsilon_0=2.33$, and $\hbar\omega_t=0.015$ ev lead to $\Theta=246$°K.20) This is to be compared with the experimental value which is 255°K. From the measured value of A, $m_p=0.33\,m$, $m^*=0.23\,m$, and $\alpha=2.65$ are obtained by numerical calculation, where m is the free electron mass. Considering the value of α which is larger than unity, the polaron theories should be adopted for the conduction electron in KBr. In the analysis after the Low and Pines theory, the discrepancy between the observed data and the theory was found at temperatures higher than Θ. This fact, however, is not surprising, because Low and Pines treated the behavior of polarons at temperatures below Θ.21)* So far as the discussion is limited in low temperature range, there is no contradiction between the theory and the experimental data.

We shall consider the co-existence of other scattering mechanisms with that of the optical scattering. The apparent mobility μ obtained in the experiment is expressed as follows by using the combination of μ_i which are supposed to be due to various scattering mechanisms:

$$1/\mu\simeq\sum_i(1/\mu_i)\,, \tag{9}$$

In the present case μ_{opt}, which corresponds to optical scattering, is the smallest and is the most effective in defining the resultant mobility. Now, we shall consider μ_{ac} corresponding to acoustic scattering and μ_n corresponding to neutral impurity scattering by F centers.

μ_{ac}, which is due to acoustic scattering, is given as follows by using the deformation potential E_1:19)

$$\mu_{ac}=\frac{e\hbar^4C_{ll}}{E_1{}^2m^{*3}}(k_0T)^{-3/2}\,, \tag{10}$$

where k_0 is the Boltzmann constant, C_{ll} the elastic constant for longitudinal acoustic wave. Assuming that $E_1=5.4$ ev, which Kawamura calculated for KCl,22) is applicable for KBr, and using that $m^*=0.23\,m$, μ_{ac} is obtained to be equal to about 9000 cm²/volt-sec at room temperature. The temperature-dependence of μ_{ac} follows the $T^{-3/2}$ law, and the mobility μ_{ac} has little effect on the resultant mobility μ in the present temperature range. The temperature at which μ_{ac} is the same order as μ_{opt} should be around 25°K.

Next, we shall consider the mobilities due to impurity scattering by ionized or neutral centers in the crystal. In the present case, the most effective impurity for scattering seems to be neutral F centers in the crystal, the density of which is about 2×10^{16}/cm³ in this case. The most part of F centers are hardly ionized under illumination. From the experiment of the photoconductivity and Hall mobility, we note that the density of the vacant F centers, which is nearly equal to the density of the conduction electron ($\simeq10^9$/cm³), should be much smaller than the density of F centers which are not ionized ($\simeq2\times10^{16}$/cm³) even at room temperature. On the other hand crystals used in this work were checked up to contain unknown impurities whose density was about 4×10^{15}/cm³.13) The densities of these impurtities are so small that their effects to the resultant mobility may be negligible. For the mobility corresponding to the neutral impurity scattering μ_n (due to non-ionized F centers in this case),23) we have

$$\mu_n=\frac{m^*e^3}{20\varepsilon_sN_n\hbar^3}\,, \tag{11}$$

where N_n is the density of the neutral center. Substituting $N_n=2\times10^{16}$/cm³ and $m^*=0.23\,m$, μ_n is estimated to be about 3000 cm²/volt-sec, the value being independent of temperature.

Considering the temperature-dependence of the μ_{ac}, μ_n, and μ_{opt}, the maximum value of the mobility μ is expected to be about 1500 cm²/volt-sec around 40°K. However, μ_{ac} and

---

* For the explanation of the temperature-dependence of the mobility at temperatures higher the Debye temperature, the expression of m_p given by Yokota, $m_p=m^*\left[\frac{\alpha}{6(2\bar{n}+1)^{3/2}}\right]$, where $\bar{n}=1/(exp\,\Theta/T-1)$, might offer some interesting suggestion.3) The better fit of the data to the Yokota mobility formula, which contains the above expression of m_p, was obtained even in the temperature range, $T\geq\Theta$. However, it seems premature to adopt the Yokota expression of the mobility in the high temperature region, because the theory lacks ample theoretical foundation for using it at high temperatures.

μ_n in this experiment should have little effect upon the resultant mobility, μ, because the measuring temperature was not so low. In conclusion, the resultant mobility μ should be equal to μ_{opt}, the mobility due to the optical scattering.

§ 4. Summary

In this work the behavior of the conduction electron in KBr has been investigated between 80°K and room temperature. The decrease of photocurrent due to space chage polarization was prevented by the use of the a. c. 330 cps field and steady illumination of white light. Exact Hall mobility was measured, by assuring that uniform electric field was applied through the specimen.

The mobility was found to be determined by the scattering of the optical mode of lattice vibration, the other scattering mechanisms being estimated to be effective below about 40°K.

Using the Low and Pines formula for the mobility, we obtained that $m^*=0.23\,m$, $m_p=0.33\,m$, and $\alpha=2.65$.

Acknowledgement

The author wishes to express his sincere thanks to Prof. H. Kawamura for his guidance and encouragement throughout the course of this work. The author has received a great deal of valuable critisism and important comments from Professors T. Nagamiya, J. Itoh, M. Ishiguro, and T. Nakamura. The author is also greatly indebted to Prof. F. C. Brown and Dr. D. Kahn for their helpful discussions and suggestions, and to Mr. H. Okura for furnishing good specimens. In addition, the author wishes to thank Mr. T. Tatsumi for his laborious assistance.

This work was supported by the Scientific Research Fund of the Ministry of Education.

Structures of Photoconductivity Spectra near the Fundamental Absorption Edge of Cadmium Sulfide

By Hiroji MITSUHASHI

Technical Research Laboratories, Japan Broadcasting Corporation, Setagayaku, Tokyo

(Received February 2, 1961)

The photoconductivity structures of CdS single crystals near the adsorption edge were investigated using polarized light at about 81°K. Field dependence of wavelengths of peaks and spectral dependence of decay time of the response were measured as well. From these experimental results, the structures are classified into two groups, one is attributed to the photoconductivity due to excitons which occurs in the shorter wavelength range ($\lambda<4870$Å) and the other to that from some imperfections involved in the crystal, which appears on the longer wavelength side.

§ 1. Introduction

The optical property of CdS crystal has been studied by plenty of investigators[1),2)], partly due to amenability of growing single crystal, in view of clarifying the phenomena which it shows. This crystal is noted as a typical photoconductor and an efficient luminescent material as well. Some of the experimental investigations[2),3)] report that the crystal of high response has quite a sharp single photoconductivity peak near the fundamental absorption edge at room temperature, from which one may estimate the energy gap between conduction and valence band to be 2.4 ev. At lower temperature the specimen shows fairly distinct structures.

The main purpose of the present investigation is to study the origin of photoconductivity structure and the related phenomena.

The photoconductivity at 77°K has been investigated by Böer and Gutjahr[4)], who found a number of fine structures near the adsorption edge. However, no attempt was made for the interpretation of the origin of the structures, irrespective of well-defined result of the structures. Bube[2)] investigated the correlation between the height of the peak at the absorption edge and the magnitude of response of the specimen at room temperature. Gross and co-workers[5)] described the complex structures of photoconductivity on the exciton model, which did not seem to make a consistent explanation on correlation with the investigations by other workers.

In the photo-electric measurements of absorption and reflection spectra of CdS with polarized light, Dutton[1)] determined accurately the temperature and frequency dependence of the absorption coefficient in the intrinsic absorption edge. According to his experiment for polarized light with E vector parallel to the crystalline c axis ($E||c$), there occurs one absorption peak at 4844Å near 80°K which is called B band; for polarized light with E vector perpendicular to the c axis ($E\perp c$), another line appears at 4874Å called A band. Appearance of the reflectance spectrum at lower temperature, as Dutton reported in his paper, gives some indication of the relationship of the exciton-like absorption structure. Recently Thomas and Hopfield[6)] found well-defined reflection peaks at lower temperatures, which lead to the assignment of three exciton series, two of which are associated with the above mentioned A and B bands and the other with C band situated at shorter wavelength than the two bands. Namely the new band C occurred near 4735Å as a considerably broader hump at 77°K. Using the Kramers-Kronig relation they determined oscillator strengths and oscillator frequencies of the reflection lines, which must correspond to the direct allowed excitons. The strength and reproducibility of the lines also made clear that the reflection spectra were not due to some impurities. The existence of three types of excitons was described in terms of the splitting of the valence band. Further quantitative estimation was made for the three valence bands at 4°K. The analysis[7)] of the absorption coefficient in the wavelength range of the absorption edge confirmed a process involving simultaneous creation of an exciton and absorption of a phonon.

The present paper describes that some of the structures of the photoconductivity near 5000Å can be explained in terms of the existing exciton model suggested by Gross and supported by reflectance and fluorescent study of Thomas and Hopfield[6].

§ 2. Experimental Procedures and Results

While a very thin sample is required for transmission measurement, conditions for the thickness of the sample will be relaxed for photoconductivity measurement. It must be taken into first consideration for the experiment that the specimen should retain the intrinsic properties of the crystal. Such treatment as polishing, etching, thermal soldering, intense heating or cooling or so must be avoided[8]. According to our experience, best results were obtained on the fresh crystals, which were grown from vapor phase and showed small traces of striants over the surfaces.

The photoconductivity data were obtained by measuring photo-induced current in the crystals with constant applied voltage. Most of the exact experiments have been made on two crystals (Nos. 7 and 8). One of the experimental difficulties was to make an adequate contact of metallic electrode with the crystal. Ohmic contact with indium is to be unexceptionally recommended for usual photoconductivity measurement of CdS[9]. During In-soldering to the specimen, however, the crystal undergoes thermal or mechanical stress with undesirable result of destroying the photoconductivity structures. Hence precaution was taken for setting the specimen in the cryostat. In-Hg paste was selected as electrode material for that purpose[10]. At first, thin small indium blocks were pasted with polystyrol binder on the Maylar polyester film, sticked to a cooling copper rod. Wiring to the specimen was made by soldering lead wires to the In blocks. On the surface of each indium block a small pellet of In-Hg paste was dropped. After the crystal was bridged across the two In electrodes, thin flakes of indium were placed over the ends of the specimen, which was left for two or three days to be enough amalgamated that stable rest of the crystal was brought about. Ohmic contact is the main consideration in the photoconductivity measurement. However,

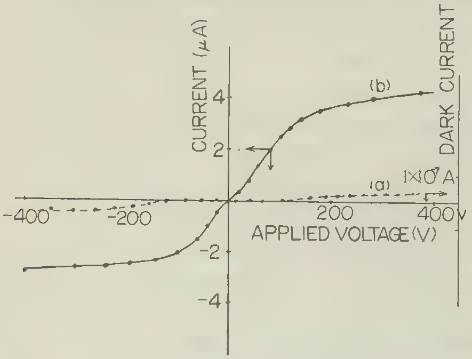

Fig. 1. Ohmic characteristic of the sample soldered with In-Hg paste (specimen No. 7, measured at room temperature), (a) in the dark (b) under ambient illumination.

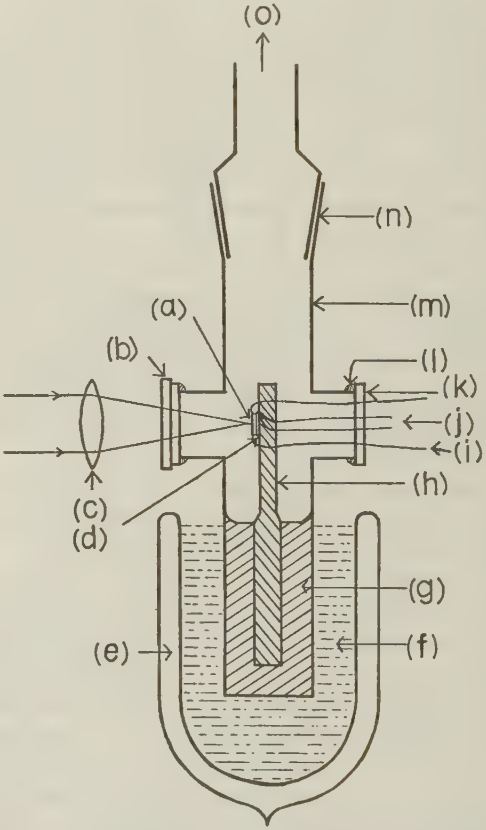

Fig. 2. Cryostat for the low temperature measurement. (a) CdS crystal under study, (b) Polaroid film polarizer, (c) achromatic glass lens, (d) Maylar film of 10 micron thick, (e) Dewar vessel, (f) liquid nitrogen, (g) copper block, (h) cooling copper block, (i) wirings to electrodes, (j) thermocouple, (k) transparent fused quartz window, (l) wax, (m) glass envelope, (n) grounded glass connection, (o) connection to vacuum pump.

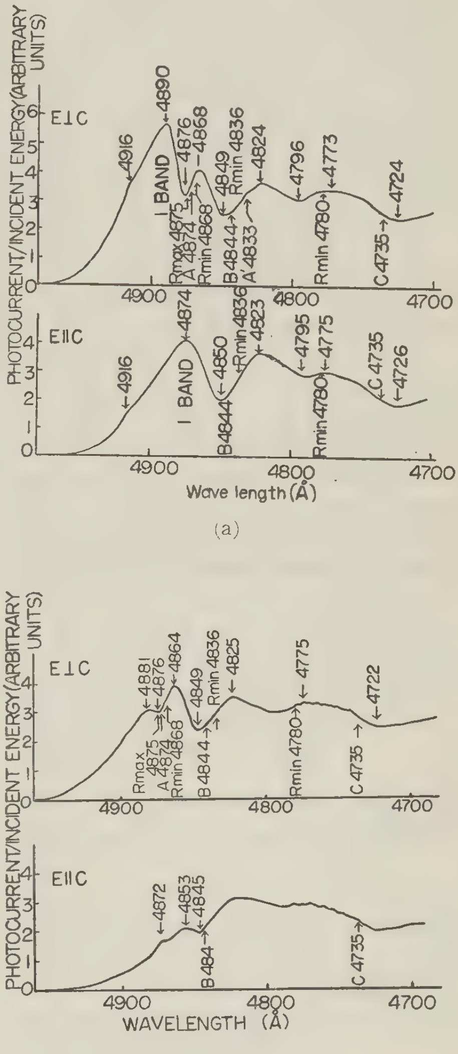
the current vs. voltage curve reveals that somewhat non-ohmic nature was unavoidable as shown in Fig. 1. Electric field was applied parallel to the c axis for all measurements.

For the low temperature experiment, a copper rod on which the crystal rested served as a conductor for cooling the specimen, as illustrated in Fig. 2. The temperature of the crystal was measured by means of a thermocouple placed in the In electrode in the visinity of the sample. Variations of the temperature were noticed from one sample to another, possibly depending on conduct of the cooling copper rod to the copper block, which was immersed in the liquid nitrogen in a Dewar. The equilibrium temperature of the crystals was estimated to be 81°±3°K.

The monochromators employed were an instrument with double flint glass prisms made by Tokyo Optical Company and modified Cary Spectrophotometer Model 14, using a tungsten lamp as a light source. The resolution of the instruments was adjusted to be about 2Å, the wavelength accuracy being within 2Å. The direction of incident light was always normal to the c axis of the crystals. Monochromatic light from the instrument was too weak to carry out wavelength scanning at tolerable speed, due to the fact that time delay of photoconductivity becomes exaggerated for feeble intensity of irradiation. Hence the scanning rate was chosen at 0.15Å/sec or less, where almost coincident data of spectral distribution were obtained for both scanning directions, i.e. from longer to shorter wavelength side and *vice versa*. Photocurrent was introduced into a vibrating reed electrometer, the output of which was lead to a recorder. Reproducibility of the data was so conspicuous as to facilitate analysis of the photoconductivity structures. The spectral intensity of the incident radiation was measured beforehand with a sensitive thermocouple connected with an amplifier at wider slit of the spectrometer. Thus correction was made for both spectral distribution of the energy of the tungsten lamp used as the light source and dispersion of the prism of the instrument. However, further corrections for the reflection loss at the crystal surface and the transmitted light were disregarded. Any traces of luminescence were not observed for the wavelength region of the incident radiation.

The photoconductivity data on two specimen are shown in Fig. 3 for different polarizations of the incident light, i.e. with E vector paralleled



(a)

(b)

Fig. 3. Photoconductivity spectra of CdS for light polarized with $E\perp c$ and A, B and C refer to the exciton bands of $n=1$ and A' to that of $n=2$, identified by Thomas and Hopfield.[6] $R_{\max}$ and $R_{\min}$ correspond to the reflection maximum and minimum observed by Dutton.[1] Electrode distance was 2.5 mm. The temperature of the specimens was 81°K

(a) For the sample No. 7 [3.5 mm $(\|c)\times 1.5$ mm $\times 0.2$ mm], at the field strength of 560 V/cm. Besides the structures due to exciton bands of $n=1$, there is a trace of a structure, presumably due to A' band.

(b) For the sample No. 8 [4 mm $(\|c)\times 1.3$ mm 0.3 mm], at the field strength of 600 V/cm.

to and perpendicular to the *c* axis. Several distinct peaks stand out in the background of the photoconductivity in the fundamental absorption region. From the appearance of the photoconductivity data presented here as compared with the reflectance structure previously reported[1], there seems to be some definite similarities between them, indicating correlation of optical and photoelectric phenomena.

A prominant photoconductivity band presents its maximum at the longer wavelength side of the absorption edge which is denoted as *I* band in Fig. 3. Its peak is generally higher for the more photoconductive material. One of the notable properties of this band is that the peak is field dependent. The wavelength at which the maximum occurs shifts to longer wavelength as the applied field strength is increased as shown in Fig. 4. A sample of poor response has, in general not well-defined shapes as seen on the specimen No. 8 (Fig. 3b). In addition such a sample does not show its band at a fixed wavelength. Other bands except *I* peak near the adsorption edge do not show a field dependent shift within the experimental errors.

The rate of decay in photocurrent vs. wavelength of the incident radiation is illustrated in Fig. 5 as determined by the time intervals required for the current to decrease to 10 percents of the initial value, due to a sudden removal of the illumination.

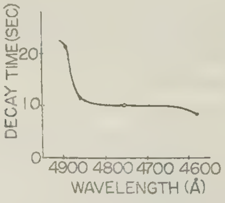

Fig. 5. Photoconductivity decay time vs. wavelength of exciting radiation, for the sample No. 8 at 81 K. ($E \perp c$)

§ 3. Assignment of the Photoconductivity Spectra

Light has been thrown on the energy band structure of the CdS by a lot of experimental investigations, such as optical studies involving adsorption, reflection and luminescence[11], and measurement of cyclotron resonance at liquid helium temperature[12]. On the other hand no attempt seems to have succeeded to make a consistent interpretation of the photoconductivity spectra near the fundamental absorption edge from the standpoint of the energy band structure.

Analysis of the photoconductivity spectra must be carried out, taking into consideration of electrical properties of carriers as well as optical behaviors of the crystal. In general some experimental difficulties are encountered in the course of the investigation, because the photoconductivity occurs by drift of free carriers generated by absorption of photons. Further the electric field seems to be not uniformly applied, especially for the sample which is "soft" soldered with In paste as mentioned in the section 2. Thus the field strength may vary from the surface to the interior of the crystal. Now owing to the fact that lifetime of the carrier depends on the wavelength of the incident light, another complication will be involed in the phenomena of the photoconductivity. An accurate information could be obtained under the favorable conditions. After making correction to various repeated experiments on several samples, we will try to describe the origin of the photoconductivity spectra. In spite of the complexity a fairly accurate nature of the photoconductivity is disclosed on some crystals which have well-defined spectral peaks.

It applies to the reflection spectra that the wavelength midway between a reflectance maximum and minimum should correspond closely with the position of an absorption peak. The analogy will hold for the photoconductivity spectra also. Careful examination of the data reveals an interesting fact that in the absorption edge some wavelengths at which the photoconductivity response shows steep slope agree with the absorption lines associated with above cited A, B and C bands reported by other investigators[1),6)]. Spectral response distribution in the ranges from 4880Å to 4868Å for $E\perp c$ and those from 4848Å to 4825Å for both $E\perp c$ and $E\|c$ are coincident quite well with the reflection spectra measured by Dutton at nearly same temperature (80°K), each dip of the photoconductivity corresponding to the reflection peak and *vice versa*. Near the wavelength range of 4750Å, another broad hump appears which occurs at the separate dip of the reflection spectrum corresponding to the C band. Spectra due to I band of some samples show complex form of one peak or more which sometimes emerge in the range of A band, causing confusion in assignment of the spectra. In addition, a difference in the lifetime of the carrier is noticed between excitations by the I band and by other bands. Thus the I band is different in nature from those due to A, B and C bands.

It will be reasonably admitted that the photoconductivity structures in the wavelength range of A, B and C bands occur from exciton absorption, owing to the close correspondence between the structures and exciton lines with regard to the positions and the number of peaks which can be just inferred from the selection rule according to the direction of polarization of incident light. On the other hand the band denoted as I emerges outside the exciton band where the absorption coefficient is considerably lower[7)] (about $10^2\ \text{cm}^{-1}$ or less). Therefore the free carriers are primarily generated in the bulk while the exciton creation is restricted near the surface of the crystal.

There is some trace of fine structures which appear as several extraordinarily sharp lines overlapped with the main peak of the I band. Origin of such fine structures cannot be understood at present.

Physical interpretation of the I band is difficult according to the experimental data of the present work. It may be supposed, however, that some defect or impurity involved in the crystal is accounted for. This band is supposed to be located near the conduction band. Therefore we tentatively make an assignment for the center corresponding to the I band after the Lambe-Klick model[13)], in which the trapping level responsible for luminescence and photoconductivity is located near the conduction band in the forbidden band. Thus the electron in the I band will be in the similar state to that of the trapping center of the above model, whose wave function has the same symmetry of conduction band (Γ_7) or is close to it. Birman[14)] made the same assumption for describing the polarization of 6200Å luminescence of CdS.

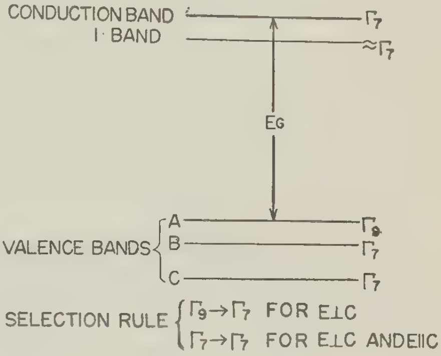

Fig. 6. Energy band structure of CdS. The levels A, B and C correspond to the valence bands to which the excitons series A, B and C belong. The symmetry is expressed by the Bethe's notations for hexagonal symmetry.

In Fig. 6 is shown the schematic diagram indicating the energy band structure of the crystal.

It may be summarized for the assignment of the structures that photoconductivity near the absorption edge peaks can be described along the line consistent with the existing exciton scheme and the impurity center model.

§ 4. Discussion

The mechanism of exciton photoconductivity is not clearly explained for the present situation of the investigations. However, it may be inferred that (i) exciton generated by the optical absorption will migrate through the crystal and happens to dissociate by absorption of a phonon into a free electron and a free hole, drift of the electron inducing the current; (ii) when the migrating exciton comes to the neighbourhood of some imperfection where an electron is trapped and this electron will be ionzed into the conduction band by the interaction of the exciton; (iii) an alternative but related explanation is the indirect optical absorption, simultaneously participated by an exciton and a phonon, which may produce a free electron. Some of the above-mentioned processes will be in action to exciton photoconductivity. On the other hand, the photoconductivity due to the imperfections is different from that due to exciton in feature.

As the stated in the section 2 the peak of *I* band undergoes field-dependent shift, although such a shift is hardly observed for the exciton spectra of photoconductivity within the experimental errors. These phenomena are possibly due to the difference of field strength in the region where generation of the free carriers occurs. The spectral characteristics due to the impurity photoconduction varies from one sample to another. Exact identification of the centers responsible for this band will provide some clue to growing the crystals of high sensitivity which are to be used as photoelectric detectors. Furthermore the non-ohmic character of the crystal shows similarity to the field dependence of the wavelength of the peak due to *I* band, as readily seen in comparison of the plots of Fig. 1 with Fig. 4, suggesting existence of the regions of strong local field strength, presumably near the imperfections involved in the crystal. Other investigators[15),16),17)] report that the optical absorption edge tends to shift to longer wavelength with an increase of applied electric field on account of space charge effect or tunnel effect of optically excited electrons. It must be pointed out here that the decay time of photoconductivity is longer for the *I* band than for the exciton band. The trend of the decay time is in principal accord with the interpretation of the lifetime of the free carrier by Bube[2)], i.e. for a photosensitive material, the volume lifetime is much longer than the surface lifetime. The latter should be associated with exciton absorption and the former with impurity absorption for our case. Thomas and Hopfield[6)] discussed the fluorescence phenomenon of CdS, suggesting that the radiative decay of excitons occurs from "impurity" exciton states and "impurity" states provide a favorable mechanism for the radiative decay of excitons. There seems to exist a close correlation between the imperfection that gives rise to the *I* band photoconductivity and the "impurity" states which take part in the fluorescence.

Several interesting problems remain to be investigated. At lower temperature (e.g. 4°K) the photoconductivity structures will become more sharp. Hence it is expected that identification of the spectra will be made feasible. The structure due to excited state of exciton ($n=2$) would be expected. It would be quite interesting to study temperature dependence of the response at the *I* band in the wider range of temperature. This study would also provide a fairly accurate information on the nature of the imperfections of the crystal. In spite of the experimental troubles involved in the measurement owing to obscurity of the behaviors of the free carriers, a qualitative explanation of the structures on the basis of the reproducible data should lead to clarification of the precise nature of photoconductivity.

§ 5. Conclusion

The photoconductivity structures near the absorption edge in pure CdS can be divided into two classes from the above argument:

(i) One is closely associated with the excited absorption. Photoconductivity structures belonging to this class are intrinsic to the crystal. The carrier lifetime of the carriers due to this band is rather short.

(ii) The other is presumably due to the imperfection of the crystal. The structures occur on the longer wavelength side of the exciton band, though the peaks and the shape vary from sample to sample. The physical nature of the center responsible to the structures cannot be clarified enough by the present work.

The author wishes to express his appreca-tion to Prof. S. Makishima, Dr. G. Kuwabara and Dr. S. Shionoya of Tokyo University for illuminating discussions and to the members of the Research Group on Solid State for helpful advice and to Director S. Shima, Vice Director T. Nomura and Dr. H. Kuroda of the Laboratories for their continued encouragement. The author is indebted to Dr. S. Ibuki of Mitsubishi Electric Company for the crystals used in this study.

Smoke Observation on Boundary Layer Transition Caused by a Spherical Roughness Element

By Masako MOCHIZUKI

Department of Physics, Ochanomizu University,
Otsuka, Tokyo, Japan

(Received December 2, 1960)

Observations were made in the boundary layer along a flat plate in a wind tunnel. A sphere of various diameters was placed on the plate as an isolated roughness element and the resulting flow patterns were examined by the smoke emitted from various heights and positions relative to the sphere. The patterns were stereographically photographed from upper and lateral sides, in order to make clear the mechanism of the change of patterns with varying velocities, namely Reynolds numbers. At low velocities, peculiar vortex filaments are formed. With increasing velocity, they begin to be deformed periodically and a characteristic row of arch-shaped vortices is formed. As the velocity is further increased, the wedge-shaped turbulent region appears downstream and gradually approaches the sphere, encroaching upon the laminer part. Vortex filaments parallel to the direction of the main stream appear with a constant spacing with their heads along the sides of the wedge. These observations were compared with measurements by hot-wire and with the results of visualization reported by other investigators.

§1. Introduction

In the early stage of development, the prime object of researches in turbulence was isotropic turbulence, but recently anisotropic turbulence, and furthermore, as a fundamental problem, the production mechanism of turbulence itself, have come to attract more and more attention. Schubauer and Klebanoff[1] have examined natural transition and the transition caused by spark or three-dimensional roughness by hot-wire technique, and interpreted the transition with the conception of turbulent spot. Gregory and Walker[2] and Weske[3] have investigated, by visualization techniques the transition mechanism and the process caused by three-dimensional roughness in boundary layers. However, the final conclusion on the production mechanism of turbulence seems to have been not yet obtained.

In the present stage, it seems to be the first necessity to examine the mechanism visually. With a view to clarifying the production mechanism, we examined in detail the process in which flow patterns around a sphere changed with Reynolds numbers, by photographing the flow structure in each process.

For the visualization of the flow patterns in the air, the smoke or china clay method has usually been used. The latter only shows results in which the intensities of disturbances of air flow over a solid surface are averaged over a long time. On the other hand, the smoke method is able to show not only the fluid motion at any position by changing the positions of the smoke source, but also the patterns of flow over a wide region and in detail at every moment; moreover, the method can show mean behavior of fluid motion by taking long-exposure photographs. For these reasons, we adopted the smoke method for the present study.

§ 2. Experimental Arrangement and Method

The experiments were made in a 50×50×200 cm closed Göttingen-type wind tunnel in our University, having windows on both lateral and upper sides. A laminar boundary layer was formed on a flat plate which was placed holizontally at a distance of 15 cm above the bottom of the tunnel. The plate was made of black-enameled aluminum and black acryl resin to get good photographic effect, and it was divided into 2 or 3 parts in order to emit the smoke from the gaps. The arrangement is shown in Fig. 1. In order to regulate the flow for zero pressure gradient, wire gauzes were stretched across above the plate at the downstream end of the measuring section.

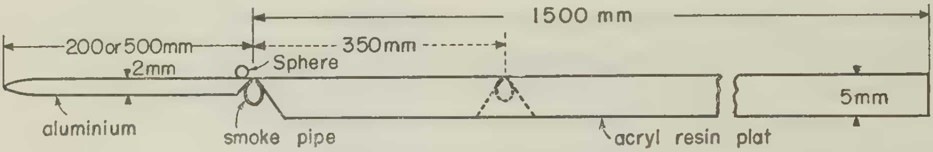

Fig. 1. Arrangement.

As the roughness element, a bearing ball was used, whose diameter (k) was 0.71, 0.55, 0.33 and 0.23 cm, respectively. The roughness element was set at various distances from the leading edge of the plate.

Flattend pipes, which were made from brass pipes of 0.3 mm in diameter and 35 cm in length, were attached to the lower side of the gaps (about 1 mm wide) between the parts of the plate, with their sharpened sides up and down. These pipes have holes at an interval of 2 mm along their upper side. In order that the smoke blown in from both ends of the pipe might be emitted uniformly, the hole size was increased gradually from the ends towards the center (0.4~0.7 mm). In the early stage of experiments the smoke of tobacco was used, but it turned out inconvenient for continuous emission for a long time. Therefore, the smoke of evaporated liquid paraffine was used for the subsequent observation. Without the roughness element, the smoke crept in clear lines along the plate. In order to examine in detail the pattern in the neighborhood of the roughness element, the smoke was emitted at various streamwise positions and heights by the following methods. In the early stage the smoke was emitted from a flattend pipe which was made from a brass pipe of 1 mm in diameter and pierced with holes at an interval of 1 mm. But at a later stage, in order to diminish disturbances to the flow, a smoke sheet was formed by electrically heating a nichrome ribbon (0.1 mm thickness, 0.8 mm width) with liquid paraffine rubbed on.

The flow patterns revealed by the smoke were photographed stereographically both from the upper and lateral sides.

§ 3. Outline of Changing Process of Flow Pattern

Placing the sphere in front of the gap in the plate surface and emitting smoke from it, the changes in the flow pattern produced by the sphere were observed by increasing the wind velocity. Some of the results are

shown in Fig. 2. When the wind velocity was very small, there were observed only a reversed flow of smoke close behind the sphere and a single smoke streak trailing downstream from it. As the velocity was increased a little, a pair of smoke spirals (we may call them fixed vortices) appeared close behind the sphere and two parallel smoke filaments (we may call them trailing vortices) trailed downstream parallel to the plate from the top of the spiral vortices. At the same time a horseshoe-shaped smoke filament (we may call it horseshoe vortex) appeared, which circled round the front of the sphere (Fig. 3). These filaments changed their shapes successively as the velocity is in-

creased.

The trailing vortex filaments begin to wave and then the raised parts begin to show an evident twist (Fig. 3-c and d). These transformations are small near the sphere and develops over some distance, and beyond there, they ceases to grow; the raised parts are stretched by shearing stress in the boundary layer. The horseshoe vortex filament detaches itself upward from the plate as the velocity is increased. Then, the twist of trailing vortex filaments develops into rol-

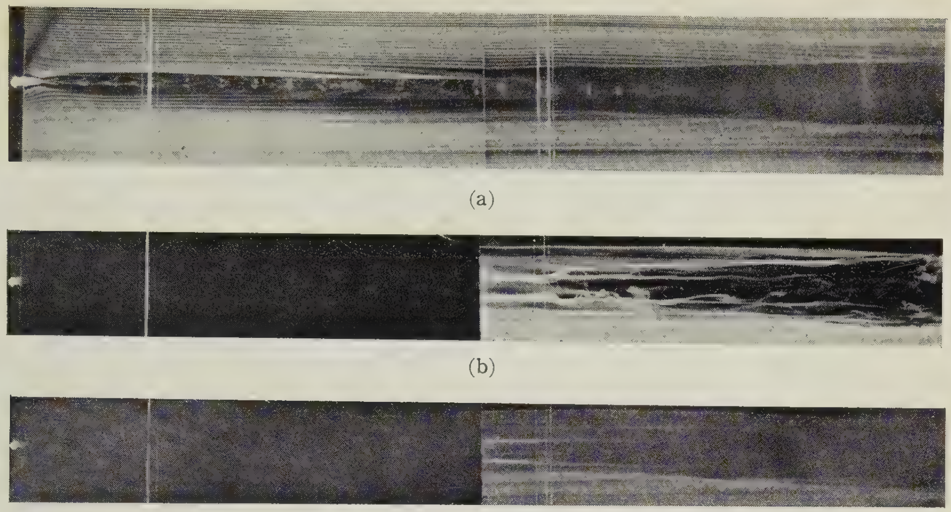
ling-up and the rolled up parts of the two filaments stand in pairs at equal intervals. These vortex-shaped patterns have their axes rising gradually upright until they become nearly vertical at some distances from the sphere. Beyond that, the rotating energy of the vortex-shaped patterns is weakened, and they were stretched downstream owing to the shearing stress. Finally, the vortex-shaped patterns take an arch-shaped configuration. In this stage, the horseshoe vortex filament also show three-dimensional deformations with the period which is the same as that of the arch-shaped vortices.

As the velocity is further increased, the definite periodic shapes of these patterns disappear to be replaced by a turbulent state starting from the downstream location. At the same time the turbulent part gradually encroaches the laminar part of parallel smoke lines. This turbulent part may be regarded as the so-called turbulent wedge, whose apex proceeds upstream and finally reaches the sphere.

These transition processes hold good for different sizes and positions of spheres. In the following sections, each process may be considered in detail.



(a)

§ 4. Structure of Vortex

When we compare Fig. 2, in which smoke is emitted from downstream of the sphere, with Fig. 4, in which smoke is emitted from upstream, it may be considered that the horseshoe vortex filament is formed from upstream of the sphere and the trailing vortex filaments are formed in its downstream. In order to make clear the structure of these vortex filaments, the smoke is emitted from various positions relative to the sphere and the plate, and the photograph was taken of the flow pattern in the neighborhood of the sphere in magnified scale.

The following processes are observed from Fig. 5 in which the smoke is emitted from downstream of the sphere. There appear a pair of spiral smoke filaments vertical to the plate at about one diameter downstream from the sphere (the distance seems to increase with the flow velocity). On rising level with the top of the sphere, the smoke filaments trail downstream parallel to each other and to the plate. It is observed from Figs. 5–B and 5–C in which the smoke is emitted from up- and downstream positions of the center of the spiral, respectively, that these spiral filaments are cylindrical vortices. It is seen from the photographs that the smoke deposited over a certain region on the plate is sucked up and raised spirally. At low velocity, the rotation of the fixed vortices is weak and the trailing vortex filaments are straight lines; with increasing velocity, the trailing vortex filaments show waviness as stated above (Fig. 3-c). At still larger velocity, the fixed vortices become a large turbulent lump (Fig. 5-C-c) so that the spiral motion disappears and the trailing vortex filaments show turbulence at slightly downstream of the sphere.

At a certain velocity, a row of vortices is formed very clearly by the following process. A pair of waving trailing vortex filaments are distored into saw-teeth shapes at regular intervals (Fig. 3-d). Their oblique sides of the saw-teeth are twisted in such a way that, looking from downstream, the right filament rotates clockwise, while the left filament anticlockwise. With increasing velocity, the tips of the saw-teeth are raised and the bottoms lowered. Further, the twisted sides are strengthened until finally rolled up two or three times to form seemingly a series of vortex pairs (Fig. 3-b). These vortex-shaped structures are clearly noticed in the stereographs. As the vortex-shaped patterns grow still further, the individual vortex pair joins together at the heads and takes arch-type shape (Fig. 6). The height of the vortices increases rapidly near the sphere and their tops are raised out of the boundary layer. In further downstream region, the vortices cease to grow and then diffuse gradually.

When the largest sphere is used and the smoke is emitted from the plate surface, these arch-type vortices are not easy to observe. In this case, it can be surmised that the smoke emitted from the surface is not always able to wind around the arch-shaped vortices up to their tops. In order to make sure this explanation the smoke source (nichrom wire) was set at various heights downstream of the sphere, and the resulting patterns of flow were photographed stereographically. Some of them are shown in Fig. 7. The smoke emitted from rather low height is rolled up higher than that emitted from the plate surface. The smoke emitted from a certain height indicates a pattern rotating just around the horizontal part of the arch.

The frequency of shedding vortices is measured from the photograph of row of vortices, with a view to examining the relation between the Strouhal number based on sphere diameter and the Reynolds number, based on velocity at sphere top. The Strouhal number is smaller than that of a sphere but larger than that of a cylinder, both placed in a free stream, and it increases from about 0.1 to 0.23 as the Reynolds number is increased.

In the next place the horseshoe vortex is considered. There is a region around the sphere in which the smoke does not enter as shown in Fig. 4 and 5-A, in which the smoke is emitted from upstream of the sphere. This fact shows that there is a horseshoe-shaped vortex which wraps round the front of the sphere and trails downstream, as has been observed by other researchers. The flow patterns upstream of the sphere are further examined with the smoke source at various heights upstream of the sphere (Fig. 8). The results show that the smoke emitted from lower than sphere center descends and turns back in front of the sphere, and that there exists a vortex having its center close to the sphere and the plate. In the downstream of the sphere and at low velocity, the vortex trail two filaments which are parallel to each other and approach the plate. As the velocity is increased, the filaments raise from the plate and show periodic transformations induced by the arch-shaped vortices. In the case of the smoke emitted from the plate, the smoke filaments stand up rapidly at about three diameters downstream of the sphere and combine with the horseshoe vortex filament.

We shall compare the above-mentioned phenomena with that in the flow around a sphere in a free stream. The photographs of the flow around a sphere were taken in water by Möller[4] and Taneda[5]. In these cases, the fixed vortex takes a rising shape close behind the sphere; but in the present case of boundary layer flow two vortices are formed rising vertically from the surface, and two vortex filaments trail downstream from the respective head of the fixed vortices; these filaments correspond to that from the center of the ring-shaped vortex in the case of the free stream. In the free stream case the vortices shed from the sphere can orientate freely, but in the boundary layer case the vortices can be shed only in such a way that they take the arch shape. Thus the vortices formed at the back of the sphere are considered to originate in quite the same process both in the free flow and the boundary layer. However, the horseshoe vortex is occasioned only by the existence of the solid surface. The parallel flow diverges in every direction at the stagnation point of the sphere in the free flow, while in the boundary layer, the flow which would be directed to the surface turns back against the sphere resulting the formation of the horseshoe vortex.

§ 5. Turbulence Wedge

As the velocity is increased, the turbulent region or the so-called turbulence wedge is formed downstream. With further increase in velocity, the vertex of the wedge advances upstream until finally attaches to the sphere. Gregory and Walker[2] have observed by means of the china clay technique that the wedge formed by a cylindrical or conical roughness on a flat plate has the vertex angle of 7°～16°. Schubauer and Klebanoff[1] have examined the turbulence wedge of a sphere by using a hot-wire anemometer. They found a half vertex angle of 6.4° for a fully turbulent region and that of 10.6° including an intermittent region. Tani, Komoda and Iuchi[6] have also made the measurements on the transition effect of a cylinder on a flat plate with zero pressure gradient by using a hot-wire anemometer. In this case the transition was defined by the point where the fluctuation had the intermittency factor of about 50%. Under the condition that $x_t=x_k$, the relation between critical roughness Reynolds number $R_k=ku_k/\nu$ and transition Reynolds number $R_k=Ux_k/\nu$ was obtained, where k is the height of the roughness element, u_k the mean velocity at the top of the element, ν the kinematic viscosity of fluid, x_k the distance along the surface to the roughness location, x_t the distance along the surface to the transition location and U the velocity outside the boundary layer.

In the present experiment, the position of the vertex of the wedge and wedge angle are determined on the photographs, by drawing border lines between the turbulent region and the outer laminar region and the position of the vertex is considered as the transition point. By placing a sphere (of diameter k) at a certain distance x_k, the transition location x_t for various velocities are measured from the respective photographs. From the curve of x_t against the velocity, the velocity corresponding to $x_t=x_k$ is determined. R_k and R_t are evaluated from these values for various k and x_k. The result is shown in Fig. 9, in which the above-mentioned result obtained by Tani, Komoda and Iuchi is shown by a solid line, and the extrapolated curve which corresponds to the present measurement is shown by a broken line. It is interesting to note that the transition point determined by the smoke observation coincides with those determined by the hot-wire observation. The side of the wedge is not a single straight line but is composed of two straight lines linked together at lower velocities, inclusive of critical velocity when the vertex attaches to the sphere. At higher velocity or when the wedge developed into a fully turbulent one, the side becomes a straight line and a definite wedge angle can be determined. Consequently, at the critical velocity two wedge angles are obtained, namely near the sphere and downstream, respectively, while at large velocities, a single angle is measured. These angles are plotted against the velocity in Fig. 10. It can be seen from this figure that all the measured points for various sizes and positions of the sphere are on the lines for respective cases. Above mentioned result of Schubauer and Klebanoff may be regarded to be on the extrapolated line of the present results of the fully developed turbulence wedge. It is interesting to see that the results obtained from the smoke pattern and those from the hot-wire measurements are in

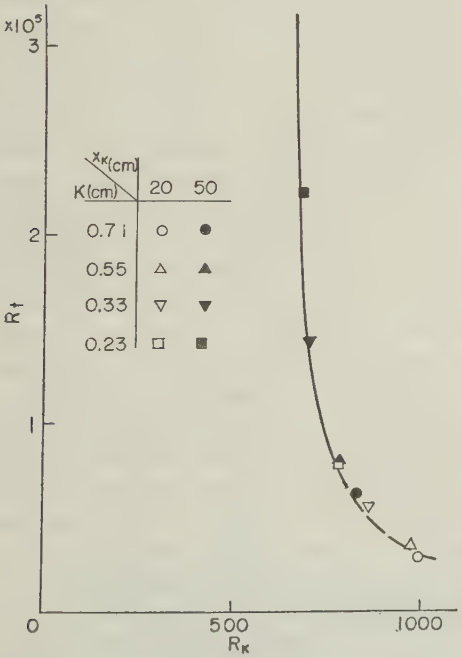

Fig. 9. Variation of transition Reynolds number with critical roughness Reynolds number.

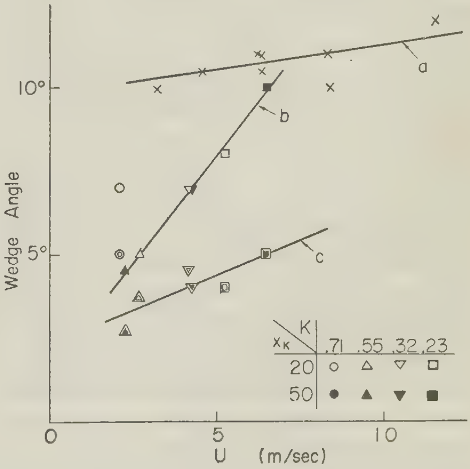

Fig. 10. Relation between angle of turbulence wedge and mean velocity. (a) State of developed turbulence wedge; (b) Near the sphere; (c) Downstream, critical state at which vertex attach to sphere.

good agreement. As the sides of the wedge are seen clearly in the smoke observation, the conception of the wedge is more easily to be understood.

Gregory and Walker have observed that the china clay record of the wedge revealed the fine structure. We examined what corresponds to the fine structure in the present case. The china clay method shows the time averaged results occurred on the plate surface. Smoke particles can depart from the plate surface following the local motion of fluid, even though they are emitted initially on the surface. In order to make the results of the smoke method equivalent to those of the china clay method, another smoke is emitted on the plate further downstream, and the pattern is photographed exposed for a long time. The results show some strong filaments (cf. Fig. 11) which may be regarded as those corresponding to the fine structure of the china clay record. The Reynolds numbers at which the fine structure appears in the experiment of Gregory and Walker are lower than the Reynolds number at which the wedge just attaches to the sphere in the present experiment. Before the wedge developes fully, some dense filaments are observed, which are considered to correspond to the fine structure of china clay. As the wedge develops, however, the smoke filaments disappear just after they are formed. Before the turbulence wedge is formed, the dense smoke filaments parallel to the direction of the main stream appear behind the sphere, but after the turbulent wedge is formed, the smoke filaments which converge and then twist appear along the side of the wedge. It may be thought that these filaments suggest the existence of a vortex in their neighborhood, though it can not be asserted that the position of the filament shows immediately that of the vortex. Such converging and twisting of smoke seem to occur at a constant spacing along the sides of the wedge. The interval measured perpendicularly to the direction of the main stream is about 7 mm, though it becomes larger with decreasing velocity. If it is considered that the filaments are Görtler vortices on the concave wall, the wave length corresponds to those within the unstable region. Therefore, this consideration does not contradict with the present result. But the details will be left for future consideration.

§ 6. Discussion and Conclusion

The transition process of flow patterns caused by a spherical roughness element on the flat plate may be summarized here. The process begins with the formation of distinct vortex filaments, namely two trailing vortex filaments which trail from the head of the fixed vortices behind the sphere and horseshoe vortex filament which circles round the front of the sphere and trails downstream. Weak waviness occurs on the trailing vortex filaments and it grows as the velocity increases. Then at a certain velocity arch-shaped vortices are formed by the rolling up of the trailing vortex filaments. In each stage, the degree of transformation reaches its maximum at a certain distance downstream from the sphere, and the distance varies with the velocity; further downstream these transformed parts cease to grow and are stretched obliquely by shearing stress of the stream. The arch-shaped vortices raise their heads out of the boundary layer, so they are no longer stretched and are diffused as twisting force weakens. The horseshoe vortex filament is also waved owing to the influence of the arch-shaped vortices. At still larger velocities the characteristic forms are lost and a wedge-shaped turbulent state is formed from downstream. The turbulent wedge encroaches the laminar region, and its vertex advances toward the sphere as the velocity is increased. There appear vortex filaments parallel to the main stream, having a constant spacing along the sides of the wedge. The region in which an isolated roughness element can make the flow turbulent is restricted within the wedge. The vertex angle of the wedge becomes larger in proportion to the velocity, as is shown in Fig. 10. It is thought from the above observation that in the transition process the flow pattern passes through the vortical state or state of rotating motion until finally developing into turbulence. The rotations are due to the shearing flow caused by the boundary layer of the plate and the wake of the sphere.

In order to examine the process of the change of the flow pattern a little more quantitatively, the velocities at which the trailing vortex filaments begin to show waviness and those at which the arch-shaped vortices take the maximum height are determined for each size and position of the sphere from the photographs such as Fig. 2. The roughness Reynolds numbers $R_k = ku_k/\nu$ and k/δ_k were calculated for these states, where δ_k is boundary layer thickness at the position of the sphere. The results are shown in Fig. 12 together with the roughness Reynolds number at which the vertex of the wedge reachs to the sphere. The marks in the figure scatter considerably, because of the ambiguity of determining from the photographs the states such as the initiation of waviness and the most developed state of vortices. However, a tendency may be noticed: namely, as R_k is increased, in the case of large k/δ_k, first the trailing vortex filaments begin to wave, the periodic vortices appear and reach to their maximum height, and then the turbulence wedge is formed; but in the case of small k/δ_k the wedge is formed before the most developing state is attained. This means that the vortices grow still in the wedge, and therefore that the arch-shaped vortices have necessarily to raise their heads out of the boundary layer. This state can be clearly recognized in Fig. 6 in which the bottom part begins to be turbulent, in spite of the tops of arch-shaped vortices being still very clear. From above mentioned results the heads of the arch-shaped vortices seem to be independent of the transition. Accordingly, the transition to turbulence should be influenced by the vortices existing in the boundary layer, namely the horseshoe vortex, the trailing vortices and leg of arch-shaped vortices. In the periodic vortices including those of very slight waviness of the trailing vortices, the resulting deformation reach to a maximum at a certain distance from the sphere. This may be regarded as the same phenomenon as the existence of the unstable state of the Tollmien-Schlichting wave. However, the waviness of the trailing vortex filament does not seem to fit with the same stability curve. If the state of initiation of waviness is compared with the condition of the neutral stability by Shen[7], R_δ shows nearly the critical value 420, but $\beta_r\nu/U^2$ shows too large a value, where β_r is circular frequency of the partial oscillation.

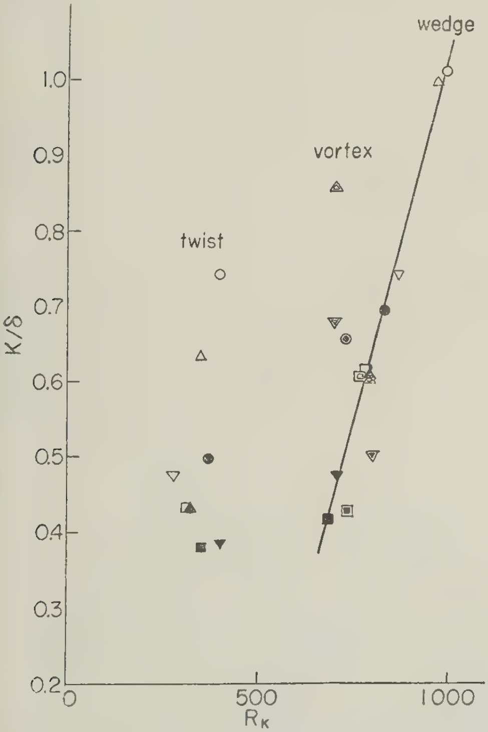

Fig. 12. Relation between roughness Reynolds numbers at which waviness of trailing vortex filament begins, arch-shaped vortices develope mostly and vertex of turbulence wedge attachs to sphere.

The visulization techniques by smoke can grasp well the appearance in the flow field, but on the other hand, a full understanding of the meaning of each pattern is difficult to obtain. Therefore, in order to understand the indication of smoke patterns more clearly, experiments are now being carried on by using the smoke and the hot-wire techniques simultaneously.

The author wishes to express her cordinal thanks to Prof. Jiro Sakagami for his kind guidance and constant encouragement throughout the course of this investigation. She is also grateful to the members of the Boundary Layer Research Group directed by Prof. Itiro Tani for their helpful discussions.

Vibration of a Plate and Sound Radiation Generated by an Impulsive Force

By Yasuo Tokita

Kobayasi Institute of Physical Research, Kokubunji, Tokyo

(Received January 25, 1961)

Measurements were made on the vibrational acceleration of a point on a plate and the sound pressure near the plate surface. Attention was given to the initial values of the above quantities, together with coincidence frequency and the waveform of impulsive force, and the following results were obtained.

1) There is a close relation between the hammer momentum (mv) and the initial value (A_0) of the acceleration or the sound pressure, as expressed by the empirical formula; $A_0=K_2(mv)^{K_1}$. The physical meaning of these coefficients is considered.

2) The correspondence between vibrational acceleration and sound pressure is fairly complex and depends upon the mechanical properties and thickness of the plate. The coincidence effect was observed.

3) The waveform of the impulsive force was observed with different stiffnesses and with various velocities of the hammer. The frequency spectrum of the vibration depends on this waveform.

§ 1. Introduction

The modes and responses of vibrational systems have been investigated fairly well in the steady state case, and the steady state sound radiation from vibrating bodies have also been studied and reported as the radiation and scattering problems[1]. However, the transient phenomena for the complicated systems have not yet been solved.

An important class of sound is that the sounds produced when an elastic body is set into vibration by some sort of impulses. The sound from musical instruments and bells; the noises from machines and vehicles; tapping noises in corridors, all these are transient phenomena excited by impulses.

The purposes of this work are, first, to find techniques for investigating complicated transient phenomena, through observation of the transient vibration excited by an impulse on a specific vibrating system, and the sound emitted thereby, second, to obtain, for practical purposes, fundamental knowledges that might be useful for the reduction of noise and of the excess vibration, and third, to study the mechanisms of transmission of impulsive waves through elastic materials. The transient response of simple bodies such as a stretched string or a drum head and three dimensional bodies such as a sphere[1], as well as their sound radiation have been throughly studied[1)-4)]. It has also been reported that a pistol noise which contains many frequency components over a wide band of frequency may be used for the study of architectural acoustics[5),6)]. The present work was started with the hope that the study of vibrations, excited by an impulsive force might likewise be useful in the study of acoustical and vibrational properties of materials.

In this paper, the relationship between the vibration and the sound generated when an impulsive force is applied to a two-dimensional homogeneous plate is studied.

§ 2. Experimental Procedure

2.1 *Experimental method*

When a homogeneous plate suspended by a fine string is subjected to an impulsive force almost at the center, a great many modes of flexural vibration are excited. These modes of vibration decay gradually on account of the radiation of sound and the internal friction of the plate.

The amplitude of the vibration and the sound pressure for each mode can be described in an exponential form;

$$A = A_0 \exp(-\alpha t) \qquad (1)$$

here A is the amplitude of either the vibration or the sound pressure, A_0 is its initial value and α is a reduction constant. If we observe the amplitudes of the vibration and the sound pressure of a single point as a whole at the same time, these quantities would not be described by Eq. (1), because the values of A_0 and α for each mode excited by the impulsive force are different from each other. In the observation within a narrow band of frequency, however, the amplitude of these may be almost represented by Eq. (1).

A schematic diagram of the experimental equipments is shown in Fig. 1. The vibration is detected by an acceleration pick-up fixed near the center of the plate. The sound pressure is received by a microphone at about 10 cm apart from the plate.

The wave patterns of these two quantities, acceleration amplitude and sound pressure, can be observed by a double beam oscilloscope, and at the same time they are recorded on a two channel magnetic taperecorder, and afterwards they are analyzed by a frequency analyzer.

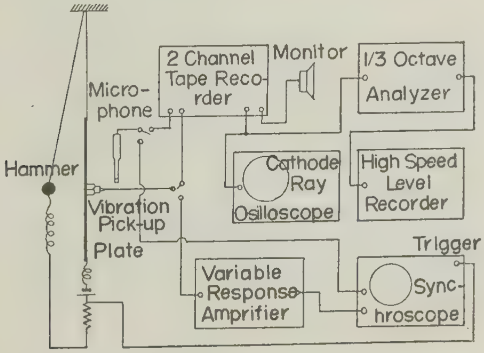

Fig. 1. Schematic diagram of the experimental equipment.

In order to observe how the impact force behaves during the contact, a piezo-electric elements was fixed on the plate and was struck directly by a hammer.

2.2 *Experimental apparatus*

Three different materials were chosen as the sample of plate; iron, glass, and plywood. The dimensions of these plates (length × width × thickness in cm) were (50×50×0.5), (50×50×0.3), (50×50×0.1), (100×100×0.3), (125×125×0.1) and (150×150×0.3) for iron plates, (50×50×1.1) for glass plate and (50×50×2), (60×90×0.6) for plywood plates.

The measurements were carried out under various conditions of the impact; that is different materials of hammer (impact instrument), say steel and rubber; different weights of hammer; various impact velocities and different shapes of the contact surface of the hammer.

A tiny condenser-type microphone was used for receiving the sound. The vibration pick-up used[7] was acceleration type and was made of $Pb(Zr\text{–}Ti)O_3$ ceramics. The weight and the acceleration sensitivity were 25 grams and 40 mv/g (where g is acceleration of gravity) respectively. The pick-up was cemented by "Eastman 910" almost at the center of the plate. The reason why the pick-up was cemented is to prevent some unexpected resonances for fixing the pick-up[8].

At each observation of the frequency responses for each impact, the output voltages of the microphone and the pick-up were recorded simultaneously on a two-channel magnetic tape recorder (a modified "Sony" type 552), in order to enable observation of the correspondence. The reproduced voltage of the tape recording was analyzed by a one-third octave analyzer ("Rion" type SA 2704). The frequency spectra thus obtained were recorded on high-speed level recorder ("Brüel and Kjaer" type 2204). Fig. 2 shows the characteristics of the magnetic recording systems, which record the out-put voltage of the microphone under a constant sound pressure, and also the induced voltage of pick-up under a constant acceleration amplitude. As is clear from this figure, it is not necessary to make correction in the range of frequency used.

A synchroscope (" Iwasaki " type 5101) was used for the observation of wave forms of the vibration and the sound, and the time duration of contact and the wave pattern of impulsive force. The sweep was triggered by the galvanic contact of the hammer with the plate so that it operates just at the instant of contact. A conductive silver paint (" Du pont ") was used for the non-conductive materials like rubber, plywood and glass.

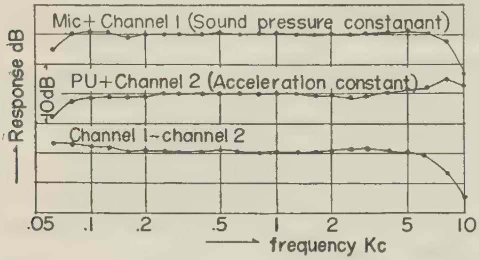

Fig. 2. The frequency characteristics of the two channel tape recorder.

The out put voltage of the pick-up which is proportional to the acceleration of the vibration were transformed to velocity and displacement through an amplifier which has an integrating circuit in itself. The cut-off frequency of the amplifier is 30 c.p.s.

§ 3. Experimental Results

3.1 *Decay curve*

Both the sound pressure and the acceleration of vibration behave almost in the way described by Eq. (1) within a range of one-third octave frequency band, and the slope of these patterns becomes straight in a logarithmic scale. The value of A_0 has been determined by extrapolating these straight lines into the time of zero. An example of the decay curve is shown in Fig. 3, in which each number indicates a center value of one-third octave band.

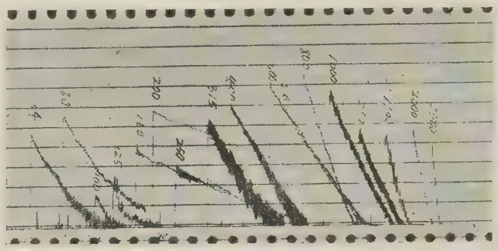

Fig. 3. Example of decay curve.

3.2 *One-third octave band spectrum*

By arranging the values of A_0 for each frequency band, as shown in Fig. 3, in respect to the frequency values concerned, a one-third octave band spectrum for the vibration and the sound is obtained. An example of the results is shown in Fig. 4. The dimensions of plates examined were (50×50×0.5), (50×50×1.1) and (50×50×2.0) for iron, glass and plywood respectively. The hammers used were a steel ball (3.0 cm in diameter), and three rubber hammers which had 80–85° hardness which was given different stiffness, by changing the radius of curvature of the balls (refer Table I). The sound pressure and the acceleration of the vibration are shown in decibel scale (dB) in Fig. 4. The characteristic pattern of each spectrum in this figure doubtlessly resulted from the distri-

M-6	60-65	0.5	0.17	17
S-1	30-35	25	0.24	12.3

bution of the characteristic frequencies of each plate itself.

3.3 *Variation of spectrum with the stiffness of hammer*

It has been well known that the tone of the sound emitted by a body struck by a hammer differs according to the difference in stiffness of hammers. In Fig. 5 it is shown how the spectra of vibration are affected by the stiffness of hammers. In these experiments, the steel and rubber hammers had almost same weight, and they struck the plates with the same impact velocity. In Fig. 5, all the spectra are shown relative to that for the steel ball. Pertinent data for the rubber hammers are shown in Table I. In this table, stiffness have been determined from the observation of the weight-to-deflection curves, and weight of these hammers are almost 75 grams.

It can be concluded from these experimental results that; with decreasing stiffness of the hammer, the levels of the spectrum in the high frequency range decrease considerably, while no substantial differences can be found in the low frequency range. This will be discussed in detail paragraph 4.

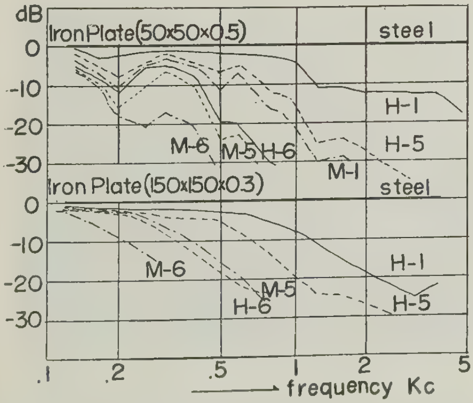

Fig. 5. Spectrum variation due to the hammer stiffness.

3.4 *Relation between A_0 and the momentum of the hammer*

The quantity A_0, the initial value of the sound pressure or of the acceleration of vibration, may be assumed to be a certain function of the impact condition of the hammer. It was therefore examined which quantity was just responsible for the determination of this initial value, among velocity, momentum and the kinetic energy of the hammer. Fig. 6 shows an experimental result for the

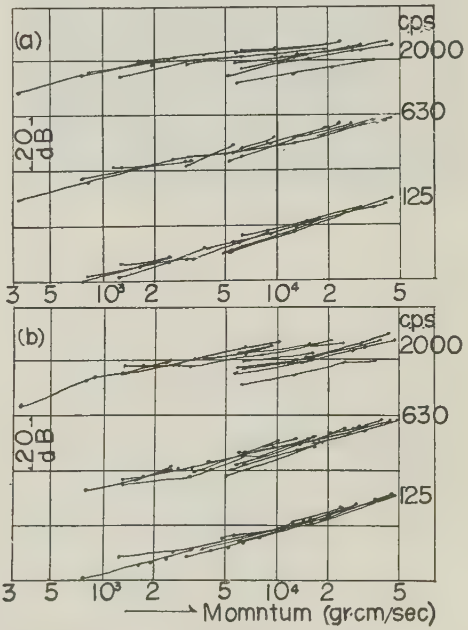

Fig. 6. Relation between A_0 and the momentum of the hammer.
(a) acceleration, (b) sound pressure.

relationship between A_0 and the momentum of the steel ball, both axes being shown in logarithmic scale.

In the case of the rubber hammer which has smaller stiffness than steel ball, the relation between A_0 and the momentum is not as uniform as in the case of the steel ball. When the observed values of A_0 are arranged in respect of velocity and kinetic energy, the relation between A_0 and the velocity or that between A_0 and kinetic energy looks like more fluctuating compared with the case of A_0 and momentum. There exists almost a linear relation in logarithmic scale between the momentum and the relative value of A_0. In the range of low frequency, the increase of twice of the momentum just corresponds to the change of +6 dB of A_0. However, the slope of this line gradually decreases and the linearity becomes diffuse in the range of high frequencies.

3.5 *The correspondence between the vibration and the sound pressure*

It is important to know the correspondence between the vibration of the body and the sound emitted from the vibrating body. In Fig. 7, the experimental data of the ratio of sound pressure to the acceleration of the vibration are plotted in dB scale against the frequency. Fig. 7(a) shows results for an iron plate (50×50×0.5), a glass plate (50×50×1.1) and a plywood plate (50×50×2.0), and (b) shows those for an iron plate of size (150×150×0.3), (100×100×0.3) and (50×50×0.3) respectively. The fluctuations of response curves seem to be caused by the resonance of the plates.

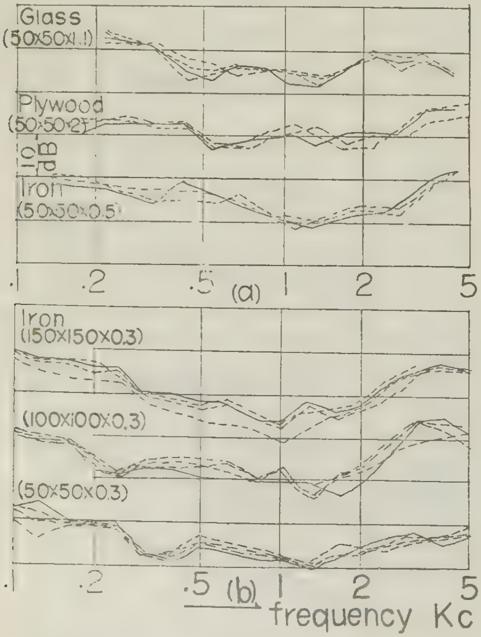

Fig. 7. Relation between the acceleration level and the sound pressure level.
(a) various samples with same size,
(b) various size of iron plate.

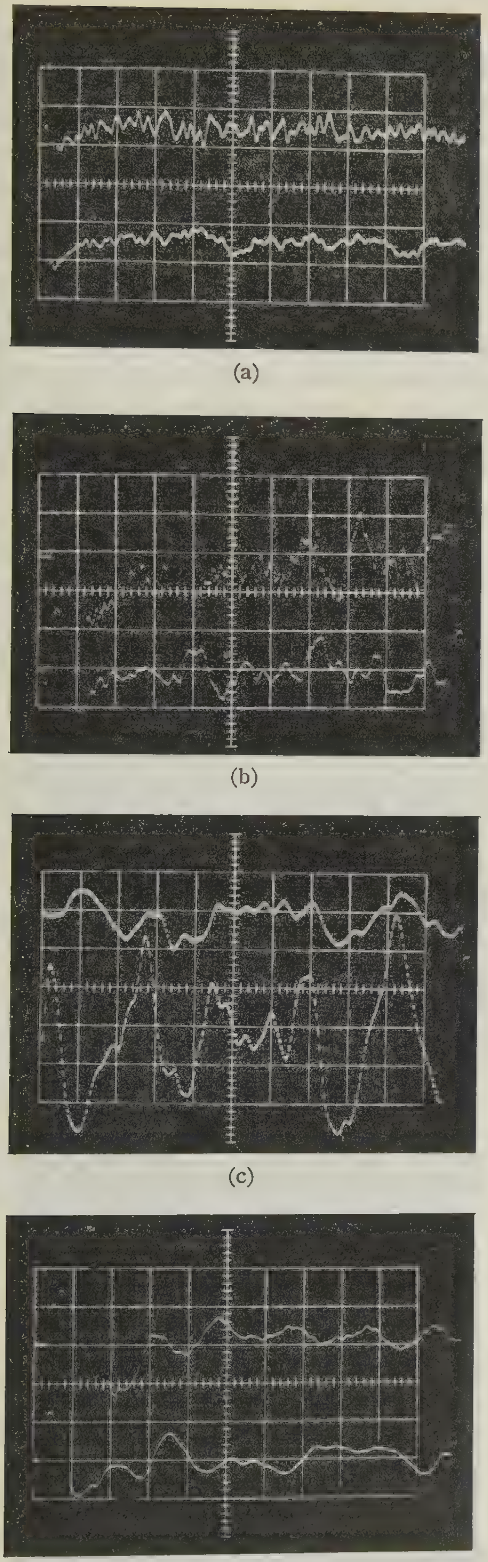
It can be concluded from the experiment that the behavior of the correspondence between the sound pressure and the vibration follows different characteristic patterns for each plate according to the physical properties of the plates, but that the correspondence is independent of the properties of the hammer for each same plate.

If the correspondence line is parallel to the abscissa, this behavior means that the sound pressure corresponds to the acceleration of the vibration. According as the slopes of these correspondence curves decline at a rate of −6 dB/octave or of −12 dB/octave, the sound pressure would correspond to the velocity or the displacement of the vibration respectively. If it goes upwards at a rate of +6 dB/octave, it would means that the sound pressure corresponds to the derivative of the acceleration.

From the experimental results shown in Fig. 7, it is hard to decide which correspondence is the most favorable among the velocity, the acceleration, the derivative of acceleration and the displacement. These behaviors seem to be dependent on the geometrical and physical properties of the plates themselves. This problem will be discussed later.

3.6 *Photographic observation*

Next, the experimental results on the waveform of the sound and the vibration and on the force pattern observed by a synchroscope will be described. The waveform are affected by the properties of both plate and hammer. Fig. 8 shows the waveforms for various kinds of plates, which are struck approximately at the center of plate. The hammer is a rubber H-1. The results for the sound pressure and the acceleration are shown in the upper and the lower traces of Fig. 8 respectively. Fig. 8(a) shows the result for an iron plate (100×100×0.1), in which case the sweeping speed of the synchroscope is 5 msec/unit scale. Fig. 8(b) is for an iron plate (100×100×0.3) and



(a)

(b)

(a) H-1

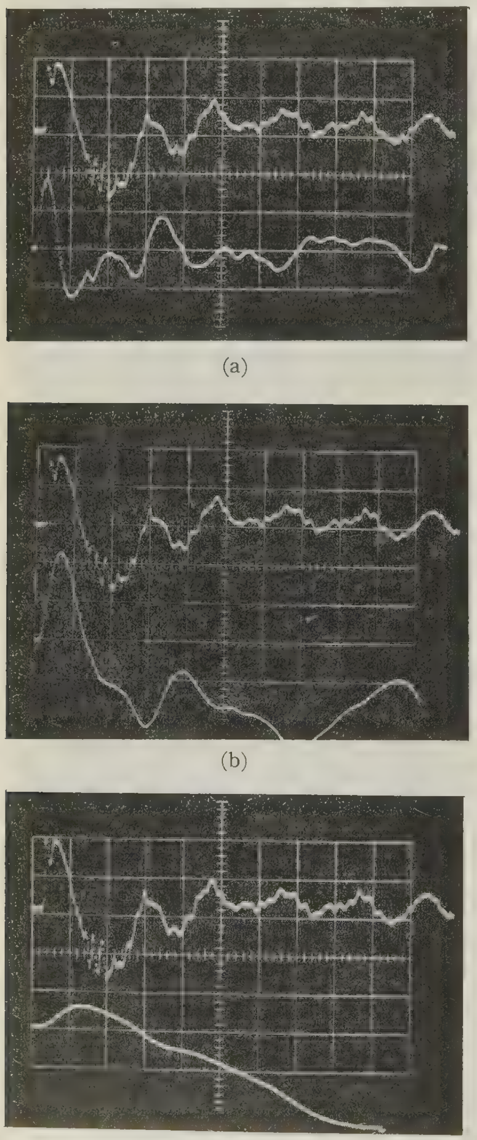
(b) H-5

(c) M-5

Fig. 9. C.R.O. traces for acceleration of the glass plate which is struck by rubber hammers of various stiffnesses.

the sweeping speed is 500 μsec/unit scale. Fig. 8 (c) is also for an iron plate (50×50×0.5) under the same sweeping speed as Fig. 8 (b). Fig. 8 (d) is the case of plywood (60×90×0.6), in which the sweeping speed is 1 msec/unit scale. It is observed clearly that the waveform for thin plates, for example Fig. 8 (a) and Fig. 8 (d), contain less amounts of high frequency components. When they are struck by a steel ball, which has a greater stiffness than a rubber hammer, these waveformes contain more amounts of high frequency components and also have more complicated and fine appearance.

The effect of the stiffness of the hammer on the vibrational behavior of the plate will be seen not only in the spectrum, but also in the waveform. Fig. 9 shows the waveform of the acceleration of a glass plate, which has been struck by rubber hammers of various stiffnesses. As is shown in Fig. 9 the fine maxima and minima in the waveform tend to disappear with decrease of the stiffness of the hammer, or, in other words, a remarkable change occurs in the high frequency range, but no significant difference can be observed in the low frequency range.



(a)

(b)

(c)

Fig. 10. Waveforms of sound pressure and vibration.

(a) sound pressure and acceleration.

(b) sound pressure and velocity.

(c) sound pressure and displacement.

Next, it was examined what correspondence existed between the waveform of the sound and that of the velocity or the displacement of the vibration, both of which was obtained from the acceleration by an amplifier of suitable characteristics. The results are shown in Fig. 10. The material of plates is plywood (60×90×0.6). Fig. 10 (a) indicates the correspondence between the waveform of the sound pressure and that of acceleration of the vibration, (b) gives sound pressure and velocity of vibration, and (c) gives sound pressure and displacement. Fig. 10 (a) indicates that there exists a fairly good correspondence between sound wave and the acceleration except for a maximum observed at the initial period.

An example of the observation of the contact time is shown in Fig. 11. These photographs are the results for an iron plate (50×

(b)

Fig. 11. Contact time and the acceleration.

50×0.5) which was struck by a rubber hammer H-1, (a), and H-6, (b). The upper trace shows the current through the contact point. The irregularity of the contact current as in Fig. 11 (b) has been observed very often, and would have been caused by the rebound of the hammer on the plate.

An example of the observation of the impact force is shown in Fig. 12. These figures have been obtained for the iron plate (150×150×0.3) and using various hammers. The upper curves indicate the voltages induced in a piezoelectric ceramic caused by the impact force, the lower curves in Fig. 12 (a), (b), (c) show the acceleration, and those in (d), (e), (f) show the velocity. The sweeping speed is 500 μsec/unit scale, and the hammer velocity is about 55 cm/sec.

§ 4. Discussion

4.1 *Relation between the spectrum and the stiffness of the hammer*

Let us observe the experimental results when an iron plate was struck by rubber hammers with different stiffnesses. Fig. 13 indicates haw the waveform of the force is affected by the stiffness of the hammers in the impact of constant velocity (about 55 cm/sec). In this case the slope of the force at the initial instant: $(dF/dt)_{t=0}$, becomes less steep with the decrease of stiffness of the hammer, and also the duration of the force becomes longer.

Fig. 14 shows the results when the impact velocity of the hammer is changed. The stiffness of this hammer H–5′ is equal to that of H–5 but the weight is 175 grams. From these data it can be observed that the force figure becomes steeper with increase of hammer stiffness, and also, the time duration becomes longer with increase of the impact velocity.

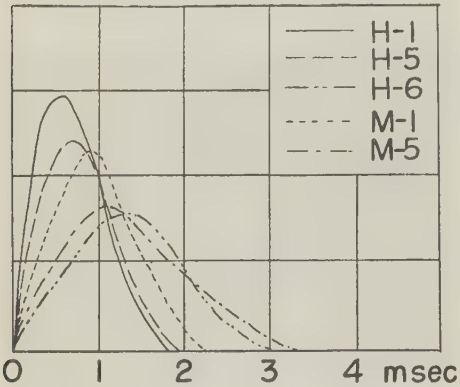

Fig. 13. Waveforms of the impact force for hammers of various stiffnesses.

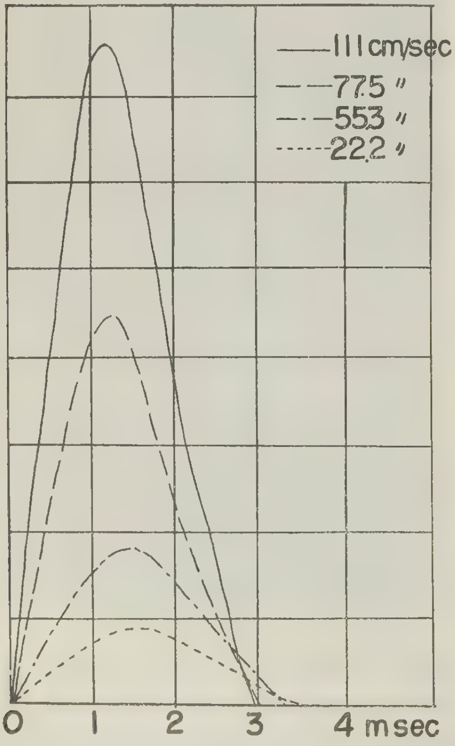

Fig. 14. Waveforms of the impact force for various velocities of the hammer (H–5′).

Let us consider the frequency components involved in the force figure. The sharp pattern in the force figure means that the wave contains more amount of high frequency component and the short time duration means that the impulsive force have a higher cut off frequency. As is seen from Figs. 13 and 14, the case with a harder hammer shows a sharper pattern in the force figure. This evidence just coincides with the fact that the higher components appear in the one-third octave spectrum with increase of the stiffness of hammer. The C.R.O. observation of the acceleration also indicates the same behavior (refer Fig. 9). Similar patterns were obtained even if the rubber hammer of different hardness was used.

The contact time can be determined from Fig. 11. But no definite relationship between the contact time and the duration of the impact could be found. This indefinite relationship seems to be caused by the movements of the plate and the hammer in the same direction, or the plastic deformation of both materials.

However it can be seen from Fig. 11 that the contact time is shorter with the larger hammers, and also with increasing velocity of the hammers. Also, the contact time becomes longer, as we may suppose, in the cases of low stiffness hammer, or in the case of a plywood plate which is struck by a hard steel ball, because of the plastic deformation during impact.

4.2 *Relationship between A_0 and hammer momentum*

The results in Fig. 6 are reproduced by

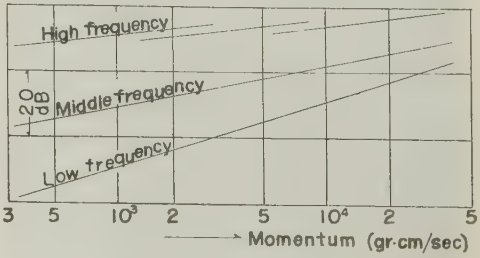

Fig. 15. Reproduction of Fig. 6 to show general trend.

single lines in Fig. 15, in which each line shows fairly well the characteristic relationship between A_0 and momentum at the low frequency region. The fact that the line goes up linearly means that there exists a parallelism between A_0 and momentum. In the medium frequency region, however, the slope of the line tends to go downwards, and at a high frequency region, there is some scattering in the plots.

The behavior of A_0 and momentum can be related by the following empirical formula;

$$A_0 = K_2(mv)^{K_1} \qquad (2)$$

where A_0 is an initial value of sound pressure or of vibration described by Eq. (1), (mv) is the momentum of hammer, and K_1 and K_2 are the coefficients which will be explained now.

K_1 is a coefficient which represents the slope of the straight line in Fig. 15. In the low frequency region, the value of K_1 is unity, in which case A_0 is proportional to (mv). K_1 becomes less than unity in the high frequency region. This means that, in the high frequency region, the increase of momentum of the hammer is not used effectively for the excitement of vibration. When the plate is struck vigorously, the component of high frequency is relatively weakly excited, and the low frequency component predominates.

It is supposed that an excess amount of impact energy above a certain level only contributes to extend the impact duration because of the elastic deformation of material, and is not used effectively to increase the initial amplitude of vibration. The same situation is observed in the waveform just after the impact.

K_2 is another coefficient which may be called the reduction factor. This factor shows how much amount of momentum can be transferred effectively to the vibration, and may be a complicated function of frequency, physical property and shape of contact surface of the hammer etc.. If a certain amount of momentum is applied at an impact, the vibration, corresponding to the momentum multiplied by K_2, is excited. Accordingly, if we try to shift the waveform parallel to the time axis by an amount that depends on K_2, the pattern becomes a simple line, the slope of which is determined by K_1.

The scattering of the data from the straight line in Fig. 6 seems to be caused by the fact that a part of impact energy is spent in some other forms of energy, for instance plastic deformation. Such a behavior is conspicuous in soft materials like plywood. The coefficient K_2 is too complex to be analyzed quantitatively.

When a rigid object like a steel ball is used as a hammer, the impact momentum can be transferred without hardly any rebound on the surface. However, in the case of elastic ball like rubber, a part of the momentum of the hammer is spent for the deformation of the ball. Accordingly, the experimental data in such a cases scatter considerably.

4.3 *Correspondence between the vibration and the sound pressure*

It has been well known in the problems of sound radiation due to the flexural vibration of a plate that there exist abnormal phenomena which have been called by L. Cremer[9] as coincidence effect. Afterwards, it was made clear by M. J. Brillouin[10], K. Gösele[11], W. Westphal[12], and M. Heckel[13] that the coincidence effect can be observed above a certain value of frequency, at which the wave length of the flexural vibration of the plate just coincides with that of sound in air.

The radiation factor, which means the efficiency of the sound radiation, becomes substantially different above and below this critical frequency, f_c. Taking the efficiency above f_c as a standard, there is an abnormal maximum of efficiency in the vicinity of f_c, and it falls off considerably in the lower frequency region.

The propagating velocity of flexural vibra-

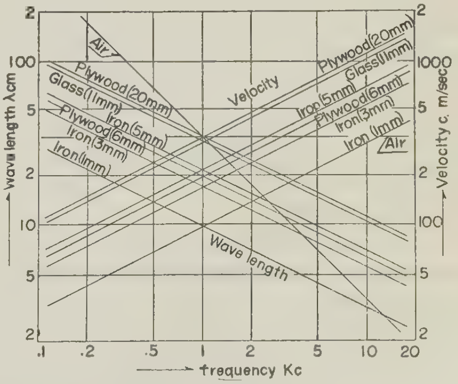

Fig. 16. Propagation velocity and wave length of flexural vibration.

tion of the plate is described as follows[9];

$$c^2=\omega\bar{r}\sqrt{\frac{E}{\rho(1-\mu^2)}}\ , \qquad (3)$$

here c is the propagating velocity, ω is the angular frequency, E is Young's modulus, ρ is the density, μ is the Poisson ratio and $\bar{r}$ is the radius of gyration which is $t/\sqrt{12}$ for a plate with a thickness t.

In Fig. 16, the wave lengths of the plates calculated by Eq. (3) are shown, together with that of sound in air. The values of f_c for the plates used are shown in Table II.

Table II.

Sample	Thickness (cm)	f_c (c.p.s.)
Iron	0.5	2,500
〃	0.3	4,000
〃	0.1	12,500
Glass	1.1	1,150
Plywood	2.0	1,000
〃	0.6	3,000

No anomaly as remarkable as would be expected from the theory was observed above and below the frequency, f_c, as shown in Fig. 7. It is remarked that Westphal also did not find any large anomaly but just a trend of being lower in the lower frequency range.

From our observation, it is found that the sound pressure is almost proportional to the velocity of the plate at lower frequencies, tends to be proportional to the acceleration with increase of frequency, and becomes proportional to the derivative of acceleration in the vicinity of f_c. In the case of high damping materials like a plywood, the amount of reduction of efficiency is so small in a lower frequency range than f_c, that sound pressure can be regarded as proportional to acceleration. As the radiation factor is a certain function of the internal friction of the plate[12),13)], it would be possible to treat this case theoretically.

It is necessary and important to examine what type of vibration pick-up attached to the plate can best reproduce the sound emitted by the plate. It is concluded that neither velocity nor acceleration type is satisfactory, but that the acceleration type looks like better below a few thousands cycles. However, in case f_c is too low or too high, the sound pressure would rather correspond to the velocity.

In Fig. 10, the waveforms of acceleration, velocity and displacement are shown together with that of sound pressure, and as will be seen from this figure, the best fit is found between sound pressure and acceleration. However, for the initial segment of the waveform, a better fit is obtained between sound pressure and velocity (Figs. 10 and 11). This correspondence can be understood from the consideration that in the vibration of a piston, the sound pressure is described by a function of vibrational velocity of the surface of the piston. It seems reasonable that the waveform of the sound pressure is just proportional to that of acceleration, because A_0 is the extraporated initial value of the sound pressure associated with the vibration of the plate, after its own characteristic vibrations have been excited.

§ 5. Conclusions

From the observation of the initial values of the sound and the vibration, A_0, of a plate subjected to an impact, it is concluded that;

1) With reducing stiffness of the hammer, the components of high frequency of sound and vibration tend to disappear, but no much difference is observed in the lower frequency region.

2) The initial value A_0 is closely related to the momentum of the hammer, and this relationship can be represented by Eq. (2). The coefficients K_1, K_2 in Eq. (2) is interpreted qualitatively.

3) The correspondence between the vibration and the sound is fairly complex and depends upon the properties of materials. The coincidence effect was observed in the radiation of sound from a plate, but it is not so marked as expected from the theory.

4) A good coincidence was observed in waveforms of A_0 between impulsive force, velocity and sound pressure just at the initial stage of impact. However, after the characteristic frequencies of the plate were excited, acceleration had a better correspondence with sound for common materials.

5) The relation between the contact time and the duration of the impact force has not yet been clarified.

Acknowledgement

In conclusion I wish to express my sincere thanks to Dr. H. Kawai and Dr. U. Kohasi whose help in discussion has been invaluable. I am also indebted to Mr. M. Koyasu, Mr. K. Negishi and Mr. S. Nakamura for their helpful suggestions, and to Mr. T. Shimizu and Mrs. K. Takeda for their willing aid for the experiment.

On the Relation between the Change in Modulus of Rigidity of Brass Wires by Cold-Rolling and Rolling Textures

By Jun KUROYANAGI

Department of Physics, Faculty of Liberal Arts and Science, Yamagata University

(Received December 28, 1960)

Pole figures for the brass specimens which had been used for the measurement of the change in modulus of rigidity in the previous investigation[1] and had received 90 per cent reduction in cross-sectional area by cold-rolling were obtained. In the pole figure of copper, the most intense rolling texture was {112}<111>. In the pole figure of brass containing 10.14 per cent zinc, the most intense texture was {110}<112> and the {110}<001> texture also appeared in the figure in considerable degree. The intensity of the {110}<001> texture increases with the increase of zinc content. The existense of the β-phase in the brass wire containing 40.24 per cent zinc was ascertained, which had been predicted in the previous paper[1]. On the basis of these results the variation in the modulus of rigidity of the specimens, 57.5 per cent cold-rolled, with various zinc contents was investigated.

§1. Introduction

Previously[1] the present author studied on the change of rigidities of brass wires containing 10.14, 30.15 and 40.24 per cent zinc caused by cold-rolling. The results showed that (1) in well annealed state, the modulus of rigidity of the specimens decreased quasi linearly with the increase of zinc content, (2) the modulus of rigidity of all specimens decreased with the increase of the degree of cold-rolling (3) the relative decrease of the modulus of rigidity of brass wires compared with the decrease of the equally cold-rolled pure copper wire was different according to the zinc content, for instance, in the specimens cold-rolled by 10.5 per cent in cross-sectional area, the modulus of rigidity of the brass wire containing 10.14 per cent zinc was larger than that of pure copper wire and the modulus of rigidity in the brass wires containing 10~40 per cent zinc content decreased slower than that for the well annealed specimens with increasing zinc content, (4) in the specimens cold-rolled by 57.5 per cent, the modulus of rigidity of the brass wire containing 10.14 per cent zinc was greater considerably than that of pure copper wire and it increased gradually with the increase of zinc content up to 30.15 per cent zinc, but the modulus of of rigidity of the brass wire containing 40.24 per cent zinc was grater considerably than that of the brass wire containing 30.15 per cent zinc.

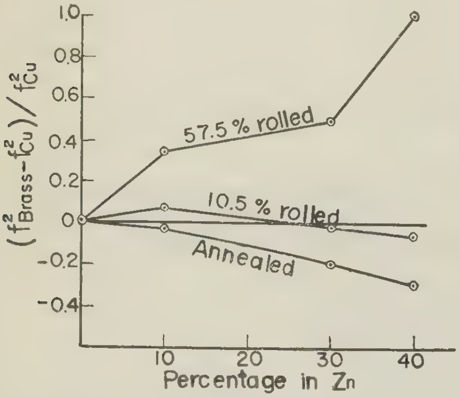

Fig. 1. Modulus of rigidity *vs* percentage of zinc content for annealed and cold-rolled brass wires.

The above relations are represented again in Fig. 1. The cause of the change in modulus of rigidity of the well annealed specimens and of the specimens cold-rolled by 10.5 per cent have discussed in detail in the previous paper[1)], but the discussion of the cause of the change in modulus of rigidity of the specimens cold-rolled by 57.5 per cent was unsatisfactory. Consequently, the present author investigated this problem again.

Cook and Richards[2)] found the following facts from X-ray studies; (1) when polycrystalline copper and brass strips are cold-rolled, the deformation proceeds by a slip mechanism up to about 33 per cent in thickness for copper and slightly more for brass, and beyond this stage it proceeds by a breakdown of the crystals into minute blocks (2) marked preferred orientation increases progressively with the increase of cold-rolling. The large variation in modulus of rigidity of brass wires with cold-rolling must arise from the formation of the preferred orientation, because the modulus of rigidity of copper single crystal decreases from 7,700 kg/mm^2 in the direction [100] to 3,100 kg/mm^2 in the direction [111][3)] and the modulus of rigidity G of *f.c.c.* metal depends on the orientation according to the formula[4)],

$$\frac{1}{G}=\frac{1}{G_{\max}}+3\left(\frac{1}{G_{\min}}-\frac{1}{G_{\max}}\right)\cdot F$$

$$F=\frac{h^2k^2+k^2l^2+l^2h^2}{(h^2+k^2+k^2)^2}$$

where h, k, l are the Miller indices. As $F_{\min}=0$ for [100] and $F_{\max}=1/3$ for [111], it follows that the modulus of rigidity is largest in the direction [100] and smallest in the direction [111]. On account of the above mentioned reasons it is expected that the variation in modulus of rigidity of the specimens, 57.5 per cent cold-rolled, with the change in zinc content to be affected in great degree by the preferred orientations developed during cold-rolling. Thus the preferred orientations in the cold-rolled specimens developed during cold-rolling were studied using the same materials which were used for the measurement of the change in modulus of rigidity. And also the existence of the β-phase in the brass wire containing 40.24 per cent zinc was ascertained, which was predicted in the previous investigation[1)].

§ 2. Experimental Procedure

(1) *Measurement of preferred orientation*

Specimens for pole figure determination were prepared from the wires which had been used for the change in modulus of rigidity and had received 90 per cent reduction in cross-sectional area by cold-rolling in order to obtained diffraction patterns showing the preferred orientation. Cu K_α radiation obtained with 15 mA at 30 KV was used for all diffraction patterns. The X-ray beam was collimated through a pinhole system. The specimen was mounted in a goniometer which permitted accurate measurement of the angle of rotation about the vertical axis of the specimen without removing the specimen from its mounting during the entire series of exposure. The starting position was selected such that the X-ray beam was perpendicular to the rolling plane and the rolling direction of the sheet specimen was vertical. A series of transmission patterns was obtained from 0° to 60° at intervals of 10°, by rotating the specimen clockwise about the vertical axis. The distance from the specimen to the X-ray, film was 40 mm.

(2) *Confirmation of the existence of β-phase*

In the previous investigation the existence of β-phase which should coexist with α-phase in the brass wire containing 40.24 per cent zinc could not be confirmed. Nevertheless, the coexistence of β-phase with α-phase in annealed brass containing 40.24 per cent zinc was successfully confirmed using FeK($\alpha+\beta$) radiation obtained with 20 mA at 15 KV and with the exposure of 10 hours in the present case.

§ 3. Results

(1) *Preferred orientation*

The {111} pole figures obtained from the diffraction patterns for the cold-rolled copper and brass sheets are shown in Figs. 2∼5. The {200} pole figures for these specimens were also obtained to ascertain the results obtained from the {111} pole figures. The intensity of Debye rings for the {111} and {200} planes were estimated by eye and graded into seven classes. These grades are indicated in these figures with cross lines, lines at regular intervals, lines and dots, crosses, and dots respectively in order of intensity.

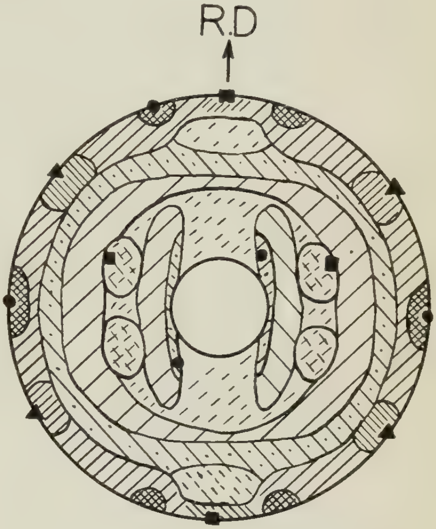

Fig. 3. {111} pole figure for 90 pct cold-rolled brass sheet containing 10 pct zinc. Ideal orientations indicated as follows: Solid circle, {110} <112>. Solid square, {112}<111>. Solid triangle, {110}<001>.

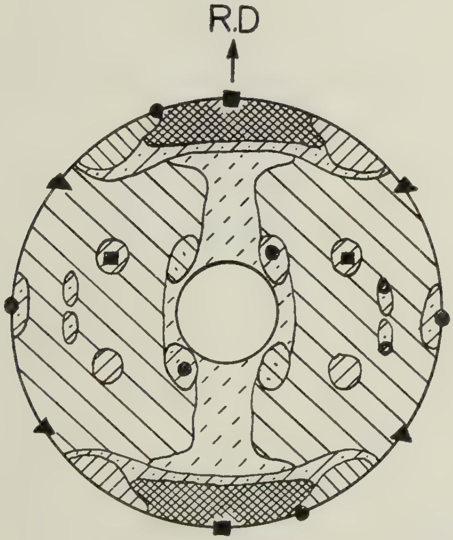

Fig. 2. {111} pole figure for 90 pct cold-rolled copper sheet. Ideal orientations indicated as follows: Solid circle, {110}<112>. Solid square, {112}<111>. Solid triangle, {110}<001>. Open circle, {210}<001>.

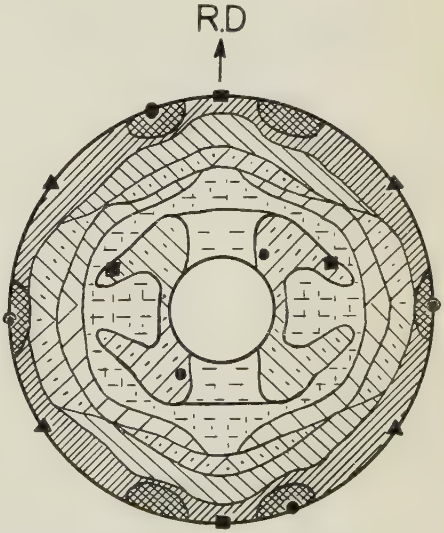

Fig. 4. {111} pole figure for 90 pct cold-rolled brass sheet containing 30 pct zinc. Ideal orientations indicated as follows: Solid circle, {110} <112>. Solid square, {112}<111>. Solid triangle, {110}<001>.

Comparison of these pole figures with one another indicates a number of gradual changes taking place with increasing zinc content. In the pole figures of copper, Fig. 2, the most intense orientation spread is the one centered around the {112}⟨111⟩ orientation. Moreover, a {110}⟨112⟩ texture and a twin {210}⟨001⟩ texture can be found in Fig. 2. Nevertheless, these textures are present to a less degree than the {112}⟨111⟩ texture. In the pole figure of brass containing 10.14 per cent zinc, Fig. 3, the most intense texture is the {110}⟨112⟩ orientation and the intensity of the {112}⟨111⟩ texture becomes weaker as compared with that of copper. Moreover, a {110}⟨001⟩ texture appears in this figure in considerable degree.

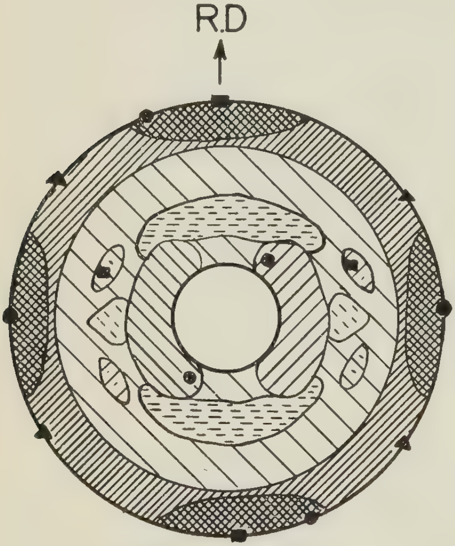

Fig. 5. {111} pole figure for 90 pct cold-rolled brass sheet containing 40 pct zinc. Ideal orientations indicated as follows: Solid circle, {110} <112>. Solid square, {112}<111>. Solid triangle, {110}<001>.

As seen in the pole figures, Figs. 3∼5, the texture represented by {011}⟨112⟩ is present in large amount for any zinc content in the range from 10 to 40 per cent and the intensities of which increase with zinc content; relative intensity of {112}⟨111⟩ texture is almost independent on the zinc content but is weak as compared with that of copper; the intensity of the {110}⟨001⟩ texture increases with increasing zinc content.

(2) *Existence of β-phase*

Fig. 6 shows the powder X-ray photograph of the annealed brass containing 40.24 per cent zinc obtained by the above mentioned method. From this figure the coexistence of of β-phase (*b.c.c.*) with α-phase (*f.c.c.*) in this brass is clear.

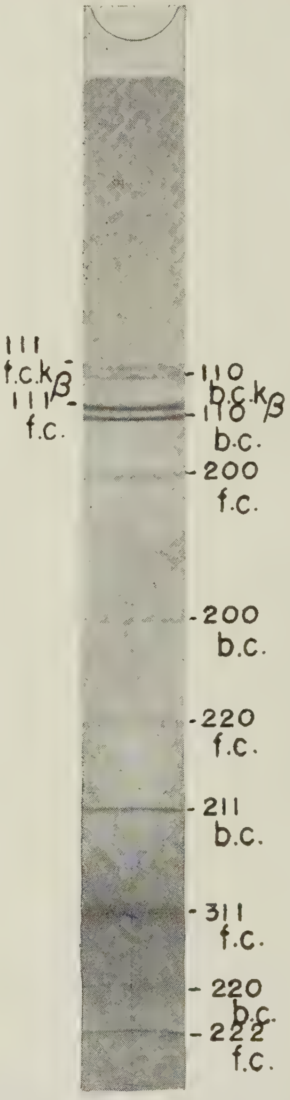

Fig. 6. Power photogram of annealed brass contatining 40 pct zinc. FeK($\alpha+\beta$) radiation, 15 KV, 20 mA 10 hrs.

§ 4. Discussion

The above mentioned rolling textures obtained for the copper and brasses are not completely consistent with the results obtained by Merlini and Beck[5]. These discrepancies may be due to the difference of compositions or history of the specimens and method of measurement. Especially, the specimens used for the measurement of rolling textures in this experiment were prepared from the wires about 1 mm in diameter. Nevertheless, the change in modulus of rigidity of the brass wires cold-rolled 57.5 per cent associated with the change of zinc content, reported in the previous paper[1], can be explained with the above mentioned experimental results as follows. (1) The variation in the modulus of rigidity of the heavily cold-rolled specimens such as in this case should be greatly affected by the preferred orientations developed by cold-rolling. (2) The decrease of the modulus of rigidity should chiefly be due to the development of the preferred orientation represented {112}⟨111⟩, for which the value of the modulus of rigidity is smallest, among the textures of various orientations. (3) The fact that the modulus of the brass wire containing 10.14 per cent zinc surpasses that of pure copper wire in amount at this stage of cold-rolling should be attributed to the change of the strongest preferred orientation from {112}⟨111⟩ to {110}⟨112⟩ by the addition of 10 per cent zinc. (4) The gradual increase of the relative amount of the modulus of rigidity of the 57.5 per cent cold-rolled brass wires against that of copper wire with the incrase of zinc content from 10 per cent to 30 per cent, as shown in Fig. 1, should be due to the gradual increase of the intensity of the preferred orientation represented by {110}⟨001⟩, for which the value of modulus of rigidity is largest, with the increase of zinc content. (5) For the rapid increase of the relative amount of the modulus of rigidity of the 57.5 per cent cold-rolled brass wire containing 40 per cent zinc against that of copper wire, as shown in Fig. 1, two factors may be considerable, namely, (a) the increase of the intensity of preferred orientation {110}⟨001⟩, (b) influence of the β-phase coexisting with α-phase. The difficulties of the confirmation of the existence of β-phase by x-ray photograph, the rapid increase of Vickers hardness at the neighbourhood of 40 per cent zinc content as shown in the previous investigation, and furthermore the fact that the tensile strength shows a maximum value at about 40 per cent zinc content may indicate the existence of the precipited β-phase in the form of very minute particles in the brass containing 40.24 per cent zinc. The decrease of the grain size would increase the modulus of rigidity. This problem is now under investigation.

The author wishes to express his sincere thanks to Mr. Toyojirō Isano for his assistance.

Dielectric α- and β-dispersions in Polyvinyl Butyral (PVB)

By Yūzō TAKAHASHI

Laboratory, Hokkai Can Mfg. Co., Ltd., Otaru, Hokkaido

(Received March 9 1961)

Since there is relatively few reports concerning both dielectric α- and β-dispersions measured for the same sample of polymers, this paper deals with these two dielectric dispersions in PVB. The sample of PVB, which is heat-treated at 200°C for 30 min., was measured for the frequency dependence of dielectric loss ε'' in the temperature region from -70 to 120°C and over the frequency range of 0.3 to 10^6 c/s. The apparatus was the same as the previous one[1].

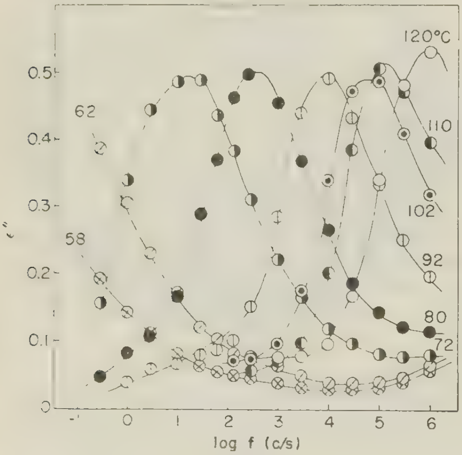

Fig. 1. Frequency dependence of ε'' at various temperatures for PVB (in high temperature region)

The results obtained are shown in Fig. 1 and 2. Two dielectric dispersions, i.e., the higher and lower temperature dispersions which are labled as α and β respectively, can be observed, while these two dispersions are also detected by the mechanical measurement[2]. If $\log f_m$ is plotted against $1/T$, where f_m is the frequency at which ε'' is maximum, we obtain a curve for the α-dispersion, but a straight line for the β-disperion as shown in Fig. 3. Therefore, the apparent dielectric activation energy ΔH^* for the former are 93, 66, 53, 42 and 34 kcal/mol at 80°, 92°, 102°, 110° and 120°C respectively, calculated using the equation of WLF[3]. On the other hand, ΔH^* for the latter is about 12 kcal/mol and independent of the temperature. This difference between the α- and β-dispersions in PVB seems to be based on the difference whether the dielectric relaxation is related to the segmental movements of the main chain or to the movements of the local parts such as the side groups.

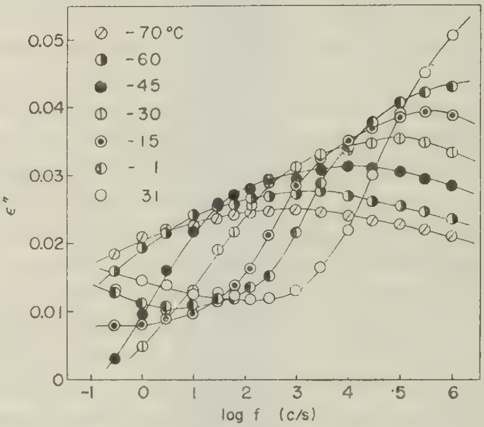

Fig. 2. Frequency dependence of ε'' at various temperatures for PVB (in low temperature region).

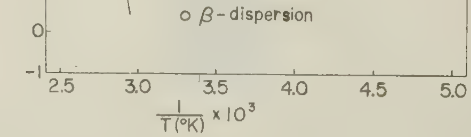

Fig. 3. Plot of logarithmic dispersion frequency against reciprocal of absolute temperature.

The author wishes to thank Professors J. Furuichi and M. Kaneko, Faculty of Science, Hokkaido University, for their continual interest and discussion.

The Double-Grid Ionization Chamber

By Iwao OGAWA and Tadayoshi DOKE

Department of Physics,
Rikkyo (St. Paul's) University, Tokyo

(Received February 15, 1961)

Pulses extracted from the grid of a gridded ionization chamber may be conveniently used as a signal containing the information on the orientation of tracks of alpha particles emitted from the cathode of the chamber[1]. As was shown by Botchagov *et al.*, the negative pulse-height V_g of a grid pulse is approximately given by

$$V_g=(Q_0/C_g)\cdot\{1-(R^*/d_1)\cos\theta\}\ , \qquad (1)$$

where Q_0 denotes the total charge of the ions produced by an alpha particle, C_g the capacity of the grid system, d_1 the distance between the cathode and the grid, and θ the angle between the particle track and the normal to the cathode K, while R^* is a quantity representing a length very close to the particle range R independent of $\cos\theta$.

From (1) it is seen that the pulse-height distribution of those grid pulses which are counted in coincidence with the collector pulses belonging to a particular peak in the energy spectrum would represent the angular distribution in terms of $\cos\theta$ for the particles of the particular energy.

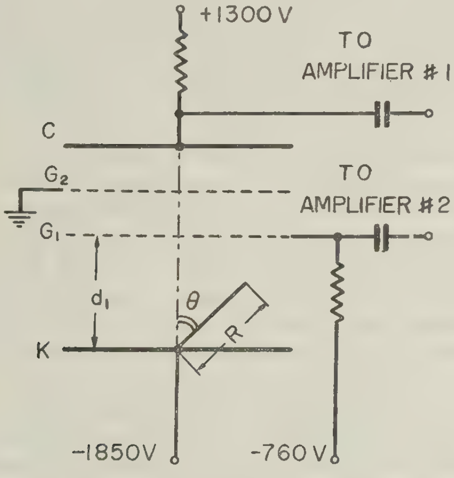

Fig. 1. Schematic view of the double-grid chamber.

In an ordinary *single*-grid ionization chamber, however, simultaneous extraction of both the collector and grid pulses generally impairs the shielding efficiency of the grid and results in a serious loss in the energy resolution.

In order to overcome this difficulty, we have constructed a *double*-grid ionization chamber shown schematically in Fig. 1. Signals are taken out from the first grid G_1 as well as from the collector C. An additional grid G_2 is directly grounded and serves as a screen grid.

The energy spectrum of the alpha particles from a natural uranium source ($\sim 50\,\mu$g/cm^2 thick) obtained with this chamber is given in Fig. 2A. The resolution is fairly good despite the simultaneous extraction of the grid pulses. Fig. 2B shows the grid pulse-height distributions due to U^{234} (curve (a)) and U^{238} (curve (b)) obtained by the collector-grid coincidence method described above, by which we can select a praticular peak of the energy spectrum. The corresponding ranges in the collector pulse-height are indicated by the arrows in the energy spectrum. Thus we can see that the separation of the grid pulses is satisfactory in spite of the rather small difference in energy of the both alpha particles.

Grid pulses due to the particles emitted from G_1, G_2 or C are essentially *positive* at least in the first approximation. Making use of this fact, we have succeeded in a background reduction by a factor of about three in the energy spectrum merely by counting those collector pulses which are accompanied by a *negative* grid pulse. The full account will shortly be published elsewhere.

Thermoelectric Behaviours of Rutile

By Kimiko SAKATA

National Research Institute for Metals,
Meguro-ku, Tokyo, Japan

(Received February 20, 1961)

The present note describes the results of experiment in which the temperature dependence of conductivity and that of thermo e.m.f. were simultaneously measured for rutile samples sintered in different oxygen atmosphere. The experimental procedures are the same as previously described[1].

Curves in Figs. 1 and 2 represent, respectively, σ vs. $1/T$ and Q vs. $1/T$ for various oxygen partial pressures P_{O_2} (σ: conductivity in $\text{ohm}^{-1}\,\text{cm}^{-1}$, Q: e.m.f. per degree in mV/degree, T: absolute temperature in °K). Each curve was obtained by successive measuremeuts carried out with decreasing temperature. Each measurement at a certain temperature was carried out after assuring that an equillibrium state had been established in the sample, although below 700°C it could not be attained within a defined time, when a certain final state has been settled. An exception is the case of curve 6, i.e., it was obtained by successive measurements with increasing temperature for the sample which had been rapidly quenched from the equilibrium at 1200°C in the prescribed atmosphere.

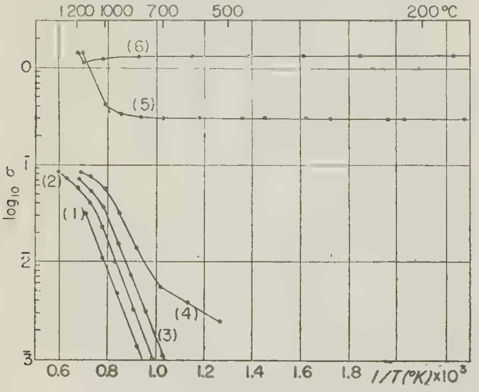

Fig. 1. Conductivity vs. reciprocal absolute temperature for various oxygen partial pressures.
(1) 1 at. O_2 (2) 1 at. air
(3) 100 mm Hg air (4) 10 mm Hg air
(5) 1 at. deoxidized Ar (6) 1 at. deoxidized Ar

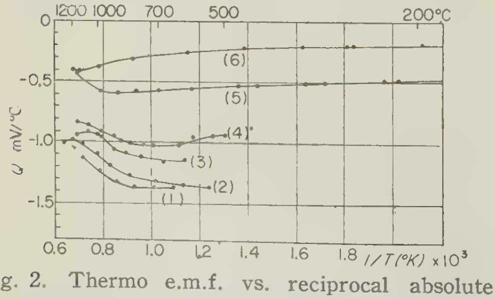

Fig. 2. Thermo e.m.f. vs. reciprocal absolute temperature for various oxygen partial pressures.
(1) 1 at. O_2 (2) 1 at. air
(3) 100 mm Hg air (4) 10 mm Hg air
(5) 1 at. deoxidized Ar (6) 1 at. deoxidized Ar

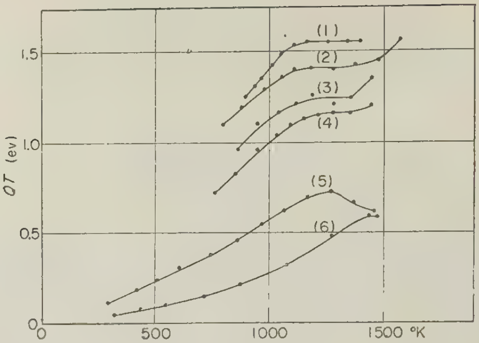

Fig. 3. QT product vs. absolute temperature various oxygen partial pressures.
(1) 1 at. O_2 (2) 1 at. air
(3) 100 mm Hg air (4) 10 mm Hg air
(5) 1 at. deoxidized Ar (6) 1 at. deoxidized Ar

The activation energy of conduction determined by each curve in Fig. 1, in the temperature range of 700°~1000°C, tends to increase with increasing P_{O_2} up to 3.0 ev (curve 1), which may correspond to the value of forbidden energy gap reported by Cronemeyer[2]. The asymptotic value of corresponding QT-curve (Fig. 3, curve 1) tends to 1.55 ev, indicating that the Fermi level approaches to half way of the forbidden gap in the intrinsic region. The conductivy behaviour as well as the corresponding thermo e.m.f. (curve 6 in each figure) suggest that in highly reduced rutile its metallic conduction takes place in the narrow d-band, as pointed out by Morin[3], and the intrinsic conduction begins to predominate at about 1150°C.

Curves 2, 3, 4 and 5 in each figure show intermediate behaviours between those of curve 1 (nearly intrinsic) and curve 6 (highly reduced). It should be pointed out that a contribution to these observed behaviours from a temperature dependent change in oxide composition cannot be ignored. This fact is obvious when one compares curve 5 with curve 6; in the latter case, the above contribution may be neglected. In the former case, on the other hand, the composition change is proceeding in the direction of approaching to stoichiometry with decreasing temperature in the range from 1200°C to about 700°C, where a certain state with a certain composition is frozen in.

Magnetic Anisotropy of Heusler Single Crystal

By Keizô Aoyagi and Makoto Sugihara

Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation 1551, Kichijoji, Musashino-shi, Tokyo, Japan

(Received February 25, 1961)

The Heusler alloy of which the typical composition is Cu_2MnX, where X=Al, In, Sn, is the well known ferromagnetic alloy composed of non ferromagnetic elements. It was found by many investigators[1)] that ferromagnetism of the Heusler alloys is associated with body-centred cubic β phase with a face-centred cubic superlattice in the highly ordered state and especially both the saturation magnetization and the curie temperature of Cu_2Mn Al alloy change with the condition of heat treatments, namely both show minimum values in the state quenched from high temperatures and increase with aging at low temperatures. It may be interesting to investigate the effect of heat treatment on the ferromagnetic crystal anisotropy of Cu_2MnAl, in connection with the experimental facts mentioned above. Furthermore, so far any quantitative measuring datum on the ferromagnetic crystal anisotropy of Cu_2MnAl was not publicated except the qualitative datum of small single crystal specimens by Potter[2)]. The authors have tried to grow a large single crystal of Cu_2MnAl and to measure ferromagnetic crystal anisotropy using the crystal and they have got satisfactory results.

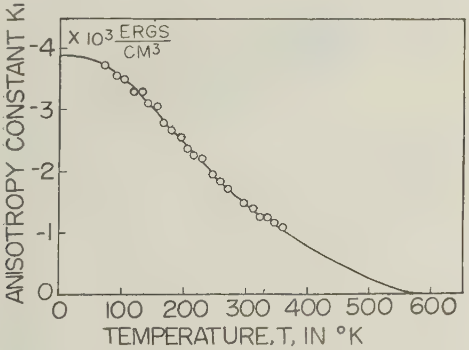

Fig. 1. The temperature dependence of anisotropy constants, K_1, of a Cu_2MnAl alloy in the state quenched from 750°C.

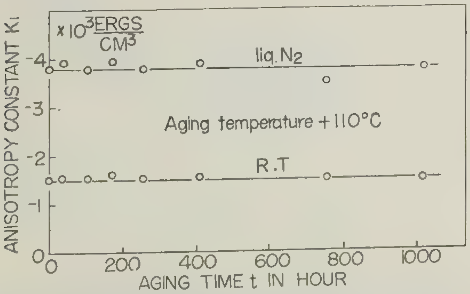

Fig. 2. The change with aging at 110°C of anisotropy constants, K_1, of a Cu_2MnAl alloy.

A single crystal employed was grown in argon furnace from the melt of the ingot of Cu_2MnAl alloy which was preliminary cast and grinded to remove the scale. To prevent the precipitation of non ferromagnetic phase, after the melt was solidified it was immediately cooled rapidly, and then circular disk, 11.834 mm in diameter and 1.001 mm in thickness, with plate surface coinciding with the (100) plane, was cut out from the single crystal ingot. The results of chemical and X-ray analysis on the remainder of a single crystal ingot showed that its accurate composition was $Cu_{1.990}Mn_{1.007}Al_{1.003}$. The crystal structure was exactly the same Heusler type as observed by Bradley et al[3)], and any other line was not observed in X-ray analysis. Anisotropy measurements by the automatic recording torque magneto meter[4)] were performed at the temperature between liq.N_2 and +80°C in the state cooled rapidly by the cold jet of argon gas after annealing for one hour at 750°C, and were performed also at liq.N_2 and room temperature in the state aged at 110°C after heat treated as mentioned above. Measuring magnetic field applied parallel with the (100) plate surface was about 8200 oe, and cubic anisotropy constants, K_1, were determined accurately by Fourier analysis of the measured torque curves.

The results obtained are summarized as follows:

(1) The values of K_1 were -3.7×10^3 ergs/cm³ and -1.5×10^3 ergs/cm³ at liq.N_2 and room temperature, respectively, in the state cooled rapidly from 750°C. Change of K_1 with the measuring temperature was shown in Fig. 1. This temperature dependence was well described by $[I_T/I_0]^5$ curve, where I_T and I_0 were the intensity of Magnetization observed by Heusler[5)] on Cu_2MnAl at the temperatures of T and 0°K, respectively.

(2) Measurements of change of K_1 with aging at 110°C were made from 0 to 1000 hours, but any change of K_1 was not observed. (Fig. 2)

Dielectric α-, β- and γ-Dispersions in the Thermosetting Phenolic Resins

By Yūzō TAKAHASHI

Laboratory, Hokkai Can Mfg. Co., Ltd., Otaru, Hokkaido

(Received February 4, 1961)

A number of works on the dielectric behavior of the thermosetting phenolic resins have been reported. However, systematic classification of the characteristic dielectric dispersions of this resin based on measurements over a wide range of frequency and temperature is lacking. It is of interest to classify the dielectric dispersions since it generally gives us informations about the state of motions of the molecules or its local groups. In the present work, the frequency dependence of the dielectric constant ε' and the loss ε'' was measured for the ammoniac resol type of phenolic resin, cured at 200°C for 30 min. over the frequency range of 0.3 to 10^6 c/s and the temperature range of -60 to 170°C. Three characteristic dispersions were either obtained or suggested and are labeled as α, β and γ in the order from higher temperature or from lower frequency side.

The resin was synthesized from phenol, o-cresol and formaldehyde under a catalyser NH_4OH aq. (weight ratio of phenol to o-cresol is 60:40). The sample film had been dried almost completely. The measurements were made by means of a mutual inductance bridge¹⁾ and a modified resistive-ratio-arm bridge¹⁾. Values of ε'' at high temperatures have been corrected for the steady d-c conductance. Results are shown in Fig. 1 and Fig. 2. In Fig. 1, the values of ε'' show rapid increase at high temperature and low frequency side, although no maximum of ε'' can be observed within the range investigated. There will possibly be a maximum outside this region due to the motions of macromolecules of phenolic resin, i.e., the α-dispersion. On the other hand, Hartshorn et al.²⁾ have reported the dielectric α-dispersions of novolac type of phenol- or cresol-formaldehyde resin at 1 kc/s. in the temperature range of 37 to 75°C. The difference between the behaviors of the α-dispersion for these two types may be due to the complexity of their molecular structures after curing. In Fig. 2 a maximum of ε'', i.e., the β-dispersion, is observed for each curve in the frequency range of about 0.3 to 10^3 c/s. They may be caused by the motions of local parts such as unreacted methylol and amino groups in the phenolic resin molecule³⁾. Finally the remarkable upswing of ε'' values on the high-frequency side suggests the existence of another maximum, i.e., the γ-dispersion. This may corre-

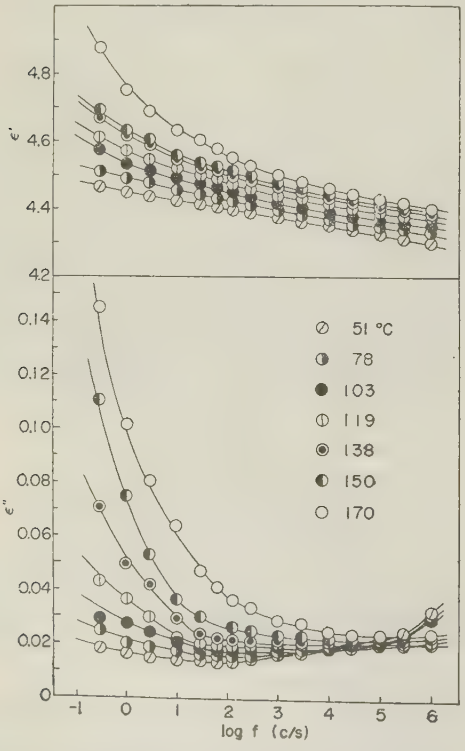

Fig. 1. Frequency dependences of dielectric constant and loss for the ammoniac resol type of phenolic resin in high temperature region.

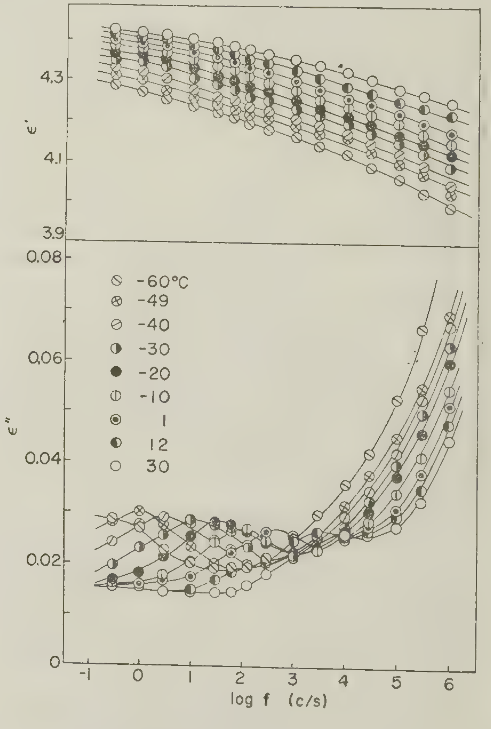

Fig. 2. Frequency dependences of dielectric constant and loss for the ammoniac resol type of phenolic resion in low temperature region.

spond to the dielectric dispersion found by Yager[4] and Kawai et al.[5] at about 10^7 c/s at room temperature for the dried paper-laminated phenolic resin, although Yager interpreted this dispersion as due to an intrinsic properties of cellulose contained in the specimen. In order to confirm the γ-dispersion, it would be necessary to extend the measurement to higher frequencies or to lower temperatures.

The author wishes to thank Professors J. Furuichi and M. Kaneko, Faculty of Science, Hokkaido University, for their invaluable discussions.

Forward Characteristics of Si *pπn*-Junctions

By Masakatsu TOKUNAGA and Katsufusa SHONO

Research Institutes, Yuasa Battery Company, Takatsuki, Osaka

(Received February 10, 1961)

A series of Si *pπn*-junctions were manufactured from *p*-type Si with resistivity ranging between 2 and 5 ohm cm as the starting materials. The junction was formed by diffusing boron from the one side and phosphorous from the other side. This process was done on (111) faces of the crystal at about 1250°C and the width of π-region of junction was adjusted by changing the duration time of diffusion.

Sah, Noyce and Shockley[1] predicts an apparent $\exp(qV/kT)$ dependence of the forward current in a *pn*-junction, where $1 \leqq n \leqq 2$. It is pointed out that the forward current consists of two parts, the diffusion current and the recombination-generation current; and in usual devices the effect of the body resistance of the π-region is added. The diffusion current outside the space charge layer at large forward bias is expressed as

$$J_d = \frac{2qn_pL_0}{\tau_0} \exp\left(\frac{qV}{kT}\right) \qquad (1)$$

where n_p is the density of holes, L_0 and τ_0 are the diffusion length and the lifetime of minority carries, respectively. The recombination-generation current in the space charge layer at small forward bias is given by

$$J_{rg} = \frac{kTn_i}{\tau_0 E} \exp\left(\frac{qV}{2kT}\right) \qquad (2)$$

where n_i is the density of carriers in an intrinsic specimen and E is the electric field at the junction, provided the recombination centers are not very close to the band edge.

We have measured the forward voltage-current characteristics at the temperature range between 200°K and 500°K of *pπn*-junctions which had various width of π-region. The solid lines in Fig. 1 shows the forward characteristics at 300°K. As shown in the figure, in case of $W=0$ (W: width of π-region), the forward current in proportional to $\exp(qV/1.74kT)$ at small forward voltages and to $\exp(qV/1.00kT)$ at larger voltages. With the increasing of W, the forward characteristics deviates from the straight line corresponding to the case of $W=0$. This is due to the body resistance of π-region.

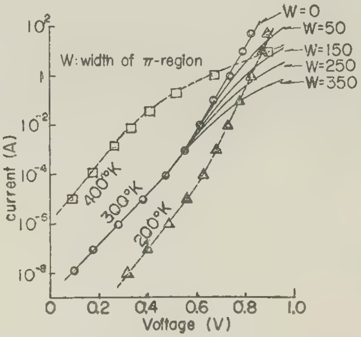

Fig. 1. Forward current voltage characteristics for Si *pπn*-junctions of various width of π-region.

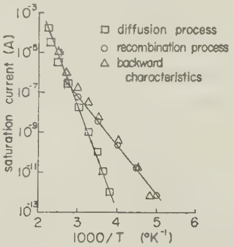

Fig. 2. Saturation current vs 1000/T for Si *pπn*-junctions.

The dashed lines in Fig. 1 show the current-voltage characteristics at 200°K and 400°K of the sample with $W=0$. The dependence of the characteristics on the width of π-region was similar to that observed at 300°K. At 200°K the forward current is proportional to $\exp(qV/2.00kT)$ at small forward voltages and to $\exp(qV/1.00kT)$ at larger voltages. It is found that the experimental results at 200°K are consistent with the theoretical considerations, expressed by Eq. (1) and (2). At 400°K, we can only observe the straight line which is expressed by $\exp(qV/1.00kT)$ in the small forward bias region and the curved line resulting from the body resistance of Si material.

Since the experimental curve for the sample with $W=0$ at each temperature in Fig. 1 can be approximated by two straight lines, we can get the two kinds of forward saturation current I_s in the temperature range between 200°K and 500°K, extrapolating these straight lines to $V=0$, and obtain the results illustrated in Fig. 2. From Fig. 2 we obtain an activation energy of about 0.6 eV for recombination-generation current and the activation energy of 1.2 eV for the diffusion current. This temperature dependence is to be expected from equations (1) and (2), and hence would verify the assumptions made in the calculations, that is, that the recombination centers lie near the center of the energy gap. The reverse saturation current has also been measured and we have obtained the activation energy which is in good agreement with the value from the forward saturation current as shown in Fig. 2.

The author is deeply indebted to Professor J. Yamaguchi and Mr. Y. Hamakawa of Osaka University for their encouragement and interest in this work.

Viscous Forces and Brownian Motion

By Naokata Takeyama

Institute of Biophysics,
Kyushu University, Fukuoka

(Received February 24, 1961)

This note describes an attempt to investigate the interrelation between the molecular dynamical theory[1)] of irreversible processes and the thermodynamical ensemble theory[2)].

The common starting point of any theory can be found in the Liouville's equation

$$i\,\partial f/\partial t=Lf\,, \tag{1}$$

where L is the Liouville's operator which is defined by

$$Lf=\begin{cases} i[H,f] & \text{(for the phase space distribution function } f\text{)}\,, \\ \hbar^{-1}[H,f] & \text{(for the density matrix } f\text{)}\,, \end{cases}$$

and H is the Hamiltonian function or operator of the total system.

Our interest is focused on the temporal behavior of a Brownian particle, whose Hamiltonian is $H_0=\vec{\boldsymbol{p}}^2/2M+U(\vec{q})$, interacting with and immersed in the eqilibrium liquid system of its Hamiltonian H_l and statistical temperature $kT\equiv\beta^{-1}$. The interaction between the systems is called V. The Hamiltonian of the total system is given by

$$H=H_0+H_l+V\,, \tag{2·a}$$

and the corresponding Liouville's operator becomes

$$L=L_0+L_l+L'\,. \tag{2·b}$$

The initial f is adopted in the form of

$$\bar{f}=Z^{-1}\exp\{-\beta(H-\vec{\boldsymbol{p}}\langle\vec{\boldsymbol{v}}\rangle+M\langle\vec{\boldsymbol{v}}\rangle^2/2)\} \tag{3}$$

with

$$Z=\mathrm{Trace}\,[\exp\{-\beta(H-\vec{\boldsymbol{p}}\langle\vec{\boldsymbol{v}}\rangle+M\langle\vec{\boldsymbol{v}}\rangle^2/2)\}]\,,$$

where $\langle\vec{\boldsymbol{v}}\rangle$ is a macroscopic and averaged velocity of a Brownian particle obtained by

$$\langle\vec{\boldsymbol{v}}\rangle=\langle\vec{\boldsymbol{p}}\rangle/M=\mathrm{Trace}\,(\vec{\boldsymbol{p}}/Mf)\,.$$

It can be easily seen that $\bar{f}$ is a solution of the equation

$$M\langle\vec{\boldsymbol{v}}\rangle f=\vec{\boldsymbol{p}}\,f+M\beta^{-1}\,\partial f/\partial\vec{\boldsymbol{p}} \tag{4·a}$$

for the classical case; quite similarly

$$M\langle\vec{\boldsymbol{v}}\rangle f=f\int_0^\beta d\lambda/\beta\,\vec{\boldsymbol{p}}(-i\hbar\lambda)+M\beta^{-1}\,\partial f/\partial\vec{\boldsymbol{p}} \tag{4·b}$$

for the quantum case, where $\vec{\boldsymbol{p}}(s)$ stands for

$$\vec{\boldsymbol{p}}(s)=\exp(isL)\vec{\boldsymbol{p}}\,,$$

and the quantum mechanical differential operator with respect to $\vec{\boldsymbol{p}}$ is defined by

$$\partial f/\partial\vec{\boldsymbol{p}}=(i\hbar)^{-1}[\vec{q},f]\,.$$

After performing formally differentiation of Eqs. (4·a) and (4·b) with respect to $\vec{\boldsymbol{p}}$, we obtain

$$M\langle\vec{\boldsymbol{v}}\rangle\,\partial f/\partial\vec{\boldsymbol{p}}=\frac{\partial}{\partial\vec{\boldsymbol{p}}}(\vec{\boldsymbol{p}}f+M\beta^{-1}\,\partial f/\partial\vec{\boldsymbol{p}})\,, \tag{5·a}$$

and

$$M\langle\vec{\boldsymbol{v}}\rangle\,\partial f/\partial\vec{\boldsymbol{p}}=\frac{\partial}{\partial\vec{\boldsymbol{p}}}\left\{f\int_0^\beta d\lambda/\beta\,\vec{\boldsymbol{p}}(-i\hbar\lambda)+M\beta^{-1}\,\partial f/\partial\vec{\boldsymbol{p}}\right\}. \tag{5·b}$$

By dividing $f(t)$ into $f(t)=\bar{f}+f'(t)$, Eq. (1) reduces to

$$\partial f'/\partial t-i^{-1}Lf'=i^{-1}L\bar{f}\,. \tag{6}$$

The steady solution of Eq. (6) for f', to the first order of $\langle\vec{\boldsymbol{v}}\rangle$, can be written as

$$\begin{aligned} f_{st}'=+\lim_{t\to\infty}f_e\int_0^t dt'\int_0^\beta d\lambda \\ \times\exp\{-i(t-t')L\}\dot{\vec{\boldsymbol{p}}}(-i\hbar\lambda)\langle\vec{\boldsymbol{v}}\rangle\,, \end{aligned} \tag{7·a}$$

or in another equivalent from

$$\begin{aligned} f_{st}'=-\lim_{\sigma\to 0}f_e\int_0^\infty dt\int_0^\beta d\lambda \\ \times\exp(-\sigma t)\exp(-itL)\dot{\vec{\boldsymbol{p}}}(-i\hbar\lambda)\langle\vec{\boldsymbol{v}}\rangle\,, \end{aligned} \tag{7·b}$$

where $\dot{\vec{\boldsymbol{p}}}(s)=-i^{-1}L\vec{\boldsymbol{p}}(s)$, and $f_e=Z_e{}^{-1}\exp(-\beta H)$.

The viscous force in the steady state is obtained by

$$\begin{aligned}\langle\dot{\vec{p}}\rangle_{st}&=\mathrm{Trace}\,(\dot{\vec{p}}\,f_{st}{}')\\&=-\int_0^\infty dt\int_0^\beta d\lambda\langle\dot{\vec{p}}(-i\hbar\lambda)\dot{\vec{p}}(t)\rangle_e\langle\vec{v}\rangle\\&\equiv-\zeta\langle\vec{v}\rangle\,.\end{aligned}\tag{8}$$

Here the friction coefficient ζ has been defined by

$$\zeta=\int_0^\infty dt\int_0^\beta d\lambda\langle\dot{\vec{p}}(-i\hbar\lambda)\dot{\vec{p}}(t)\rangle_e$$

for the quantum system, and it becomes

$$\zeta=\beta\int_0^\infty dt\langle\{\dot{\vec{p}},\dot{\vec{p}}(t)\}\rangle_e$$

for the classical system, where $\langle A\rangle_e$ means to take an average of A referring to f_e.

Eq. (1) for $f_0\equiv\mathrm{Trace}_{(l)}f$, where $\mathrm{Trace}_{(l)}$ denotes to take the trace with respect to the equilibrium liquid system only, is written as

$$\begin{aligned}&\partial f_0/\partial t+i^{-1}L_0f_0\\&\quad=+i^{-1}\,\mathrm{Trace}_{(l)}L'f=-(\partial f_0/\partial t)_{\mathrm{drift}}\,,\end{aligned}\tag{9}$$

where the right hand side term of the above expresses a drift term for f_0 owing to the effect of the interaction with the liquid system, which can be written as $(\partial f_0/\partial t)_{\mathrm{drift}}=-\mathrm{Trace}_{(l)}(i\hbar)^{-1}[V,f]$.

Writing formally $(\partial f_0/\partial t)_{\mathrm{drift}}$ as $(\partial f_0/\partial\vec{p})\langle\dot{\vec{p}}\rangle_{\mathrm{drift}}$, the drift force $\langle\dot{\vec{p}}\rangle_{\mathrm{drift}}$ can be approximately replaced by the steady viscous force $\langle\dot{\vec{p}}\rangle_{st}$, Eq. (8). Thus, we obtain

$$\partial f_0/\partial t-i^{-1}L_0f_0\cong-\partial f_0/\partial\vec{p}\,\langle\dot{\vec{p}}\rangle_{st}=\langle\vec{v}\rangle\,\partial f_0/\partial\vec{p}\,\zeta\,.\tag{10}$$

The wanted Kramers-Chandrasekhar's equation[3], which governs the Brownian motion, can be derived from Eqs. (5) and (10) as the following:

$$\begin{aligned}&\partial f_0/\partial t-i^{-1}L_0f_0\\&\quad=\frac{\partial}{\partial\vec{p}}\,[\zeta(M^{-1}\vec{p}\,f_0+\beta^{-1}\,\partial f_0/\partial\vec{p})]\end{aligned}\tag{11·a}$$

for the classical system, and

$$\begin{aligned}&\partial f_0/\partial t-i^{-1}L_0f_0\\&=\frac{\partial}{\partial\vec{p}}\left[\zeta\left\{f_0M^{-1}\int_0^\beta d\lambda/\beta\,\vec{p}(-i\hbar\lambda)+\beta^{-1}\,\partial f_0/\partial\vec{p}\right\}\right]\end{aligned}\tag{11·b}$$

for the quantum system.

It has been clarified that the essential feature in the above treatment is concentrated in the replacement $(\partial f_0/\partial t)_{\mathrm{drift}}\rightarrow(\partial f_0/\partial\vec{p})\langle\dot{\vec{p}}\rangle_{st}$, and in the application of the steady viscous force derived from the thermodynamical ensemble theory, and that the correlative effect of the interaction with the "external" system on the system under consideration is brought in the friction coefficient.

Fine Structures of Photoprotons from Si^{28}

By Katsufusa SHODA, Keisuke KOBAYASHI,
Shoichi SIINA, Ken ABE and
Motoharu KIMURA
Department of Physics, Tohoku University, Sendai, Japan

(Received February 20, 1961)

We investigated photoprotons from Si^{28} using 24 MeV bremsstrahlung. The target was the powder of natural Si (9.38 mg/cm²) depositted on a Au foil (0.19 mg/cm²). The energy loss of protons by the half target thickness is about 30% for 3 MeV and about 10% for 6 MeV protons.

The Ilford G-special 600 μ emulsions were scanned by a Tiyoda binocular microscope. The number of detected proton tracks was 4366 in the

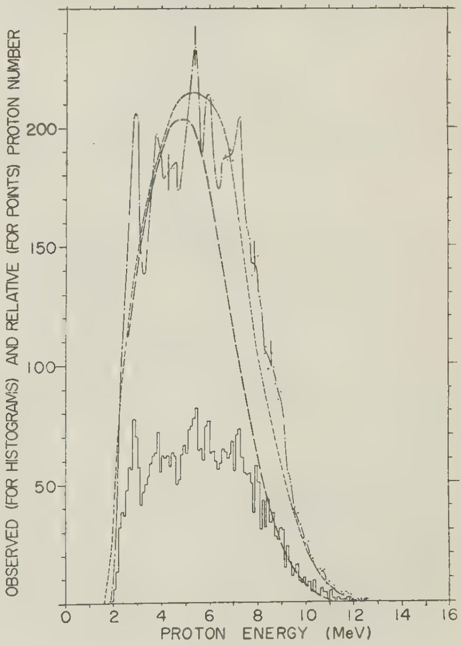

Fig. 1. The energy spectrum of photoprotons from Si. The solid line is a smoothed curve. The broken line and the dotted one are calculated curves of the statistical model with the level densities $\omega=C\exp[2\sqrt{0.45E}\,]\ \mathrm{MeV}^{-1}$ and $\omega=C\exp[E/2.8]\ \mathrm{MeV}^{-1}$, respectively.

scanned area of 1.6 cm^2.

The observed histogram is shown in Fig. 1 along with the smoothed curve using the Valoshek method$^{1)}$. Fig. 1 also includes the calculated energy spectra deduced by the statistical model with two types of level density$^{2)-4)}$. Apart from the fine structures, the calculated curve with the level density ω given by

$$\omega = C \exp[E/2.8] \text{ MeV}^{-1}$$

is in good agreement with the data.

Many fine structures were observed. They may be explained by a resonating group model$^{5)}$, which yields similar fine structures.

It may be interesting to compare the energy distribution with the cross section calculated from inverse reaction $Al^{27}(p, \gamma)$ by detailed balance. This comparison is shown in Fig. 2. For $Al^{27}(p, \gamma)^{6)-8)}$, the energy of γ_1, leading to the first excited state of Si^{28}, was used. γ_0, leading to the ground state of Si^{28} were weak by about a factor of ten, and were not separated from $\gamma_1$$^{8)}$.

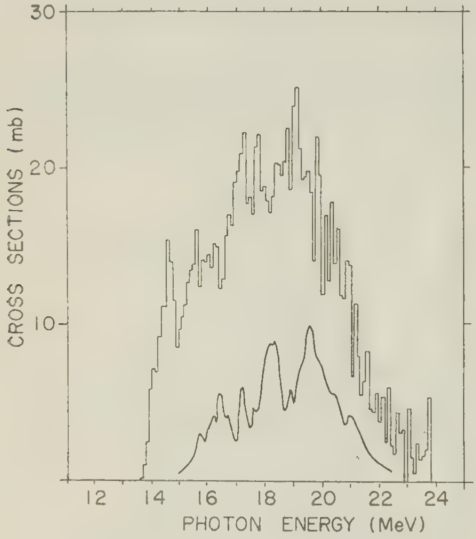

Fig. 2. The comparison of cross section of $Si^{28}(\gamma, p)Al^{27}$ (histogram) and that from $Al^{27}(p, \gamma)Si^{28}$ (solid line).

If we assume that all protons in $Si^{28}(\gamma, p)$ are emitted leaving Al^{27} in the ground state, we get the cross section of $Si^{28}(\gamma, p)$ as shown in Fig. 2 which is obtained by correcting Fig. 1 for bremsstrahlung spectrum.

The shapes of cross sections coincide fairly well, though their energy scales are not the same. This may be reasonable, because they are not exact inverse reactions.

We gratefully acknowledge helpful discussion with Dr. K. Okamoto. Authors are also indebted to Mr. Ishizuka for useful help in calculating the data.

Observation of Lattice Defects in Fission Fragment-irradiated Graphite*

By Kazuhiko IZUI and F. Eiichi FUJITA**

Japan Atomic Energy Research Institute
Tokai-mura, Ibaragi-ken, Japan

(Received February 27, 1961)

It is generally known that solid materials irradiated with high energy particles undergo structural damages consisting of not only single defects, but also of considerably large size defects, which were first predicted by the theory of temperature spikes$^{1),2)}$ and supported by a few experiments$^{3)}$. Evidences in electron microscopy for such damage effect are relatively few except the observations of fission fragment tracks in mica$^{4)}$ and uranium oxide etc.$^{5)}$ and of small dots and loops formed in neutron irradiated copper$^{6)}$ and graphite$^{7)}$. The present note reports some electron microscopic observations of large defects in graphite induced by fission fragment irradiation.

Refined powder of natural graphite, mixed with uranium oxide powder in the ratio of 10/1, was exposed to thermal neutrons in the reactor to the total doses of the order of 10^{16} n/cm^2, and observed with Hitachi electron microscopes, HU-10 and HS-5. As shown in Photo. 1, tracks of fission fragments from U^{235} were sometimes observed as straight lines about 100 Å wide accompanied by some small dots. By tilting the specimen, their contrasts turn from black to white as that of the matrix changes from white to black. This indicates that they are essentially the diffraction contrasts caused by variations in the Bragg conditions in the crystal and that these narrow linear regions have a crystallographic nature or orientation slightly different from the matrix, possibly exhibiting the thermal spike effect of fission fragments passing through the crystal. A concentric fringe pattern seen on the left hand side of the picture seems to be a large damaged region, where the lattice is buckled, presumably in such a manner as schematically shown in Fig. 1, due to the spike effect producing a number of atomic displacements. Photo. 2 shows a highly damaged region representing many concentric fringe patterns and their complex couplings. In view of the fact that these concentric fringe patterns have a close connection with moiré fringes, their image contrasts seem to be essentially the phase contrast. The dynamical calculation for their image contrast formation based on a model like one in Fig. 1, which was done by H. Hashimoto[8] will give a detailed analysis of the structure of the damaged regions. Dislocation lines became to be rugged and changed their contrasts after the irradiation, as shown in Photo. 3, probably partly due to the spike effect and partly due to absorbing many interstitial atoms produced by the irradiation.

A Note on The Electron Diffusion and The Wall Relaxation in Ferrites

By Hisashi SEKIZAWA

Department of Physics, Faculty of Science, University of Tokyo, Tokyo

(Received February 24, 1961)

A Richter type peak of magnetic loss is known to occur in ferrites[1] and in ferromagnetic garnet[2]. Snoek[3] attributed such phenomena to the diffusion of the electrons between ferrous and ferric ions in 16d sites in the ferrite. In discussions of that loss, it is mentioned[4],[5] that there is a close similarity between it and the loss due to the diffusion of carbon atoms in iron, but the remarkable difference in their situations seems to be unnoticed. And there is a confusion with regard to the interpretation of the relaxation times obtained from the loss peaks in ferrites[6]. This note wishes to clarify the relation between the motion of the electrons and the wall relaxation, and to establish the distinction between the relaxation times of them.

As is well known, the motion of a 180° domain wall can well be expressed by the following simple equation[7],

$$m\ddot{x}+\beta\dot{x}+k_w x=2\mathrm{M_s H}\ ,$$

where x is the displacement of the wall, m the effective mass which can be neglected because of its smallness, k_w the coefficient of force restoring the wall to its equilibrium position, and β the coefficient giving viscous damping. On putting $\mathrm{H}=\mathrm{H_0}\exp(j\omega t)$ and $x=x_0\exp(j\omega t)$, we get for the μ due to the wall[4]

$$\mu_w=\mu_w'-j\mu_w''\propto[1/(1+j\omega\beta/k)]\ .$$

Including the part of μ due to domain rotation μ_r, $\tan\delta$ of $\mu=\mu_r+\mu_w$ has a maximum when

$$\omega_w=1/\tau_w=\sqrt{(\mu_{r0}+\mu_{w0})/\mu_{r0}}\cdot k_w/\beta\ .$$

Clogston[8] made a calculation on the velocity of steadily moving wall based on a semi-microscopic model of the electron diffusion similar to the one proposed by Néel[9]. He assumed that there are N electrons which are migrating among ferric ions in 16d sites through jumps with a relaxation time τ_e and that each one of them accompanies a uniaxial anisotropy energy $w\cos^2\theta$ along certain crystallographical direction specified to each site. His result can be expressed in the present notation

$$\beta\approx\tau_e\sqrt{-K/12A}\,(N/kT)w^2\ .$$

Néel[9] made a theory on diffusion after-effect and calculated the pressure on the wall. His results can be expressed in the present notation

$$k_w\propto\frac{(\omega\tau_e)^2}{1+(\omega\tau_e)^2}\ ,\qquad \mu_w''\propto\frac{\omega\tau_e}{1+(w\tau_e)^2}\ ,$$

The calculation has been made on a wall moving as $x=x_0\sin\omega t$, considering the influence of the potential trough dug by the wall as a small perturbation. But it is the change with ω of x_0 that we are interested in, when discussing the wall relaxation in ferrites. Only in the cases in which the restoring force due to the other mechanisms than that due to the trough dug by the wall is dominant, and also $\tan\delta\ll 1$ even at $\omega=\omega_e=1/\tau_e$, then the calculation can be applied and the activation type loss peak will be observed at ω_e. In the region $\omega\gg\omega_e$, the trough is quenched and does not follow the wall any more. This is the case of iron containing small amount of carbon, discussed by Néel[9] and observed by Tomono[10]. On the other hand, in ferrous ferrites the trough follows the wall though lagging a little. But as β is so large that the condition $\beta\dot{x}\geq kx$ is realized on increasing ω, and the wall motion damps out[4]. This occurs at $\omega=\omega_w$ far below ω_e on the lower side slope of the peak of $\omega\tau_e/\{1+(\omega\tau_e)^2\}$. Note that as

$$\tau_w=\sqrt{\frac{\mu_{r0}}{\mu_{r0}+\mu_{w0}}}\cdot\frac{\beta}{k_w}$$

$$\approx\sqrt{\frac{\mu_{r0}}{\mu_{r0}+\mu_{w0}}}\cdot\frac{1}{k_w}\sqrt{\frac{-K}{12A}}\left(\frac{N}{kT}\right)\tau_e=C\tau_e\ ,$$

the activation energy E obtained by fitting it to $\tau_w=\tau_{w\infty}\exp(E/kT)$ coincides approximately with that of τ_e. But $\tau_{w\infty}=C\tau_{e\infty}$ has a factor C which can not be deduced merely from the elementary process of diffusion but is related with the other quantities such as k_w. So, τ_w and τ_e are two entirely different quantities only having the same activation energy, and must be strictly distinguished to each other.

The disaccommodation of the permeability observed in various ferrites would be closely related with the diffusion of electrons or ions[11]. But the relaxation time of disaccommodation is τ_e and not τ_w. Since $\tau_w\gg\tau_e$ if they belong to the same origin, the disaccommodation observed at room temperature and the loss peak at lower temperatures can not have the same origin. Only the peaks appearing at higher temperatures such as observed by Krupička[12] can have a connection with the disaccommodation at room temperature. Because $\tau_{e\infty}$ should be related with the lattice vibration and is not so sensitive to the process occurring, it seems to be of the order of 10^{-12}—10^{-14} sec. Then, such processes mentioned above must have an activation energy of the order of 1 eV no matter what are the causes of them, electrons or ions.

Weak Field Behaviour of the $\varDelta E$ Effect in Ferromagnetic Cubic Solid Solution Alloys

By Mikio YAMAMOTO and Satoshi TANIGUCHI

The Research Institute for Iron, Steel and Other Metals, Tôhoku University, Sendai

(Received March 2, 1961)

The experimentally known $\varDelta E$ effect of polycrystalline ferromagnets may be classified into three types[1]. The third-type $\varDelta E$ effect, in which Young's modulus, E, shows a maximum and then a minimum, is observed with cobalt and h c.p. Ni-Co alloys[2] and it may be interpreted as associated with the process of reversible rotation of magnetization vectors from the [0001] direction of easy magnetization towards the direction of an applied magnetic field. The first type, in which E increases monotonously with magnetization, and the second-type, in which E decreases at first and then increases to a value larger than that in unmagnetized state, are observed with cubic metals and alloys[1],[2]. Particularly, the second-type $\varDelta E$ effect is especially conspicuous in f.c.c. Ni-Co alloys. The minimum (negative) value for 50% Co-Ni alloy attains to 5% which is of the same order of magnitude as the saturation value[2].

It has already been confirmed experimentally[1] that the decrease of E at weak magnetic fields in the second-type $\varDelta E$ effect is associated with the displacements of non-180° domain walls. The second-type $\varDelta E$ effect may be resulted from the fact that the occurrence of non-180° wall displacements is difficult in unmagnetized state, and, as the specimen is magnetized, it once becomes easier but again becomes difficult. Thus, in the case where the non-180° wall displacements are extremely easy to occur, the negative minimum of the $\varDelta E$ effect may appear in very weak fields so that it may not be observed. This may be regarded as the first-type $\varDelta E$ effect.

Let us consider, for simplicity, the $\varDelta E$ effect due to the displacements of (100) 90° walls, which is expressed as

$$(\varDelta E)_{SH}/E_S \fallingdotseq (E_S-E_H)/E_S \fallingdotseq E_S(\partial\varepsilon_m/\partial\sigma)_H$$
$$=(3/2)A\lambda_e E_S/W''(U)\,, \qquad (1)$$

where E_H and E_S are the values of E under magnetic field, H, and in magnetically saturated state, respectively, ε_m is the magnetostrictive strain, σ is the stress, A is a numerical factor, λ_e is the saturation magnetostriction along the direction of easy magnetization, and $W(U)$ is the wall energy at the position displaced by U. $W''(U)=d^2W/dU^2$, and it is assumed that $E_S-E_H \ll E_S$. It can be shown, from Eq. (1), the second-type $\varDelta E$ effect occurs when internal stresses or inclusions distribute at random in the specimen, but the second-type $\varDelta E$ effect arising from such origins may change according to specimens or their states even for the same material, so that it can not explain remarkable extreme values of the $\varDelta E$ effect and their systematic composition dependence in f.c.c. Ni-Co alloys[2].

Now, when domain walls are stabilized by the induced uniaxial ferromagnetic anisotropy energy and this energy of stabilization, W_S, predominates over energies of other origins, we can put

$$W''(U)=W_S''(U/d_0)\,, \qquad (2)$$

where d_0 is the thickness of the domain wall concerned. Since the form of $W_S(U)$ curve does not strongly depend on the type of crystal lattice and on the kind of domain walls, we consider, for simplicity, (100) 90° wall in an *ideal simple cubic* alloy with the <100> direction of easy magnetization. Then, its stabilization energy is given by[3]

$$W_S=-K_u U \coth(U/d_0)\,, \qquad (3)$$

and the $\varDelta E$ effect due to the displacement of this domain wall is expressed by

$$(\varDelta E)_{SH}/E_S=(3/2)(d_0/2K_u)A\lambda_e^2 E_S/\mathrm{cosech}^2(U/d_0)$$
$$\times\{1-(U/d_0)\coth(U/d_0)\}\,, \qquad (4)$$

where K_u is the uniaxial magnetic anisotropy constant, which depends on the alloy composition, n, approximately as

$$K_u=16K_0 n^2(1-n^2)\,, \qquad K_0=\text{constant}\,. \qquad (5)$$

The behaviour of the $\varDelta E$ effect in weak magnetic fields as calculated from Eq. (4) shows a good agreement with the measured results on 50% Co-Ni alloy[2]. Also, the alloy composition dependence of the extreme value of the $\varDelta E$ effect as usually defined experimentally is expressed as

$$[(\varDelta E)_{H0}/E_0]_{\mathrm{ext}}=(\varDelta E)_{S0}/E_0-[(\varDelta E)_{SH}/E_S]_{\mathrm{ext}}$$
$$=[(\varDelta E)_{S0}/E_S]_{n=0.5}\{a-1/16n^2(1-n^2)\}\,, \quad (6)$$

where a is a numerical factor, and the composition dependence of the field where the extreme value of the $\varDelta E$ effect locates, H_{ext}, is given by

$$H_{\mathrm{ext}}=(K_0/I_S)/16n^2(1-n^2)\,, \quad (7)$$

where I_S is the saturation magnetization. Eqs. (6) and (7) are found to be in accordance with the measured results on f.c.c. Ni-Co alloys[2].

Thus, it can be concluded that the main cause of the second-type $\varDelta E$ effect is the stabilization of domain walls by the induced uniaxial ferromagnetic anisotropy. The $\varDelta E$ effect due to this origin may appear in all cubic solid solution alloys, but the occurrence of remarkable second-type $\varDelta E$ effect must satisfy several conditions. According to those conditions, the second-type $\varDelta E$ effect must be remarkable only in the composition range of 55~75% Co of b.c.c. Fe-Co alloys, it must be small in b.c.c. Fe-Al alloys, and remarkable second-type $\varDelta E$ effect can not be expected for f.c.c. Ni-Fe and Ni-Cu alloys. These expectations have already been ascertained by the observational results[1].

Remarks on the Electrical Properties of Alkali Antimonides

By Shunji IMAMURA

Technical Research Laboratories, Japan Broadcasting Corporation, Kinuta-machi, Setagaya-ku, Tokyo, Japan

(Received March 3, 1961)

This note presents the remarks on the complexity of the characteristics of rubidium antimonide and on the assignment of the acceptors in cesium antimonide.

When an evaporated antimony film is exposed to the alkali vapor, the resistivity varies in complicated ways. In the present work the high reaction temperature (about 250°C, the upper limit restricted by sublimation and dissociation of the specimen) and the thin film of antimony (about 200 Å) were employed, in order to diffuse the alkali atoms quickly. It was also necessary to increase the alkali vapor pressure at slow rate so as to overcome that of the specimen during formation process. The variation of the resistivity was continuously recorded. The other experimental details have been described in the previous paper[1]. The results are shown in Fig. 1. In the Cs-Sb system the compound corresponding to the fourth maximum was determined as Cs_3Sb by X-ray experiment.

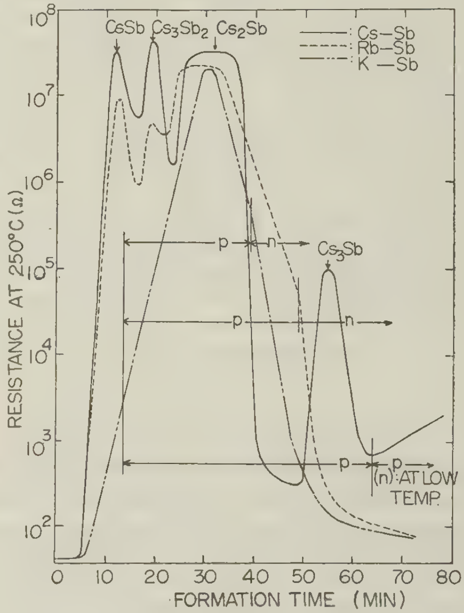

Fig. 1. Variation of the resistance of alkali antimonides. The sign of the predominant carriers at 250°C is denoted by n or by p. According to the X-ray work[5] the compounds Rb_3Sb and K_3Sb are formed just before the transition from p to n-type.

The compositions associated with the other maxima are identified as shown, by comparing with the data of Miyazawa *et al*[2] and Miyake[3]. The K-Sb system behaves in a different way from the Cs-Sb one, i.e., only one maximum exists, differing from the data of Suhrmann and Kangro[4], in which two maxima are shown. The behavior of the Na-Sb was entirely the same as that of the K-Sb. The above data suggest that the Cs-Sb system and the K-Sb (and Na-Sb) one are crystallized in different ways at each other through the formation process. The result for the Rb-Sb is interesting. It seems to indicate that the crystallization of the Rb-Sb proceeds in a similar manner to the Cs-Sb initially and to the K-Sb finally. This is not also inconsistent with the fact, recently found by our X-ray work[5], that Rb_3Sb is crystallized initially in a cubic lattice, which is the same as that of Cs_3Sb, and is transformed into a hexagonal one, which is the same as that of K_3Sb and Na_3Sb, by introducing a plenty of excess Rb atoms. From the present results it may be said that if the formation treatment of the Rb-Sb system is stopped before the transformation into a hexagonal lattice, the electrical and optical properties of the specimen are similar to those of the Cs-Sb system, and after the transformation they are simillar to those of the K-Sb (and Na-Sb). This is thought as a cause of the complexity reported in the work of several investigators[1),6),7)].

Jack and Whachtel[8)] have explained that the structure of Cs_3Sb is a disordered pseudo body-centered cubic lattice*, in which some of Cs and Sb atoms are randomly distributed. This structure makes possible to replace the Sb sites by excess Cs atoms to a certain extent. Moreover, this is describable as consisting of two interpenetrating diamond-type lattices, suggesting some of homopolar nature. Chemical analysis showed also the stoichiometric excess of cesium. In view of these facts, they have suggested that the Cs atom, which is less valent than Sb atom, positioned at Sb site is an acceptor. On the other hand, Sommer[6)] and Spicer[9)] have proposed that the vacancies of Cs atoms caused by evaporation of cesium are responsible for the acceptors. In the present experiment, the resistivity in the last stage increases gradually under an extremely high vapor pressure of cesium, which is estimated to be about 10^{-2} mm Hg, probably due to a compensation of acceptors by donors. Even in this stage, the thermo-electromotive force measurement shows p-type conduction at 250°C. This indicates that the Cs_3Sb containing excess Cs atoms is essentially a p-type semiconductor. Although the n-type conduction is observed when the cesium supply is ceased and the temperature is lowered to below about 120°C, it seems to be an apparent one due to a surface conduction caused by adsorbed Cs atoms. Consequently the author believes at present a propriety of Jack and Wachtel's model, although the other kind of acceptors may exist together with it.

---

* We have found that the desirable structure of the cubic Rb_3Sb is the same as that of the disordered one of Cs_3Sb[5)]. Hence, in an analogy the author supports the disordered one of Cs_3Sb, though Scheer and Zalm (Philips Res. Rep. **14** (1959) 143.) have proposed an ordered structure.

The Characteristics of the Discharges in the Crossed Electric and Magnetic Field

By Shigeru HAYAKAWA

Technical Research Department, Wireless Division, Matsushita Electrical Ind. Co., Ltd., Osaka, Japan

and Tokuo SUITA

Faculty of Engineering, Osaka University, Osaka, Japan

(Received March 6, 1961)

Various peculiar and interesting phenomena are observed in the case of gas discharge in crossed electric and magnetic field, however this report is mainly based on some of the experimental results having obtained along our projects on the prior stage of gas discharge in such fields.

The apparatus is shown in Fig. 1, which is similar to the Homopolar at Berkeley except for the difference that the inner electrode consists of the upper and the lower separate parts.

A uniform axial magnetic field is initially applied and an electric field introduced between cylindrical co-axial electrodes sets up the discharge to lead the formation of the so called rotating plasma round the symmetric axis. In case that voltage is introduced rapidly between electrodes, a rather long pre-

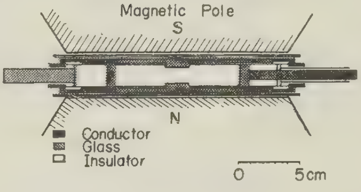

Fig. 1.

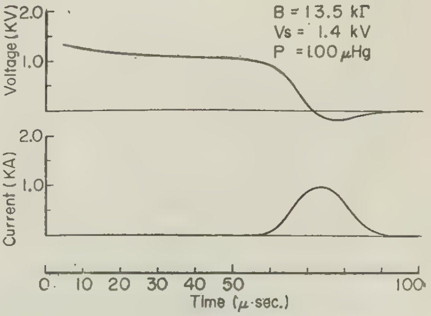

Fig. 2.

discharging period is detected before the discharge is set up. This delay time is closely related to the applied voltage, the magnetic field strength and the vacuum pressure of the system. The current-voltage characteristic for a particular discharge is shown in Fig. 2, with which the delay time of 55 μ. s. is associated.

How the applied voltage is related to the delay time under the constant magnetic field strength and the vacuum pressure is plotted as in Fig. 3.

In order to detect the space potential distribution in this pre-discharging period, double floating probes are inserted radially into the apparatus.

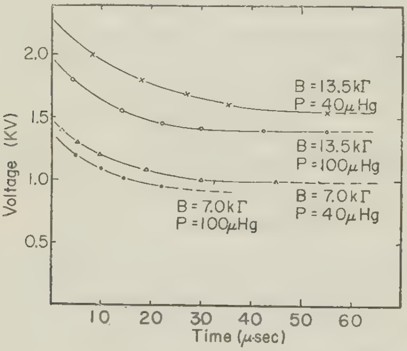

Fig. 3.

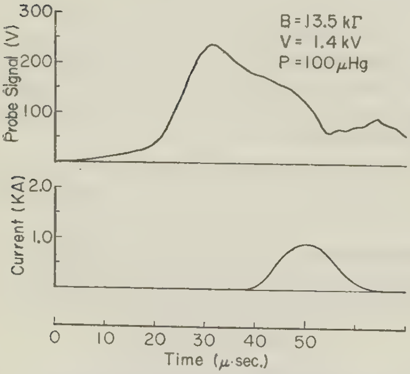

Fig. 4. Double probe signal and discharge current (probe position: 1-probe 3 mm and 2-probe 8 mm from cathode).

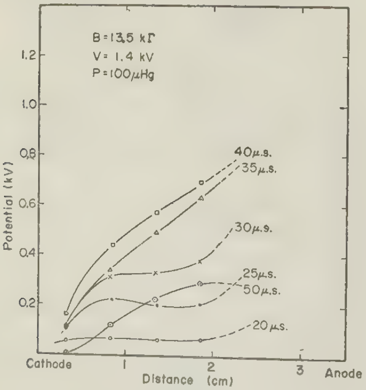

Fig. 5. Time Variation of the Potential Distribution (Discharge starts at 40 μs).

Figure 4 is an example of the detected out-put, in which the corresponding current characteristic is shown in order to make clear the discharge starting time.

By moving the double floating probes radially, the time-variation of the space potential difference between any two points is detected. Figure 5 shows the time variation of the space potential between electrodes after voltage is introduced.

It is to be assumed according to the experimental results that the space charge is accumulated between electrodes during the pre-discharging period, due to which the discharge is initiated. Therefore, if the other factors are kept constant, the delay time is dominantly related to the ion density due to the collision between molecules and electrons under the sudden application of the electric field, and Fig. 3 indicates that the delay time decreases considerably with respect to the increase in the ionization efficiency of electrons as the applied voltage is raised up.

Although we have mentioned only the effects of the applied voltage, the magnetic field strength and the vacuum pressure to the experimental results as stated above, dV/dt in the application of the voltage is so related to the delay time as is effective to the motion of electrons and therefore to the generation of the stable rotating plasma, and our projects are concentrated in this point. The experimental results on this subject matter will be reported soon in future.

The authors are grateful to S. Kisaka for his encouragement, to T. Sekiya and H. Hishida for their discussion, and to K. Wasa for his measurments.

The Electrical Properties of Zinc Telluride

By Hirosi TUBOTA, Hiromichi SUZUKI
and Kazuyoshi HIRAKAWA

General Education Department, Kyushu University, Fukuoka

(Received March 14, 1961)

Some reports have been published on the electrical properties of ZnTe in the form of evaporated thin films[1] or of polycrystalline specimens[2]. However, this compound in single crystals has been studied optically, especially on its photoconduction[3], transmission and reflection[4], but not on any purely electrical properties. We here report the information obtained about the single crystals prepared from the melt of stoichiometric composition and about those doped with indium and selenium[5].

Fig. 1 shows the electrical resistivities and the Hall coefficients. (The Hall coefficient of samples doped with In was not measurable.) The Hall coefficients of both stoichiometric and Se-doped specimens have positive signs. No reversal of the Hall coefficient is observed. We consider that the positive carriers contributing to the electrical conduction come presumably from the Zn vacancies, because the vapor pressure of Zn is much higher than that of Te, and then Zn may escape in the process of crystallization1),6). The energy gap ΔE of ZnTe, 2.12 eV, was determined for the specimen doped with In from the equation $\rho=\rho_0 \exp(\Delta E/2kT)$. This value is in good agreement with that determined from the optical data3),4).

Fig. 2 shows the Hall mobilities μ_H obtained from the Hall coefficients R_H and the electrical resistivities ρ by the use of the equation $\mu_H=(8/3\pi)\cdot(R_H/\rho)$. The temperature dependence of the Hall mobilities of ZnTe is given by $\mu_H \propto T^{-1.50}$ in the region in which the lattice scattering is predominant. This figure, 1.50, suggests that at higher temperatures the electrons are scattered mainly by the acoustical mode. Therefore, the bond in ZnTe crystal seems to be rather covalent, presumably in agreement with the fact that the difference in electronegativity between Zn- and Te-atoms is relatively small, as seen from Table I.

The authors wish to express their sincere thanks to Prof. T. Okada for his kind advice.

Internal Magnetic Field in Iron and Iron Alloys Measured by NMR

By Yoshitaka KÔI and Akira TSUJIMURA
Faculty of Engineering, Tokushima University
Tadamiki HIHARA and Toshimoto KUSHIDA
Faculty of Science, Hiroshima University

(Received March 5, 1961)

Nuclear magnetic resonance (NMR) experiments have been made in pure natural iron and iron alloys in order to measure the internal magnetic field, H_i.

The resonance frequency of Co^{59} in (Fe+1%Co) alloy is shown in Fig. 1 as a function of temperature along with newly extended measurement of Fe^{57} NMR frequency in pure iron. The values of the internal field corresponding to the resonance frequencies are shown as well. The resonance frequency extrapolated to 0°K by assuming $T^{3/2}$ law is 289.2 Mc/sec, corresponding to an internal field of 289.7 koe. This value is smaller by about 30 koe than the value deduced from specific-heat measurements at low temperatures[1)]. Here it is to be emphasized that the NMR measurement is by orders of magnitude more accurate. The H_i at Co nuclei in the alloy is larger in magnitude than that in pure cobalt metal by about 60∼70 koe[2),3)]. The possibility that Co atoms lose some of their 3d electrons when dissolved in iron[4)] would be responsible for this increase of H_i.

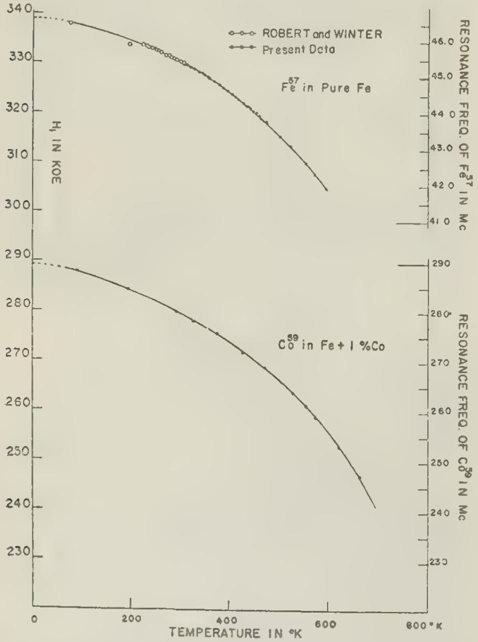

Fig. 1. Fe^{57} NMR frequency in pure iron and Co^{59} NMR frequency in (Fe+1%Co) alloy as a function of temperature.

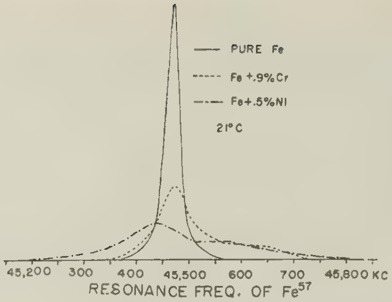

Fig. 2. The line shape of Fe^{57} NMR line (shown as the derivative of the resonance line) in iron alloy.

Since it is interesting to compare the temperature dependence of the resonance frequency of Co^{59} embedded in iron with that of Fe^{57} in pure iron[5),6)], the latter has been measured up to 320°C. Above this temperature the intensity of the line decreased below the noise level. It is to be noted that the resonance frequency of Co^{59} drops off with increasing temperature more rapidly than that of Fe^{57} in spite of the fact that the alloy has a higher Curie point than pure iron[7)].

The line shape of Fe^{57} resonance is strongly affected by alloying; preliminary results for alloying are presented in Fig. 2. Flat satellite lines are observed at higher-frequency wing of the main line for (Fe+0.9%Cr) and (Fe+0.5%Ni) alloys. These structures reflect the distribution of H_i caused by alloying more directly than the observed structures in Co^{59} resonance lines in cobalt alloys[8)], because Fe^{57} nucleus has no quadrupole moment.

Slow Decay of Reverse Current and Noise in Field Effect on Ge P^+-N Junction

By Hiroshi EDAGAWA, Yoshinori MORITA,
Syun-ichi MAEKAWA
Kobe Kogyo Corp. Kobe
and Yoshio INUISHI
College of Engineering, Osaka University

(Received March 6, 1961)

Slow decay measurement of the reverse current increment ΔI_r and the mean square short circuit noise current increment $<\Delta i^2>$ due to D.C. surface field effect[1,2] were made simulteneously on Ge p^+-n junctions. Nickel plates were attached to the p^+-n junction specimen surfaces through thin mica spacer as field effect electrode as stated in the previous paper[2]. The glass tubes containing the specimen were evacuated at about 10^{-6} mm Hg for one day and sealed[2]. Fig. 1 (a), (b) are the decay characteristics of the reverse current increment ΔI_r add the noise current increment $<\Delta i^2>$ after the D.C. surface field application at $t=0$ for various temperature. The reverse bias voltage V_c on junction and applied surface field voltage V_F were 50 volt and ±360 volt respectively. By A. U. MacRae and H. Levinstein[1], the field effect decay of the $1/f$ noise in Ge single crystal was already reported. The authors have found that the decay characteristics of ΔI_r and $<\Delta i^2>$ are different depending on the type of surface layer, namely inversion or accumulation layer on high resistivity n-side. As well known, inversion or accumulation is formed on high resistivity n-side surface by negative or positive voltage respectively on the field effect electrode, while field effect on heavily-doped p-side was small[2]. In Fig. 1 (a), (b) the increment ΔI_r and $<\Delta i^2>$ at $t=0.5$ minute after the application of the field voltage were taken to be 100%. The $<\Delta i^2>$ decay associated with inversion layer on n-side follows a log t decay curve at various temperature. On the other hand, $<\Delta i^2>$ decay associated with accumulation on n-side and small inversion layer on p-side deviates from log t decay at larger t. The ΔI_r decay seems to be described by log t curve approximately. The decay time constants for ΔI_r and $<\Delta i^2>$ increase re-

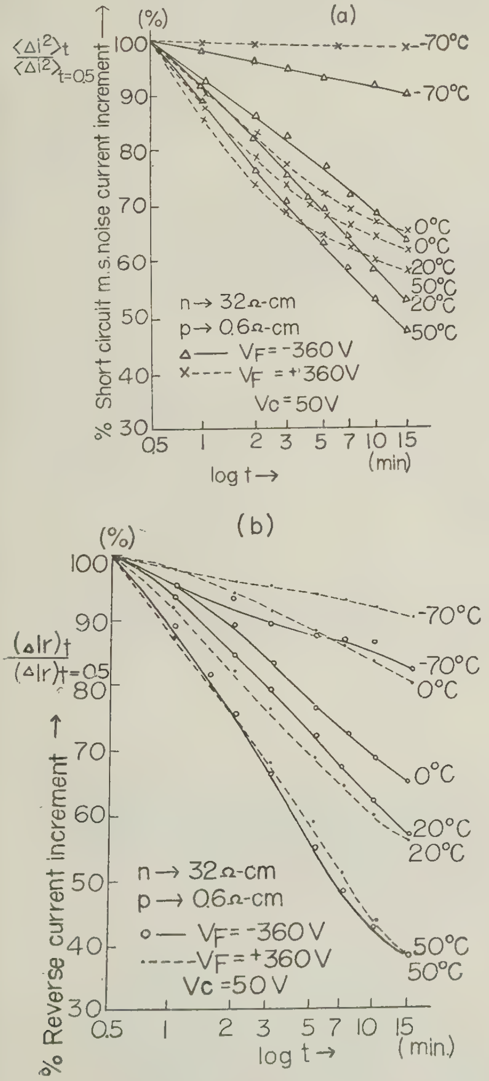

Fig. 1.

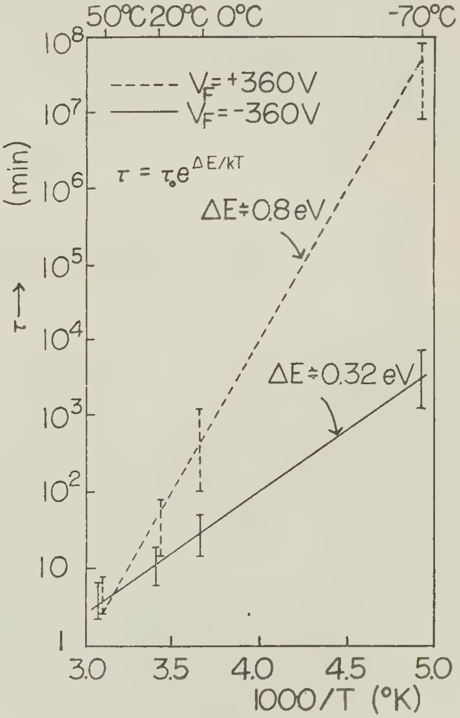

Fig. 2.

markably at lower temperature as seen in Fig. 1 (a), (b) which may be closely related to the relaxation time of carrier exchange with slow states. The time τ at which the increment ΔI_r reduces to a half of the initial value $t=0.5$ minute were plotted as a function of $1/T$ in Fig. 2. The decay time constants associated with accumulation layer on n-side and small inversion layer on p-side was larger than that with inversion layer on n-side.

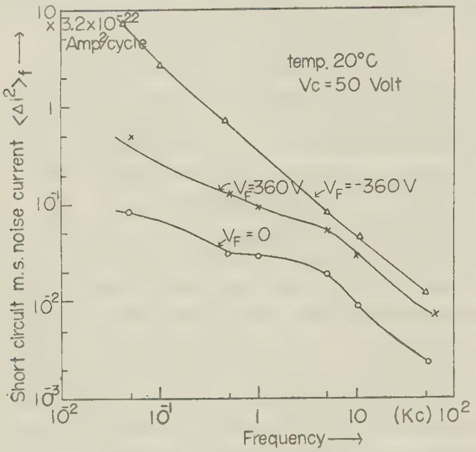

Fig. 3.

The frequency spectrum of the noise contains $1/f$ noise component, especially in case the of inversion layer on n-side surface as shown in Fig. 3.

The ratio $<\Delta i^2>/\Delta I_r$ increases with decreasing temperature below room temperature as was reported by MacRae et al.[1].

Elementary Processes Related to the Catalytic Action of μ^- for the p-d Fusion Reaction

By Yukio MIZUNO

Department of Physics, University of Tokyo

(Received February 4, 1961)

In this paper the following four problems are studied theoretically.
a) The solution of the three-body problems associated with one meson and two hydrogen nuclei.
b) The number and type of bound states belonging to the mesonic hydrogen molecular ions.
c) The determination of the dominant mechanism of molecular ion formation.
d) The relation of the process, $(p\mu d)_s \longrightarrow \mathrm{He}^3+\gamma$, to the so-called mirror reaction, $n+d \longrightarrow \mathrm{H}^3+\gamma$.
At the end of the paper, it is shown that the theory is in a good quantitative agreement with the experiment for the nuclear as well as the molecular processes.

§ 1. Introduction

Alvarez et al.[1], in observing high energy negative mesons in a normal-hydrogen bubble chamber, discovered that some of these mesons, after having once come to rest, began to move again with the high energy of 5.3 MeV. Their discovery was followed by active investigations in this and related phenomena; theoretically by Hayashi et al.[2], Zel'dovitch et al.[3], Jackson[4], Skyrme[5], and others, and experimentally by Ashmore et al.[6] and Alvarez et al.[1]. This explanation for the present phenomenon is illustrated in a slightly simplified form in Fig. 1, where the control processes are shown by dotted arrows.

In this paper, we present a theoretical study of each of those elementary processes appearing in Fig. 1. The main problems, in which we have been interested, are as follows.

(a) The solution of the three-body problems associated with one meson and two hydrogen nuclei.

(b) The number and type of bound states belonging to the mesonic hydrogen molecular ions.

(c) The determination of the dominant mecha-

$$\begin{tikzcd}
 & \text{decay} & \text{decay} & \text{decay} & \\
\mu\,(\text{stopped}) \arrow[r] & (p\mu)_{1s} \arrow[u, dashed, "\lambda_0"] \arrow[r, "c\lambda_{\mathrm{ex}}"'] \arrow[d, dashed, "\lambda_{m1}"] & (d\mu)_{1s} \arrow[u, dashed, "\lambda_0"] \arrow[r, "\lambda_{m2}"'] & (p\mu d) \arrow[u, dashed, "\lambda_0"] \arrow[r, "\lambda_\mu"'] \arrow[d, dashed, "\lambda\gamma"] & \mathrm{He}^3+\mu\,(5.3\,\mathrm{MeV}) \\
 & (p\mu p) & & \mathrm{He}^3+\gamma &
\end{tikzcd}$$

Fig. 1. Main mechanism of the reaction, $\mu\,(\text{stopped}) \longrightarrow \mu\,(5.3\,\mathrm{MeV})$, in a liquid hydrogen with deuteron impurities of very low concentration c. First, the μ^- in question is trapped by a proton in liquid hydrogen, and then forms a very small neutral atom in the ground state, $(p\mu)_{1s}$, whose radius is about 10^{-11} cm. This atom wanders in the liquid hydrogen with thermal velocity (20°K), like a neutron. Next, when this atom collides with a deuteron impurity, the μ meson transfers from the proton to the deuteron to form a neutral μ mesonic deuteron atom, $(d\mu)_{1s}$, stabler than $(p\mu)_{1s}$ by 135 eV. This newly formed $(d\mu)_{1s}$ is ejected with the energy of 45 eV, but rapidly comes down to the thermal velocity by repeating elastic collisions with the nuclei in liquid hydrogen. Then, this atom captures a proton and forms a very small molecular ion, $(p\mu d)$. In some these molecules, finally, the nuclear fusion reaction between the proton and the deuteron, $p+d \longrightarrow \mathrm{He}^3+5.5\,\mathrm{MeV}$, occurs of which 5.3 MeV is given to the μ^- and 0.2 MeV to the created He³ nucleus. This process can be repeated. The dotted lines in the above figure show the main hindrance processes against the reaction in question. "Decay" means the natural decay of the μ meson, $\mu \longrightarrow e+2\nu$, whose decay constant λ_0 is $4.5\times10^5\ \mathrm{sec}^{-1}$.

nism of molecular ion formation.

(d) The relation of the process, $(p\mu d) \longrightarrow \mathrm{He}^3+\gamma$, to the so-called mirror reaction, $n+d \longrightarrow \mathrm{H}^3+\gamma$.

The first problem is discussed in § 2, by adopting the charge transfer process as an example. The second and third problems are treated in § 3 and § 4, respectively*. The last problem is studied in § 5, where the reader will find a good quantitative agreement between theory and experiment for not only the molecular but also the nuclear process. To avoid duplication of the calculation by Cohen et al.⁸⁾, of which the details have recently been published, we do not treat the problems (b) and (c) quantitatively on the basis of an approximation similar to that in § 2. A numerical value found by Cohen et al. is used in § 5 to make quantitative comparison between theory and experiment. Except for the last problem (d) and a few problems related to the $(d\mu d)$ molecule, there is no marked disagreement between Cohen et al.'s conclusion and ours.

§ 2. The Charge Transfer: $d+(p\mu)_{1s} \longrightarrow p+(d\mu)_{1s}$.

We here attempt a theoretical evaluation of the cross-section for the above process. The incident energy may be thought of as less than the zero-point energy of the proton bound in the ordinary hydrogen molecule, ($\sim\frac{1}{4}$ eV). The simplest treatment will be to apply the first order Born approximation. However, its validity for the present slow collision is somewhat doubtful, because the interaction between d and $(p\mu)$ or p and $(d\mu)$ is strong enough for the $(p\mu d)$ system to have a few bound states, though not many. This interaction causes not only the deviation of the interatomic motion from the plane wave but also the distortion of $(p\mu)_{1s}$ and $(d\mu)_{1s}$ themselves. In our calculation, we intend to take into account both effects at the same time. A feature of the present system is that the mass ratios of the nuclei to the meson are somewhat larger than unity. We then adopt the adiabatic approximation. However, the ratios are never so large as they are for electronic molecular systems, to which the naive adiabatic approximation has been applied with great success. Accordingly, a certain refinement of this approximation will be made.

In the usual approximation, the Hamiltonian of the present system is given by

$$\mathscr{H}_{\text{total}} = -\frac{\hbar^2}{2M_p}\Delta_p - \frac{\hbar^2}{2M_d}\Delta_d - \frac{\hbar^2}{2\mu_0}\Delta_\mu - \frac{e^2}{r_p} - \frac{e^2}{r_d} + \frac{e^2}{R}. \quad (2.1)$$

The meaning of these symbols will be obvious to the reader, the meson mass μ_0 being taken to be 207 times the electron mass throughout the paper. The part of (2.1) associated with the internal motion can be expressed as

$$\mathscr{H} = -\frac{\hbar^2}{2M}\Delta_R - \frac{\hbar^2}{2\mu}\Delta_r - \frac{e^2}{r_p} - \frac{e^2}{r_d} + \frac{e^2}{R}. \quad (2.2)$$

The first term is the kinetic energy operator for the relative motion between the proton and the deuteron. The second is that between the meson and the centre of gravity G of the two nuclei. The reduced masses M and μ are, of course, given by

$$\frac{1}{M} = \frac{1}{M_p} + \frac{1}{M_d}, \quad (2.3a)$$

$$\frac{1}{\mu} = \frac{1}{\mu_0} + \frac{1}{M_p+M_d}. \quad (2.3b)$$

The symbols $\boldsymbol{R}$ and $\boldsymbol{r}$ stand for the distance vectors from d to p and G to μ, respectively. Now, in the ordinary adiabatic approximation, every low-energy eigenfunction of (2.2) can be written in the form:

$$\Phi(\boldsymbol{r}, \boldsymbol{R}) = \varphi_1(\boldsymbol{r}; \boldsymbol{R})G(\boldsymbol{R}) + \varphi_2(\boldsymbol{r}; \boldsymbol{R})U(\boldsymbol{R}). \quad (2.4)$$

Here, φ_1 and φ_2 denote respectively the normalized lowest σ_g and σ_u molecular orbitals. They are exactly the same as the corresponding orbitals for the electronic hydrogen molecular ion, except for the scale factor. The G and U are eigenfunctions describing the relative nuclear motions under the respective adiabatic potentials. As is well-known, with increasing R, the φ_1 and φ_2 approach the forms:

$$\varphi_1 \sim \frac{1}{\sqrt{2}}\{\varphi(r_p)+\varphi(r_d)\},$$

$$\varphi_2 \sim \frac{1}{\sqrt{2}}\{\varphi(r_p)-\varphi(r_d)\},$$

where $\varphi(r)$ means the $1s$ orbital of the mesonic hydrogen atom. Therefore, (2.4) takes the form, for large R,

---

[*] §§ 2, 3, 4 form a detailed report of our study which has been published in form of short note.⁷⁾

$$\Phi \sim \frac{1}{\sqrt{2}}(G+U)\varphi(r_p) + \frac{1}{\sqrt{2}}(G-U)\varphi(r_d) . \tag{2.5}$$

Hence, if G and U are the eigenfunctions having the asymptotic forms:

$$G+U \sim e^{i\boldsymbol{K}_+\cdot\boldsymbol{R}} + F_+(\Omega)\frac{e^{iK_+R}}{R} , \tag{2.6a}$$

$$G-U \sim F_-(\Omega)\frac{e^{iK_-R}}{R} , \tag{2.6b}$$

then Φ corresponds to the collision of interest. The total cross-section for charge transfer is related to the scattering amplitude $F_-(\Omega)$ through

$$\sigma_{\text{ex}} = \frac{K_-}{K_+}\int |F_-(\Omega)|^2\, d\Omega . \tag{2.7}$$

However, the above treatment based on the naive adiabatic approximation has a serious defect. Namely, that it cannot explain the energy release of 137 eV at all. In other words, it results in the relation, $K_- = K_+$. Hence, the σ_{ex} is greatly underestimated, so long as the formula (2.7) is adopted, and some improvement must be made. If an arbitrary, but physically acceptable, function $\Psi(\boldsymbol{r}, \boldsymbol{R})$ is orthogonal to (2.4) in the extended sense that $\int \Psi^*\Phi\, d\boldsymbol{r} = 0$, its energy expectation value must be much higher than the energy of interest. Added to this, in (2.2), the mass ratio M/μ is somewhat larger than unity. Accordingly, the deviation of the exact eigenfunction from the form of (2.4) is expected to be inconsiderable. We, therefore, here attempt to refine the above naive treatment without extending the functional form (2.4).

To determine the functions G and U, we use the variation method based on the Schrödinger variation principle:

$$\delta\iint \Phi^*(\mathscr{H} - E)\Phi\, d\boldsymbol{r}\, d\boldsymbol{R} = 0 .$$

Substituting (2.4) in the above, we obtain the simultaneous equations:

$$\Delta_R G + \frac{2M}{\hbar^2}(E - \mathcal{E}_1)G + \Delta_{11}G = -\left(\Delta_{12} + \nabla_{12}\frac{\partial}{\partial R}\right)U , \tag{2.8a}$$

$$\Delta_R U + \frac{2M}{\hbar^2}(E - \mathcal{E}_2)U + \Delta_{22}U = -\left(\Delta_{21} + \nabla_{21}\frac{\partial}{\partial R}\right)G , \tag{2.8b}$$

where

$$\mathcal{E}_i(\boldsymbol{R}) = \int \varphi_i\left(-\frac{\hbar^2}{2\mu}\Delta_r - \frac{e^2}{r_p} - \frac{e^2}{r_d} + \frac{e^2}{R}\right)\varphi_i\, d\boldsymbol{r} , \tag{2.9a}$$

$$\nabla_{ij}(\boldsymbol{R}) = \int \varphi_i \frac{\partial}{\partial R}\varphi_j\, d\boldsymbol{r} = -\nabla_{ji}(\boldsymbol{R}) , \tag{2.9b}$$

$$\Delta_{ij}(\boldsymbol{R}) = \int \varphi_i \Delta_{\boldsymbol{R}}\varphi_j\, d\boldsymbol{r} . \tag{2.9c}$$

The first interals $\mathcal{E}_i$ are the so-called adiabatic potentials, for which we here adopt the highly accurate values calculated by Teller[9]. The ∇_{ij} and Δ_{ij} are both the integrals which are neglected in the naive adiabatic approximation. In this paper, they are evaluated by using the simple LCAO approximation for φ_1 and φ_2:

$$\varphi_1 = \frac{\varphi(r_p) + \varphi(r_d)}{\sqrt{2(1+S)}} , \tag{2.10a}$$

$$\varphi_2 = \frac{\varphi(r_p) - \varphi(r_d)}{\sqrt{2(1-S)}} , \tag{2.10b}$$

S being the overlap integral: $S = \int \varphi(r_p)\varphi(r_d)\, d\boldsymbol{r}$.

The results for $R=0$ and $R=\infty$ are as follows, the full expressions being given in Appendix 1.

$$\lim_{R\to\infty}\nabla_{12} = \lim_{R\to\infty}\nabla_{21} = 0 , \tag{2.11a}$$

$$\lim_{R\to\infty}\Delta_{11} = \lim_{R\to\infty}\Delta_{22} = -\frac{1}{2}\left\{\frac{M_p{}^2 + M_d{}^2}{(M_p + M_d)^2}\right\}\frac{1}{a^2} , \tag{2.11b}$$

$$\lim_{R\to\infty}\Delta_{12} = \lim_{R\to\infty}\Delta_{21} = -\frac{1}{2}\left(\frac{M_d - M_p}{M_d + M_p}\right)\frac{1}{a^2} , \tag{2.11c}$$

$$\lim_{R\to 0}\nabla_{12} = -\lim_{R\to 0}\nabla_{21} = -\frac{1}{2\sqrt{3}}\left(\frac{M_d - M_p}{M_d + M_p}\right)\frac{1}{a} , \tag{2.12a}$$

$$\lim_{R\to 0}\Delta_{11} = -\frac{1}{2}\left\{\frac{M_p{}^2 + M_d{}^2}{(M_p + M_d)^2} - \frac{1}{2}\right\}\frac{1}{a^2} , \tag{2.12b}$$

$$\lim_{R\to 0}\left(\Delta_{22} + \frac{2}{R^2}\right) = \text{finite} , \tag{2.12c}$$

$$\lim_{R\to 0}\left(\Delta_{12} - \frac{4}{R}\nabla_{12}\right) = \text{finite} , \tag{2.12d}$$

$$\lim_{R\to 0}\Delta_{21} = -\frac{1}{2\sqrt{2}}\left(\frac{M_d - M_p}{M_d + M_p}\right)\frac{1}{a^2} , \tag{2.12e}$$

where a represents the mesonic Bohr radius: $a = \hbar^2/\mu e^2$. The first three of these results are exact, and fortunately the following five are also exact so far as their divergent terms are concerned, because the nature of the singularity at the origin is uniquely determined simply from the values of angular momentum associated with the atomic orbitals to which φ_1 and φ_2 tend as $R \to 0$. The non-divergent parts, however, are fairly sensitive to the detail of the approximation, although this is considered to be not serious for our purpose. Approximate curves of our $\mathcal{E}_i$, Δ_{ij}, ∇_{ij} are illustrated in Figs. 2, 3, 4, 5. Clearly, the Δ_{ii} gives a direct correction to the $\mathcal{E}_i$; Δ_{11} makes the valley of $\mathcal{E}_1$ deeper, while Δ_{22} does the slope of $\mathcal{E}_2$ steeper. We here note the inequality:

$$\Delta_{ii}(R) \leqq 0 \ . \tag{2.13}$$

It is easily proved that (2.13) is always valid if the φ_i is a real function having a definite norm independent of R. The physical meaning will be clear for the reader. The negative sign of Δ_{12} and Δ_{21} (cf. Fig. 3) means that the energy of the total system can be lowered by transferring the meson from the proton to the deuteron. This tendency is, however, sometimes intensified and sometimes deminished by the velocity-dependent terms, $\nabla_{ij}(\partial/\partial R)$. If $M_p = M_d$, of course, all these non-diagonal integrals vanish identically.

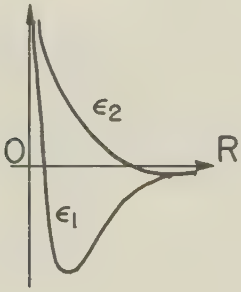

Fig. 2.

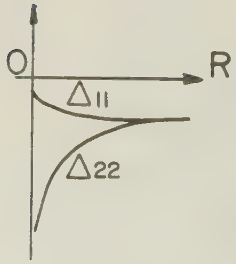

Fig. 3.

The above $\mathcal{E}_i$, ∇_{ij}, Δ_{ij} are all spherically symmetric. Hence, the coupled equations (2.8a, b) are invariant with respect to the rotation of the $\boldsymbol{R}$ space, and we can conveniently use the partial wave method to find the collision solution. Each partial wave (harmonic wave) has the form:

$$G = g_K(R) Y_{KM}(\Omega) \quad \text{and} \quad U = u_K(R) Y_{KM}(\Omega) \ , \tag{2.14}$$

where Y_{KM} denotes the spherical harmonic of angular momentum K and magnetic quantum number M. It is easy to see that the related full wave functions $\varphi_1 g_K Y_{KM}$ and $\varphi_2 u_K Y_{KM}$ have a definite total orbital angular momentum and a definite component of it, which are just equal to K and M, respectively. They are, howeve., not eigenfunctions of L^2, the squared angular momentum operator associated with the relative rotation of the two nuclei. Instead, the component of the total angular momentum along the molecular axis is quantized to zero. If $K=0$, this is strictly a constant of the motion, together with K and M. If $K \neq 0$, however, this is not the case but, in the region of short nuclear distance, the function $\varphi_2 u_K Y_{KM}$ couples strongly with the wave function associated with the $2p\pi$ molecular orbital. This results in the phenomenon called the L uncoupling in the field of molecular physics.[10),11)]

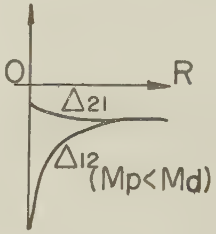

Fig. 4.

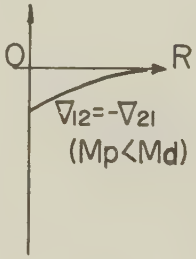

Fig. 5.

Now, substituting (2.14) in (2.8a, b), we obtain for g_K and u_K the coupled equations:

$$\left[\frac{1}{R^2}\frac{d}{dR}\left(R^2\frac{d}{dR}\right)+\frac{2M}{\hbar^2}\left\{E-\mathcal{E}_1-\frac{\hbar^2}{2M}\left(\frac{K(K+1)}{R^2}-\varDelta_{11}\right)\right\}\right]g_K=-\left(\varDelta_{12}+\nabla_{12}\frac{\partial}{\partial R}\right)u_K\,, \tag{2.15a}$$

$$\left[\frac{1}{R^2}\frac{d}{dR}\left(R^2\frac{d}{dR}\right)+\frac{2M}{\hbar^2}\left\{E-\mathcal{E}_2-\frac{\hbar^2}{2M}\left(\frac{K(K+1)}{R^2}-\varDelta_{22}\right)\right\}\right]u_K=-\left(\varDelta_{21}+\nabla_{21}\frac{\partial}{\partial R}\right)g_K\,. \tag{2.15b}$$

On the other hand, the boundary conditions for large R can be found by multiplication of (2.6a, b) by Y_{KM}^* and integration over angles. The result is

$$g_K+u_K\sim\int Y_{KM}^*(\Omega)e^{i\boldsymbol{K}_+\cdot\boldsymbol{R}}\,d\Omega+f_{KM}^+\frac{e^{iK_+R}}{R}\,, \tag{2.16a}$$

$$g_K-u_K\sim f_{KM}^-\frac{e^{iK_-R}}{R}\,. \tag{2.16b}$$

The $f_{KM}^\pm$ are expansion coefficients of the scattering amplitudes $F_\pm(\Omega)$ in terms of the spherical harmonics:

$$F_\pm(\Omega)=\sum_{KM}f_{KM}^\pm Y_{KM}(\Omega)\,. \tag{2.17}$$

The boundary conditions at the origin are clearly that

$$\lim_{R\to0}Rg_K=\lim_{R\to0}Ru_K=0\,, \tag{2.16c}$$

in so far as we neglect the phase shifts due to the nuclear force between p and d, cf. § 5. As one would naturally expect, Eqs. (2.15a, b) have two and just two sets of linearly independent solutions, which obey the condition (2.16c) at the origin:

$$g_K{}^{(i)}\sim a^{(i)}R^K\,, \tag{2.18a}$$

$$u_K{}^{(i)}\sim b^{(i)}R^{(\sqrt{4K(K+1)+9}-1)/2}\,. \tag{2.18b}$$

Therefore, the general solution subject to (2.16c) is given by

$$g_K=\lambda_1g_K{}^{(1)}+\lambda_2g_K{}^{(2)}\,, \tag{2.19a}$$

$$u_K=\lambda_1u_K{}^{(1)}+\lambda_2u_K{}^{(2)}\,, \tag{2.19b}$$

where λ_i are arbitrary constants. The value of the exponent in (2.18b) is not an integer, except for $K=0$. This is due to the fact that the $\varphi_2u_KY_{KM}$ is not an eigenfunction of L^2 even at the origin, unless $K=0$. To remove the defect, it is necessary to take into account the L uncoupling effect stated above.

With increasing R, the differences $\mathcal{E}_2-\mathcal{E}_1$, $\varDelta_{22}-\varDelta_{11}$, $\varDelta_{21}-\varDelta_{12}$, $\nabla_{21}-\nabla_{12}$ go to zero as rapidly as $\exp(-R/a)$. Hence, for large R, (2.15a, b) may be transformed into the two independent equations:

$$\left[\frac{1}{R^2}\frac{d}{dR}\left(R^2\frac{d}{dR}\right)-\frac{K(K+1)}{R^2}+K_\pm{}^2(R)\right](g_K\pm u_K)=0\,, \tag{2.20}$$

where

$$K_\pm{}^2(R)=\frac{2M}{\hbar^2}\left\{E-\frac{\mathcal{E}_1+\mathcal{E}_2}{2}+\frac{\hbar^2}{2M}\left(\frac{\varDelta_{11}+\varDelta_{22}}{2}\pm\frac{\varDelta_{12}+\varDelta_{21}}{2}\right)\right\}. \tag{2.21}$$

Further, in these regions, the above $K_\pm{}^2$ may be approximated as

$$K_\pm{}^2(R)\simeq K_\pm{}^2(\infty)+\frac{2M}{\hbar^2}\frac{\alpha_\pm e^2}{2R^4}\,. \tag{2.22a}$$

The last term means the contribution from the polarization force, α_+ and α_- being respectively the electro-static polarizabilities of the $(p\mu)$ and $(d\mu)$ atoms:

$$\alpha_\pm \cong \frac{9}{2}a^3 . \tag{2.22b}$$

The relation between $K_+(\infty)$ and $K_-(\infty)$ can be found from (2.21) and (2.11c);

$$\frac{\hbar^2}{2M}\{K_-^2(\infty)-K_+^2(\infty)\} = -\frac{\hbar^2}{M}\Delta_{12}(\infty)=\frac{1}{2}\left(\frac{\mu}{M_p}-\frac{\mu}{M_d}\right)\frac{\hbar^2}{\mu a^2}\cong 157\text{ eV} . \tag{2.23}$$

This may be compared with a value of 137 eV, the exact internal energy difference between $(p\mu)_{1s}$ and $(d\mu)_{1s}$. This good agreement is, of course, one of the reasons why we have chosen the trial form (2.4). Now, the above polarization force is certainly not strong, but it has a comparatively long range. Accordingly, it might have a serious effect on the low-energy collision, $K_+(\infty)\sim 0$. This is the case for electronic molecular systems, as is well-known. We must now discuss whether this effect is important in the present μ mesonic system. It will be sufficient to examine the solution of (2.20) for the special case where $K=0$ and $K_+(\infty)=0$.* To the first order of the polarization force, the solution of interest can be expressed as

$$g_0+u_0 \cong A\left\{1+\frac{9}{4}\frac{M}{\mu}\frac{a^2}{R^2}\right\}+\frac{B}{R}\left\{1+\frac{M}{\mu}\frac{a^2}{R^2}\right\} , \tag{2.24}$$

where A and B are arbitrary constants. Consequently, for the distortion to be negligibly small, the following condition must be satisfied:

$$\frac{9}{4}\frac{M}{\mu}\frac{a^2}{R^2} \ll 1 . \tag{2.25}$$

In other words, the value of R must be much larger than the critical value:

$$R_c \equiv \frac{3}{2}\sqrt{\frac{M}{\mu}}\,a \cong 3.6a . \tag{2.26a}$$

For the corresponding electronic problem, the μ and a must be replaced by the electron mass m_e and the electron Bohr radius a_e. Hence, we obtain the value:

$$R_c \cong 3.6\sqrt{207}\,a_e \cong 50a_e . \tag{2.26b}$$

These two values suggest that the Born approximation will be not so drastic for mesonic molecular systems as it is for electronic systems. This is due to the following quantum effect. The value of M measured in mesonic atomic units is much smaller than that measured in electronic atomic units, while all the other quantities are exactly same for the both systems, if they are also expressed in terms of the respective atomic units. Hence, the zero-point motions of nuclei related to the uncertainty principle must be far more active in mesonic molecular systems. As a result, the effect of the potential force on the nuclear motion must be largely averaged out. Considering these favourable circumstances, we adopt the equation for a free particle, in the region $R>6a$,

$$\left[\frac{1}{R^2}\frac{d}{dR}\left(R^2\frac{d}{dR}\right)-\frac{K(K+1)}{R^2}+K_\pm^2(\infty)\right] \times(g_K \pm u_K)=0 . \tag{2.27}$$

The resulting error in the cross-section is expected to be less than a factor of 2. The solutions of (2.27) having the asymptotic forms (2.16a, b) can, of course, be written down analytically, the amplitudes $f^\pm_{KM}$ being involved in them as unknown parameters. However, the solutions (2.19a, b) for $R<6a$ need to be culculated numerically. It will be clear that the parameters λ_i and $f^\pm_{KM}$ can be determined uniquely from the requirement that these two kinds of solutions must be connected smoothly at $R=6a$. Further, it will be needless to note that the amplitudes $f^\pm_{KM}$ for $K\neq 0$ go to zero rapidly with decreasing incident energy.

In Table I, our value of

$$\lambda_{\text{ex}} \equiv N\lim_{K_+\to 0}\left(\frac{\hbar K_+}{M}\sigma_{\text{ex}}\right)=\frac{N\hbar}{M}\lim_{K_+\to 0}(K_-|f^-_{00}|^2)$$

is shown, together with those found by the other authors. Here, N represents the number density of proton in pure liquid hydrogen at 20°K, $N=3.5\times 10^{22}\text{ cm}^3$. The quantity $c\lambda_{\text{ex}}$ may be interpreted as the rate for charge transfer in liquid hydrogen of deuteron concentration c.

Now, in Table I, the value due to Skyrme[5]

---

* For this special case, (2.20) can be solved exactly.

Table I. Calculated values of λ_{ex} (in $10^{10}\,\mathrm{sec}^{-1}$).

	Skyrme	Ours	Cohen et al.	Burke et al.
λ_{ex}	60	1.50	1.14	0.18

was estimated by using the first order Born approximation. The calculation by Cohen et al.[8] is in principle similar to ours, though much more elaborate. Their value may be thought of, in practice, as the true answer which can be derived from the basic assumption (2.4) without further simplification. They found that their λ_{ex} can explain the observed value of $\lambda_{\mathrm{ex}}/\lambda_0+\lambda_{m1}$ quite satisfactorily, together with their theoretical value of λ_{m1}. The main origin of the discrepancy between their value and ours is probably the difference in the range of numerical integration: they integrated Eqs. (2.15a, b) up to $R=20a$. In Burke et al.'s calculation[12], the φ_1 and φ_2 in (2.4) was replaced by those of the naive LCAO approximation from the start. They integrated their equations up to $R=16a$.

§ 3. The Bound States: ($p\mu p$) and ($p\mu d$)

As was noted in § 2, if $M_p=M_d$, all the non-diagonal dynamic correction integrals vanish identically. For ($p\mu p$), therefore, the two equations (2.15a) and (2.15b) are exactly uncoupled with one another. For ($p\mu d$), on the other hand, the coupling terms do not vanish. Their effect is, however, expected to be only of secondary importance, except for shallow bound states and continuous states. We then put, in Eqs. (2.15a, b)

$$\Delta_{ij}(\boldsymbol{R})=\nabla_{ij}(\boldsymbol{R})=0 \qquad \text{for} \quad i\neq j\,, \tag{3.1}$$

independently of whether we are interested in ($p\mu p$) or ($p\mu d$). The effective potential in (2.15b) is certainly attractive outside the region of overlap force, if $K=0$. However, it is so weak that no bound state can exist. Hence, we have only to examine the former equation. To simplify the calculation furthermore, we replace the associated effective potentials:

$$U_K(R)=\varepsilon_1+\frac{\hbar^2}{2M}\left\{\frac{K(K+1)}{R^2}-\Delta_{11}(R)\right\} \tag{3.2a}$$

by Morse potentials:

$$V_K(R)=D_K\left\{\exp\left(-2\frac{R-R_K}{A_K}\right)\right.$$
$$\left.-2\exp\left(-\frac{R-R_K}{A_K}\right)\right\}+C_K\,. \tag{3.2b}$$

The parameters A_K, C_K, D_K, R_K are here fixed by the four requirements that $V_K(\infty)=U_K(\infty)$, $V_K(4a)=U_K(4a)$, $V_K(R_K)=U_K(R_K)$, and the position of the minimum point of V_K, $R=R_K$, should coincide with that of $U_K(R)$.

The above approximate treatment results in three bound states in all, for each of ($p\mu p$) and ($p\mu d$). Two of them are S states ($K=0$), while one is a P state ($K=1$). In the following we wish to discuss whether or not the Hamiltonian (2.2) really has three bound states of these symmetries. The present calculation of energy levels is based on the ordinary variation method. The trial function is clearly given by $\varphi_1 g_K Y_{KM}$. Therefore, the resulting energy values of S, P, D, $\cdots$ states must be respectively upper bounds for the eigenvalues of the lowest S, P, D, $\cdots$ eigenfunctions of the total Hamiltonian (2.2), although this is, of course, not strictly true on account of the Morse potential approximation. On the other hand, the energies obtained for the lower S state and the P state are both somewhat lower than the exact energy of the related dissociation products: $p+(p\mu)_{1s}$ for ($p\mu p$), and $p+(d\mu)_{1s}$ for ($p\mu d$), not $d+(p\mu)_{1s}$. We can, therefore, conclude that the existence of the above two bound states is quite certain. Concerning the upper S state, which is an extremely loosely bound state for each system, our present calculation is certainly rough. For ($p\mu p$), however, that would not be so drastic as the result is wholly wrong. Accordingly, there is every possibility that the ($p\mu p$) system actually has a real or virtual S level near the dissociation limit. For ($p\mu d$), however, this is not the case. The approximation (3.1) is obviously drastic for large R. Accordingly, if we take into account the coupling between g_K and u_K, the present result would be greatly changed. On the other hand, the coupling results in localization of the meson on the deuteron in the region of large nuclear separation. This inevitably weakens the molecular binding between the proton and the deuteron. As a result, we are led to the expectation that the real ($p\mu d$) system would have no excited S state.*

---

* This expectation is opposite to those expressed by Skyrme[5] and Zel'dovitch[3]. The former author suggested that the existence of this level might be essential for the reaction, $p+(d\mu)_{1s}\longrightarrow(p\mu d)$, to take place.

Table II. Calculated dissociation energies (in ev.)

	$(p\mu p)$	$(p\mu d)$	$(d\mu d)$
$S(K=0)$	284 (284)	239 (235)	359 (343)
$P(K=0)$	113 (136)	88 (111)	228 (244)
$D(K=2)$	——	——	80 (103)
$S'(K=0)$	14	−79	30 (202)*

* The figures in brackets are those found by Cohen et al. based on an approximation similar to that of § 2. Their value for the excited S state of $(d\mu d)$ would be wrong.

Table II shows the dissociation energy of each bound state found by the above approximate calculation, together with that of $(d\mu d)$. Here, the energy of the related dissociation products is chosen to be

$$E_{\text{dis.}}=U(\infty)-\frac{\hbar^2}{2M}|\Delta_{12}(\infty)|^2 . \tag{3.3}$$

This expression is exact to the approximation of (2.8a, b). For $(p\mu p)$ and $(d\mu d)$, the last term vanishes, and so (3.3) reduces to the usual one.

§ 4. The Molecular Formation

We first mention the formation of the ground state $(p\mu d)$ molecule by the slow collision of a mesonic deuteron atom with a proton bound in an ordinary hydrogen molecule. As has been shown in the previous section, the $(p\mu d)$ system has one excited state, P, besides the ground state, S. Therefore, the ground state molecule can be formed in the following two ways. One is the direct transition from the incident state, I. The other is the indirect transition through the excited state, P. Clearly, these transitions must be accompanied by emission of some other particle than p, d, μ under consideration. Conforming to the usual convention[13)], we here examine only the two possibilities: the emission of a photon and the emission of an electron bound around the proton. Now, the incident energy of interest is so low that we consider the transitions simply from the S wave component of the incident state eigenfunction. Then, the direct transition is just the so-called 0–0 transition, in which the radiative process is forbidden. Consequently, the transition $I\rightarrow S$ takes place exclusively by electron emission. In the indirect transition, on the other hand, both are possible, and each step of the transition is induced by an electric dipole. Table III shows our calculated values of the associated reaction rates in the pure liquid hydrogen. They have been found by making a number of simplifying assumptions given below.

(a) We used a plane wave approximation for the incident state eigenfunction:

$$\Phi_{\rm I}(\boldsymbol{r},\boldsymbol{R})=\varphi(r_d)\cdot\exp(i\boldsymbol{K}_-\cdot\boldsymbol{R})\,, \tag{4.1}$$

$\varphi(r_d)$ being the $1s$ orbital of the mesonic hydrogen atom.

(b) The bound state eigenfunctions were simplified as

$$\Phi_{KM}(\boldsymbol{r},\boldsymbol{R})=\frac{\varphi(r_p)+\varphi(r_d)}{\sqrt{2(1+S)}}\cdot\frac{1}{R}\cdot\exp[-\alpha_K(R-R_K)^2]\cdot Y_{KM}(\Omega)\,. \tag{4.2}$$

The R_K is the same as that in (3.2b), the α_K being chosen so that it shall give the correct zero-point energy. This harmonic oscillator approximation results in an under-estimation of the reaction rates for $I\rightarrow P$ and $I\rightarrow S$.

(c) The wave function for the bound electron was replaced by the $1s$ orbital of the hydrogen atom.

(d) The plane wave approximation was adopted for the ejected electron.

(e) The perturbation for electron emission was chosen as

$$\mathscr{H}_e=e^2\left(\frac{1}{r_{e\mu}}-\frac{1}{r_{ep}}-\frac{1}{r_{ed}}+\frac{1}{r_{eg}}\right), \tag{4.3}$$

r_{eg} being the distance between the electron and the centre of gravity of the $(p\mu d)$ system. From Table III, we see that the ground state $(p\mu d)$ molecule will be formed predominantly by making the two successive electron-emission transitions, $I\rightarrow P$ and $P\rightarrow S$.* In addition, the rate for $P\rightarrow S$ is so large that neither the meson decay nor the p-d fusion process cannot compete with the transition $P \rightarrow S$ at all.

---

* Jackson[4)] also estimated the rate for 0–0 transition, and obtained a very large value ($\sim10^7\ \text{sec}^{-1}$). His result is, however, not acceptable. The plane wave (4.1) orthogonalized to the bound states (4.2) will be a better approximation of the incident state eigenfunction than (4.1) itself. If this improved one is used in his calculation, the result is in good agreement with ours. His calculation is based on the formula, $\lambda\propto|\langle\Psi^-{}_f|\mathscr{H}_f|\Psi\rangle|^2$, which is famous in the formal theory of scattering[14)]. This expression results in the exact reaction rate, when Ψ is the exact eigenfunction corresponding to the present collision, $(pe)+(d\mu)\longrightarrow(p\mu d)+e$.

We next discuss the formation of $(p\mu p)$. In this case there are two independent incident state, I_+ and I_-. The former is symmetric with respect to interchange of the space coordinates of two protons, and the related wave function is given by $\varphi_1 G$ in the approximation of § 2. The latter is anti-symmetric and the wave function is given by $\varphi_2 U$. Their statistical weights are 1 and 3, respectively. On the other hand, the bound state S is symmetric, and P is anti-symmetric with respect to the same symmetry operation.

Table III. Calculated rates for formation of $(p\mu d)$ in pure liquid hydrogen (in sec^{-1}).

	$I \rightarrow S$	$I \rightarrow P$	$P \rightarrow S$
Electron emission	10^{-1}	10^5	10^{10}
Photon emission	0	10^{-1}	10^6

Therefore, the allowed transitions are two in all, $I_+ \rightarrow S$ and $I_- \rightarrow P$, $P \rightarrow S$ being forbidden in the usual approximation. The latter transition, $I_- \rightarrow P$, can occur by $E1$, just as before. The electric dipole operator for $(p\mu d)$ may be expressed as

$$\mathscr{D} = \frac{e}{2} \frac{M_d - M_p}{M_d + M_p + \mu} \boldsymbol{R} - e \frac{M_d + M_p + 2\mu}{M_d + M_p + \mu} \boldsymbol{r}' , \tag{4.4}$$

where $\boldsymbol{r}'$ stands for the distance vector from the geometrical centre of p and d to μ^-. When $M_p = M_d$, the first term vanishes identically, so that the second term alone exists for $(p\mu p)$. However, the analysis of our calculation for $(p\mu d)$ tells that the contribution of the first term to the transition matrix element is negligibly small. Hence, the reaction rate for $I_- \rightarrow P$ will be of the same order of magnitude as the corresponding value for $(p\mu d)$. This will be roughly true of $I_+ \rightarrow S$ as well. However, if $(p\mu p)$ has an extremely loosely bound S state, whether real or virtual, the situation changes. For, in this case, the collision between p and $(p\mu)$ exhibits resonance. As a results, the amplitude of the I_+ incident state wave function becomes quite large in a region of small R. Consequently, the reaction rate for $I_+ \rightarrow S$ increases considerably. We can, however, hardly expect $I_+ \rightarrow S$ to predominate over $I_- \rightarrow P$.

Lastly, we touch on the formation of $(d\mu d)$. As is shown in Table II, $(d\mu d)$ has four bound states in all, although the existence of the excited S state might be slightly uncertain. Therefore, the following four transitions can take place by collision of d and $(d\mu)$: $I_+ \rightarrow S'$, $I_+ \rightarrow D$, $I_+ \rightarrow S$, and $I_- \rightarrow P$. The last two will be essentially the same as those for $(p\mu p)$. We can, however, expect a somewhat remarkable decrease in the reaction rate, especially for $I_- \rightarrow P$.* The first reason is that the amplitude of the incident state wave function U_{I} will be smaller for $(d\mu d)$ than for $(p\mu p)$. This is because it becomes harder for a particle to penetrate into a potential barrier as the mass increases, the potential to determine U_{I} being repulsive for $R < 10a$. The second reason is that the $(d\mu d)$ molecule is smaller than $(p\mu p)$ in size. The $E1$ transition probability is roughly proportional to $R_0{}^5$, R_0 being the size of the molecule formed by collision. The third reason is the decrease in the statistical weight of the I_- state from $\frac{3}{4}$ to $\frac{1}{3}$. The fourth is the increase in the energy of ejected electron. We must now consider $I_+ \rightarrow S'$. If the energy released is not enough to ionize a bound electron, this transition is forbidden. On the other hand, if the energy is only just enough, then $I_+ \rightarrow S'$ might be able to compete with $I_- \rightarrow P$. This is because the rate for the 0–0 transition increases rapidly with increasing R_0, in proportion to $R_0{}^7$. Of course, R_0 increases as the dissociation energy decreases. According to Zel'dovitch's estimation,[3] the reaction rate amounts to $\sim 10^5\,\mathrm{sec}^{-1}$ in the limiting case that the released energy is just equal to the ionization potential. Thirdly, we must consider $I_+ \rightarrow D$. This can occur by $E2$. Usually, the $E1$ transition is more important than the $E2$. In the present case, however, the $E1$ transition $I_- \rightarrow P$ has a number of handicaps as was mentioned above. Accordingly, $I_+ \rightarrow D$ might also compete with $I_- \rightarrow P$. However that may be, the formation of the $(d\mu d)$ molecule is almost certainly more difficult than that of $(p\mu p)$ or $(p\mu d)$.*

---

* Cohen et al.'s value is $5.9 \times 10^4\,\mathrm{sec}^{-1}$ for $(d\mu d)$, while $6.5 \times 10^6\,\mathrm{sec}^{-1}$ for $(p\mu p)$[8]. Their explanation for this decrease is not acceptable. It seems possible that they may have used G_{I}, by mistake, instead of U_{I} to evaluate the former value.

§ 5. The Radiative p–d Fusion: $(p\mu d)_s \longrightarrow \mathrm{He}^3+\gamma$

1) *The initial state*: $(p\mu d)_s$

We here briefly mention the hyperfine structure associated with the $(p\mu d)_s$ state. The spins of the particles μ, p, d are respectively $\frac{1}{2}$, $\frac{1}{2}$, 1. Hence, the ground state can split into one quintet, two triplets, and one singlet. In the quintet state, the two nuclear spins are parallel; in the singlet they are antiparallel. In the triplet states, both spin states are mixed. Their mixing ratios cannot be determined, until the hyperfine interaction is specified. The ground state has zero total orbital angular momentum: $K=0$. Therefore, the most important hyperfine interaction is considered as the Fermi contact interaction of p and d with μ. The splitting caused by this interaction is estimated to be of the order of magnitude of 0.1 eV, The nuclear force between p and d, which may be expressed in the form of contact interaction in the first order approximation, is also spin-dependent. However, its contribution to the splitting is negligibly small ($<10^{-3}$ eV), cf. (5.14). The rate for p–d fusion depends, clearly, on the relative spin orientation of p and d in the initial state. Hence, each of the spin multiplets has its own reaction rate. In this paper we treat only their statistical average, which is in practice independent of the hyperfine splitting.

2) *The final state*: He^3

In the notation of Russell-Saunders coupling, the He^3 ground state is $^2S_{1/2}$ and "even" in parity. As is well-known, there are just two linearly independent doublet spin functions for three-nucleon systems. Hence, in the approximation of neglecting the non-central nuclear force the He^3 ground state wave function can be expressed in the form:

$$\Psi_f=\Lambda_f{}^+\Theta_+ + \Lambda_f{}^-\Theta_- \,. \tag{5.1}$$

Here, $\Lambda_f{}^\pm$ mean the orbital parts and $\Theta_\pm$ the spin parts. For convenience, Θ_+ and Θ_- are here chosen to be anti-symmetric and symmetric with respect to the exchange of the two protons, respectively. From well-known energy arguments, we can easily see that if the nuclear force is wholly spin-independent, the above $\Lambda_f{}^-$ must be zero.

3) *The photon emission process*: $p+d \longrightarrow {}^3\mathrm{He}+\gamma$.

In the region of short p–d distance of the order of n–d interaction range ($\sim 4\times 10^{-13}$ cm), the two nuclei in the $(p\mu d)_s$ molecule would be to such an extent in an S state, $L=0$, that their fusion reaction occurs exclusively in the S state. Accordingly, we here again examine only the transition from the S wave component. The deuteron ground state is $^3S_1$. Therefore, if the proton spin is parallel to the deuteron spin, the initial state has the symmetry $^4S_{3/2}$ as a whole, and if antiparallel, $^2S_{1/2}$. On the other hand, the final state —the He^3 ground state—is $^2S_{1/2}$. Hence, the radiative transitions can occur by a magnetic dipole. The related transition matrix elements are given, in the usual approximation, by

$$\begin{aligned} M_{if} &= \langle \Psi_i | \mu_p(s_{p_1}+s_{p_2})+\mu_n s_n | \Psi_f\rangle \\ &= (\mu_n-\mu_p)\langle \Psi_i | s_n | \Psi_f\rangle \,. \end{aligned} \tag{5.2}$$

Here, the obvious relation, $\langle \Psi_i | S | \Psi_f\rangle=0$, was used, S being the total intrinsic nuclear spin operator. From the last expression of (5.2), it will be clear that the so-called mirror reaction, $n+d \longrightarrow T+\gamma$, can be a true mirror to a fairly good approximation, notwithstanding that proton and neutron are somewhat different in their magnetic moments.** This is the case for electric dipole transitions as well, though not for higher multipole transitions. Now, suppose that the nuclear force is spin-independent, then the last term of (5.1) must vanish as was noted there. Hence, the two proton spins must be exactly antiparallel in the final state. While, in the ^4S initial state, they are always parallel. Accordingly, the $M1$ transition is forbidden for ${}^4S\rightarrow{}^2S$. We now consider the transition ${}^2S\rightarrow{}^2S$. Clearly, the initial ${}^2S$ wave function has the general form:

---

* For the $(d\mu d)$ molecule, the rate for nuclear fusion might be appreciable even in the excited states, S, P, and D. To the approximation in § 2, the D state wave function falls off much more rapidly than the P state wave function, with decreasing nuclear separation R. However, this is not true of the exact D eigenfunction, but there must be some amount of admixture of S component ($L=0$) which is finite at $R=0$. This is not applicable to the P state, whose wave function must vanish at the origin by symmetry.

** This is one of the reasons why Cohen et al.'s criticism[8] on Jackson's semi-emiempirical treatment[4] is not acceptable. The other reason would be seen from the expression (5.20c).

$$\Psi_i=\Lambda_i^+\Theta_++\Lambda_i^-\Theta_-\ , \tag{5.3}$$

so that the two proton spins can be partly antiparallel. However, (5.3) is required to be orthogonal to the one-term final state wave function, $\Lambda_f^+\Theta_+$. On the other hand, $\langle\Lambda_i^-|\Lambda_f^+\rangle=0$ by symmetry. Therefore, $\langle\Lambda_i^+|\Lambda_f^+\rangle=0$. As a result, ${}^2S\rightarrow{}^2S$ is also forbidden.* To summarize, if the nuclear force is spin-independent, the thermal radiative fusion can hardly take place. In fact, however, the nuclear force is spin-dependent, so that the above arguments cannot be applied. Actually, we can show that if the spin-dependency is taken into account, the above $M1$ transition becomes possible for both ${}^4S\rightarrow{}^2S$ and ${}^2S\rightarrow{}^2S$.** However, it does not seem easy to predict which is faster. In the well-studied case of thermal radiative p–n capture, on the contrary, one of the two possible transitions, ${}^3S\rightarrow{}^3S$, is still forbidden.[13]

4) *Semi-empirical calculation of the reaction rate for* $(p\mu d)_s\longrightarrow\mathrm{He}^3+\gamma$

We first discuss the distortion of $(p\mu d)_s$ wave function due to the nuclear force. Let R_0 be a distance of the order of the range of the nuclear force between p and d, $\sim5\times10^{-13}$ cm. Our main interest is in the region of $R>R_0$. We make the conventional assumption that, for $R>R_0$, Eqs. (2.15a, b) remain valid and the effect of the nuclear force can be taken into account simply by adjusting the boundary conditions (2.16c). For simplicity, we hereafter consider just the g component by omitting the coupling with the u. The new boundary condition may be expressed as

$$\left[\frac{d}{dR}\log(Rg)\right]_{R=R_J}=\frac{1}{R_0+F}\ . \tag{5.4}$$

The constant F is here replaced simply by the scattering length for thermal n–d elastic collision. Let E_1 be the energy shift resulting from the change of the boundary condition. The magnitude will be negligibly small as compared with the original energy E_0. We therefore consider the distortion of g just to the first order of E_1:

$$g\cong g_0+E_1g_1\ . \tag{5.5}$$

The equation for g_1 can be found by differentiation of (2.15a) with respect to the energy E:

$$\left[\frac{1}{R^2}\frac{d}{dR}\left(R^2\frac{d}{dR}\right)+\frac{2M}{\hbar^2}\left(E_0-\mathcal{E}_1+\frac{\hbar^2}{2M}\Delta_{11}\right)\right]g_1$$
$$=-\frac{2M}{\hbar^2}g_0\ . \tag{5.6}$$

As is easily seen, the solution g_1 which is bound at infinity is given by

$$g_1=-\frac{2M}{\hbar^2}\left[g_\infty+g_0\int_0^R g_\infty g_0R^2\,dR\right.$$
$$\left.-g_\infty\int_0^R g_0g_0R^2\,dR\right]\ , \tag{5.7}$$

where g_∞ denotes the improper solution of the original homogeneous equation. In the close proximity of the origin, the above g_0 and g_∞ have the forms:

$$g_0\cong g_0(0)\cdot\left(1+\frac{R}{A}\right)\ , \tag{5.8a}$$

$$g_\infty\cong\frac{1}{g_0(0)}\left(\frac{1}{R}+2\frac{1}{A}\log\frac{R}{B}\right)\ . \tag{5.8a}$$

Here, A is the distance characteristic for the Coulomb scattering:

$$A=\frac{\hbar^2}{Me^2}\cong4.32\times10^{-12}\ \mathrm{cm}\ . \tag{5.9}$$

On the other hand, B is the distance which is determined from the condition:

$$\int_0^\infty g_1g_0R^2\,dR=0\ , \tag{5.10}$$

which results from the normalization condition: $\int g^2R^2\,dR=\int g_0^2R^2\,dR=1$. However, the value of B is considered to be quite insensitive to the potential shape in the region of large R where the Coulomb repulsion is not dominant. For, the Coulomb force is so strong for small R that even a negligibly small change in B can induce an appreciable variation in g_1 for large R. Hence, B may be chosen so that the resulting g_1 of (5.7) shall coincide with the Hankel function which vanishes at infinity. After a short calculation, we find the following connection formula:

---

* Cohen et al.[8] thought ${}^2S\rightarrow{}^2S$ is allowed although ${}^4S\rightarrow{}^2S$ is forbidden. On this basis they reanalysed Ashmore et al.'s experiment[6] and found a new internal conversion coefficient which is nearly twice as large as the old one due to Ashmore et al.

** Accordingly, it is not clear whether or not Cohen et al.'s value of internal conversion coefficient is more reliable than Ashmore et al.'s value. The latter authors implicitly assumed that both transitions have the same reaction rate.

$$-\frac{\hbar^2}{2M}g_0(0)\,g_1(R)\cong\frac{1}{R}+2\frac{1}{A}\log\frac{R}{B}$$

$$\cong-\pi\sqrt{\frac{2A}{R}}H_1^{(1)}(i\sqrt{8R/A})\,. \qquad (5.11)$$

From this we obtain

$$B\cong0.42_9A\,. \qquad (5.12)$$

Substituting (5.11) and (5.8a) in (5.5) we have

$$g(R)\cong g_0(0)\Big[\Big(1+\frac{R}{A}\Big)$$

$$+\frac{\lambda}{R}\Big(1+2\frac{R}{A}\log\frac{R}{B}\Big)\Big]\,. \qquad (5.13)$$

This approximate form will be valid for R up to about $B/4$. The relation between the energy shift E_1 and the above scattering length λ is given by

$$E_1=-\frac{\hbar^2}{2M}\lambda\cdot|g_0(0)|^2\,. \qquad (5.14)$$

Substitution of (5.13) in (5.4) results in

$$\lambda=\frac{R_0^2+(A+2R_0)F}{(A-2R_0)-2(1+\log R_0/B)F}\,. \qquad (5.15)$$

Thus we obtain, for the value of g at $R=R_0$,

$$g(R_0)=C\cdot g_0(0)\cdot\Big(1+\frac{F}{R_0}\Big)\,, \qquad (5.16a)$$

where

$$C(F,R_0)=\frac{1-2\Big(\dfrac{R_0}{A}\Big)^2\cdot\Big(1-\log\dfrac{R_0}{B}\Big)}{\Big(1-2\dfrac{R_0}{A}\Big)-2\Big(1+\log\dfrac{R_0}{B}\Big)\dfrac{F}{A}}\,. \qquad (5.16b)$$

As would have been expected physically, the factor C tends to 1 with decreasing R_0/A and F/A. Hence, C may be taken as the nuclear size correction factor. Now, putting $R_0=A/10$, which would be appropriate for the present case, we obtain

$$C\cong\frac{1.19}{1+1.14F/A}\,. \qquad (5.17)$$

(5.17) diverges to infinity at $F=-0.9A$. Hence, if the n–d system has an "actual" bound state of quite low binding energy, the $(p\mu d)_s$ wave function will be distorted considerably by the nuclear force. However, this does not seem to take place, at least, in the present case. Judging from a calculation by Buckingham and Massey[15], we may expect the magnitude of F for n–d collision to be of the order of $A/10$. The sign is positive for the quartet state collision, and negative for the doublet. Accordingly, the deviation of C from 1 will not be appreciable:

$$C^2\cong1 \quad \text{for the quartet}\,, \qquad (5.18a)$$

$$C^2\cong2 \quad \text{for the doublet}\,. \qquad (5.18b)$$

In the following, for simplicity, we put $C^2=1$, independently of the relative nuclear spin orientation.

We next evaluate the reaction rate for $(p\mu d)_s\longrightarrow He^3+\gamma$. Following Jackson[4] and others, we make use of the reaction constant for $n+d\longrightarrow T+\gamma$, let σv. As was mentioned at the beginning of this section, the ground state of $(p\mu d)$ is split into four sets of spin multiplets by hyperfine interaction, and each multiplet has its own reaction rate. However, the only available experimental result for σv is the statistical average of the two possible values, $(\sigma v)_+$ and $(\sigma v)_-$:

$$\sigma v=\frac{2}{3}(\sigma v)_+ +\frac{1}{3}(\sigma v)_-$$

$$=1.25\times10^{-22}\ \text{sec}^{-1}\cdot\text{cm}^3\,. \qquad (5.19)$$

Hence, it is impossible to determine each of the four reaction rates separately. Consequently, we here estimate only their statistical average, λ_γ. Now, σv can be interpreted as the transition probability from the incident state normalized so that $\Phi_I=1+(F/R)$. We then relate λ_γ to σv through the expression:

$$\lambda_\gamma=\frac{3}{4\pi}\Big[\frac{2}{3}(\sigma v)_+\cdot\Big|\frac{g_+(R_0)}{1+(F_+/R_0)}\Big|^2$$

$$+\frac{1}{3}(\sigma v)_-\cdot\Big|\frac{g_-(R_0)}{1+(F_-/R_0)}\Big|^2\Big] \qquad (5.20a)$$

$$=\frac{3}{4\pi}\Big[\frac{2}{3}(\sigma v)_+\cdot C_+^2+\frac{1}{3}(\sigma v)_-\cdot C_-^2\Big]\cdot|g_0(0)|^2 \qquad (5.20b)$$

$$\cong\frac{3}{4\pi}(\sigma v)\cdot|g_0(0)|^2\,.^* \qquad (5.20c)$$

The value of $g_0(0)$ will be insensitive to the details of the approximation adopted in the calculation, as long as the Coulomb repulsion between p and d is correctly taken into account in the region of small R. However, one of our objects in this section is to see the true result of the basic approximation

---

* This is just the expression which can be derived from the most naive consideration. Jackson[4] adopted (5.20c) with $g_0(0)$ replaced by $g_0(R_0)$. This seems, however, difficult to justify.

(2.4) as quantitatively as possible. We therefore use the value calculated by Cohen et al.:

$$|g_0(0)|^2=1.11\times10^{28}\ \mathrm{cm}^{-3}\,. \qquad (5.21)$$

Then, we have, from (5.20c) and (5.19),

$$\lambda_\gamma=0.33\times10^6\ \mathrm{sec}^{-1}\,. \qquad (5.22)$$

If the *n–d* fusion reaction takes place predominantly from the doublet incident state, this might be an underestimate because of (5.18b).

5) *Comparison with experiment*

Ashmore et al.[6] detected the γ rays from the above *p–d* fusion process. They analyzed the related time distribution to obtain the values of λ_γ and λ_{m2}, cf. Fig. 1. As a result, they found that the following set of values can reproduce their observations satisfactorily within the error of their results:[*]

$$\lambda_{m2}\cong2.5\times10^6\ \mathrm{sec}^{-1}\,, \qquad (5.23a)$$

$$\lambda_\gamma\cong0.3\times10^6\ \mathrm{sec}^{-1}\,. \qquad (5.23b)$$

The theoretical value of λ_{m2} calculated by Cohen et al.[8] is just equal to the above λ_{m2}. In addition, a good agreement with respect to λ_γ can be seen from a comparison of (5.23b) with (5.22).

Ashmore et al.'s analysis is based on the single decay constant approximation. They implicitly assumed that all the multiplets of $(p\mu d)_s$ have the same reaction rate, which would be a defect of their analysis. However, as far as the statistical average is concerned, their simplification does not seem serious. In fact, the experimental value of λ_γ proposed by Cohen et al., who analysed the same experiment on the assumption that ${}^4S\rightarrow{}^2S$ is forbidden, is essentially equal to (5.23b), i.e. $\lambda_\gamma=3.1\times10^5\ \mathrm{sec}^{-1}$.[**] Accordingly, the error of (5.23b) would be minor. If the ${}^2S\rightarrow{}^2S$ transition takes place much faster than ${}^4S\rightarrow{}^2S$ as was supposed by Cohen et al., the theoretical value of λ_γ must be chosen to be nearly twice as large as (5.22) on account of (5.18b). This makes the above agreement slightly poor. It would, however, dangerous to arrive at a definite conclusion from this that ${}^2S\rightarrow{}^2S$ is not dominant. However that may be, the agreement between theory and experiment seems quite satisfactory.

Acknowledgment

The author wishes to express his cordial thanks to Prof. Kotani for his hearty guidance and encouragement. His thanks are also due to Dr. M. Shimizu and Dr. T. Izuyama for their assistance in the numerical calculation and their discussion.

Inelastic Scattering of Deuterons from C^{12}, Mg^{24} and Ni^{60}

By Yoshihide ISHIZAKI

Institute for Nuclear Study, University of Tokyo
Tanashi-machi, Tokyo

(Received February 4, 1961)

The absolute differential cross sections for the inelastic scattering of deuterons leading to the first excited state of C^{12} has been measured at the bombarding deuteron energies of 14.7, 15.9 and 18.1 MeV. Similar measurements were made on Mg^{24} at deuteron energies of 15.9 and 17.5 MeV and also on Ni^{60} at 18.1 MeV.

Deuterons are detected with thin CsI crystals, so that protons from (d, p) reactions do not contribute to the cross section. The energy resolution of the detectors is less than 4 percent.

The obtained angular distributions show a prominent peak at small angles in all the cases and the cross sections decrease at the extremely forward angles. Therefore it is not necessary to take into account the electric interaction to explain these reactions. These angular distributions are compared with the results at different deuteron energies given by other authors, and are observed to have an unusual energy dependence.

The data are analysed with the nuclear interaction theory of Huby and Newns. When the theoretical curve is normalized to fit to the measurement at the forward peak, disagreement between the theoretical curve and the experimental one occurs at the other places, which shows the need of modifing the theoretical calculations with the distorted wave approximation taking a proper optical potential to explain the reaction.

§ 1. Introduction

Measurements of inelastic scattering of deuterons are fewer than the cases for protons and alpha particles.

Haffner[1)] obtained the angular distributions of inelastically scattered deuterons from Li^6, Li^7, Be^9, C^{12}, Mg^{24} and Al^{27} at the bombarding energy of 15 MeV. He analysed his data according to the nuclear interaction theory of Huby and Newns[2)], the electric interaction theory of Mullin and Guth[3)], and from the stand point of compound-nucleus formation. According to his conclusion, for small angles the electric interaction theory seems to fit to the data better and for large angles the nuclear direct interaction theory gives better agreement, and the compound-nucleus formation does not seem to play a major role in the inelastic scattering of deuterons.

Yntema and Zeidman[4)] measured the inelastic scattering of 21.6 MeV deuteron by Ni, Cu, Zn, Ry, Ag, Sn, Gd, Ta, Pt and Au at the four angles of 30°, 60°, 90° and 140°. The angular distribution in each case shows a pronounced peaking in the forward direction, and no increases in the cross sections at backward angles are observed with increasing excitation of the residual nucleus. These facts suggest that the direct process plays a major role in the nuclear interaction of a deuteron and the evaporation process of deuterons from compound-nucleus does not contribute to the cross section.

The above mentioned conclusion about the formation of the compound nucleus, for the experiments at the deuteron energy near to 20 MeV, is reasonable since a deuteron is a loosely bound system and easily breaks under a slight influence of nuclear force, consequently it can not enter into the nucleus as a whole. Near 10 MeV, some experiments of inelastically scattered deuterons from relatively light nuclei were carried out by several authors[5)–14)]. These angular distributions also show a forward peak or peaking in the forward directions.

Recently the angular distributions of elastically and inelastically scattered protons and alpha particles have been found to depend strongly on the incident energy in some energy regions.[15)] This fact seems to show that, in order to discuss the reaction mechanism, measurements have to be made at various incident energies.

We also examined whether the diffrential cross section would decrease or not at extremely forward angles in order to analyse the contribution of the electric interaction process to the cross section. In our measurements at forward angles, the elastically scattered deuterons from hydrogen, which contaminates the targets, were eliminated very carefully. According to the theory of the electric interaction given by Mullin and Guth, the cross section should have a maximum in the forward direction. Most measurements of the inelastic scattering of deuterons carried out so far show a maximum in the forward direction, but these for protons do not. The influence of the electric interaction is considered to be similar for deuterons as well as for protons. Therefore, it is necessary to measure the cross sections at extremely forward angles.

§ 2. Experimental Procedure

The deuteron beam was obtained from INS (Tokyo) variable energy cyclotron.[16)] The beam entered through a focusing system into a scattering chamber. The arrangement of them and the beam collector were quite similar to those described in reference.[17)] The scattering chamber has seventeen windows with 10° interval from 10° to 170° on the wall on the right side of the incident beam direction and sixteen from 15° to 165° on the left side. Each window was covered with a sheet of aluminized mylar of 1 mil. in thickness.

Fourteen scintillation counters attached to the side windows were used at the same time.

The solid angle subtended by the detector was determined by the defining slit attached to the side window. The solid angles were made to increase from forward to backward angles. The diameters of the defining apertures, placed 505 mm apart from the center of the chamber, were 3 mm at 10° and 15°, 5 mm at angles from 20° to 60°, 8 mm from 65° to 85°, and 10 mm from 90° to 165° Such change of the solid angles made the measurements easier without large change of the beam intensity.

The scattered deuterons were detected by CsI crystals. In our targets, (d, p) reactions leading to the excited states produce protons with approximately the same energy as the inelastically scattered deuterons, and therefore it is necessary to exclude the protons having the energy near to that of the desired deuteron. We made use of the fact that the range of a deuteron in the energy region of this experiment is considerably less than that of a proton with the same energy.

Table I shows the thickness of CsI crystals used in the present experiment and energies of a deuteron and a proton corresponding to the range equal to the thickness.

Between a window of the scattering chamber and a detector, an aluminium absorber

Table I. Deuteron energy and proton energy corresponding to the range equal to the thickness of CsI crystals used in this experiment.

thickness of CsI crystal (mm)	1.1	0.77	0.70	0.51	0.36	0.22	0.16
deuteron energy (MeV)	20.0	16.0	15.0	12.5	10.0	7.2	6.0
proton energy (MeV)	15.5	12.5	11.5	9.5	7.5	5.5	4.6

was inserted, which reduced the energies of alpha particles produced by (*d*, *α*) reactions to much lower energy than that of a measured deuteron, when necessary.

We made about ten pieces of uniform crystal for each one shown in Table I.

Energies of all protons which stopped in the crystal were always made at least 1 MeV smaller than the energy of a measured deuteron. Thus, even at the widely different incident deuteron energies, we could use the fourteen scintillation counters at the same time to measure the angular distribution of the inelastically scattered deuterons from C^{12} ($Q=-4.43$ MeV), Mg^{24} ($Q=-1.37$ MeV), and Ni^{60} ($Q=-1.33$ MeV) by adjusting the thicknesses of absorbers and crystals.

The detectors were similar to those described elsewhere[16)], except for the crystals. RCA 6342 and 5819 photomultipliers were used.

The foil targets were set at the center of the scattering chamber making an angle of 45° on the right or left side of the incident beam direction. In almost all cases, detection was made at angles with 5° intervals from 10° or 15°, but in some cases at 10° intervals.

In order to minimize the fluctuation of the gains of photomultipliers, high voltage was always being fed to each counter, and the pulses from it were sent through a cathode follower and a coaxial cable to the measuring room, where electronic circuits were located. We used ten linear amplifiers and four multichannel pulse height analysers, so that we could measure the energy spectra at four angles simultaneously. For the investigation of the angular distribution, we measured the beam current by a current integrator and the yield of the monitor counter in each run of measurement. We repeated the measurement at the same angle several times on different days, and results were in satisfactory agreement with each other.

The target of self-supporting film of natural carbon was prepared from colloidal solution of graphite, and the thickness was 2.38 mg/cm²*. This did not contain any detectable impurity except hydrogen. The targets of self-supporting film of natural magnesium were measured to be 2.22 mg/cm² and 2.37 mg/cm² in thickness. Both of them were used. The foil target of Ni^{60} was manufactured by A.E.R.E. and its thickness was 2.42 mg/cm². After the measurements at fourteen angles, the scintillation counters were removed to the other angles, and exchanges of absorbers and crystals to those with proper thickness were carried out, when necessary.

The error involved in the measurement of beam energy is estimated to be 100 KeV, and energy spread may be within 1 percent.

The corrections for the slit edge effect and the multiple scattering were neglected in the analysis of the present data.

The pulse height spectra obtained for the charged particles resulting from the deuteron bombardment of the targets are shown in

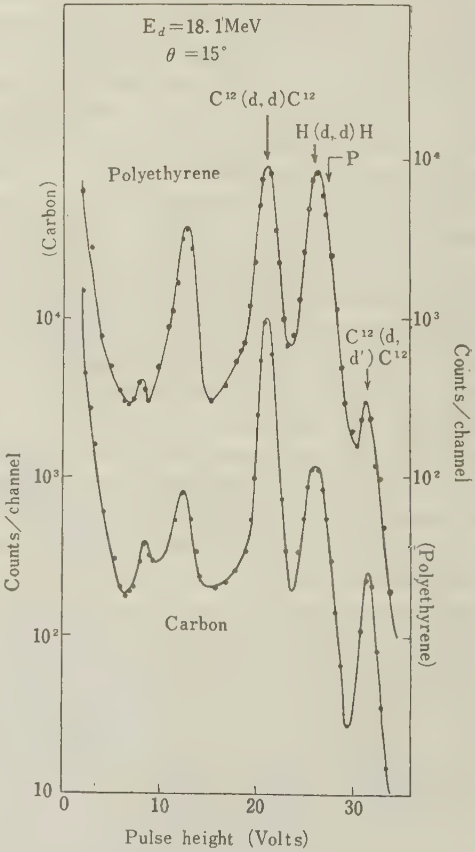

Fig. 1. The pulse height spectra of the charged particles resulting from deuteron bombardment on carbon target and polyethylene with $E_d=18.1$ MeV at 15°. Elastically scattered deuterons pass through the scintillator. Arrow *P* indicates the maximum pulse height of protons obtained in the scintillator.

---

* We are indebted to Dr. Mikumo of Institute for Nuclear Study for the preparation of the target.

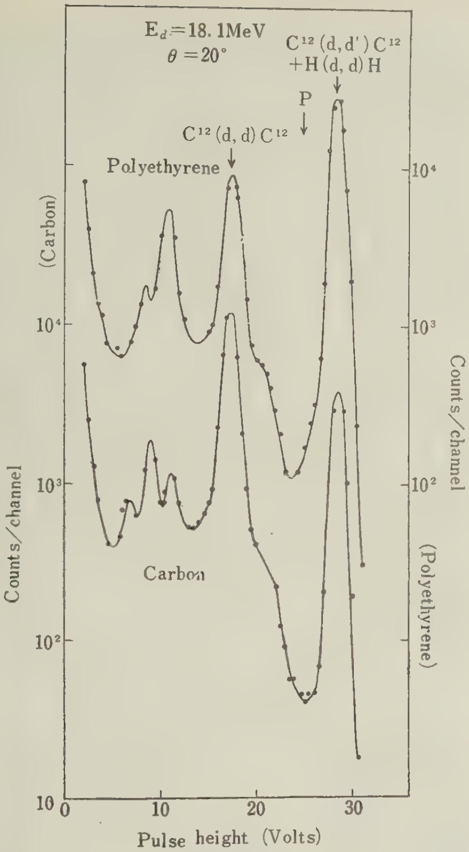

Fig. 2. The pulse height spectra of the charged particles resulting from the deuteron bombardment on carbon target and polyethlene with E_d=18.1 MeV at 20°. Elastically scattered deuterons pass through the scintillator.

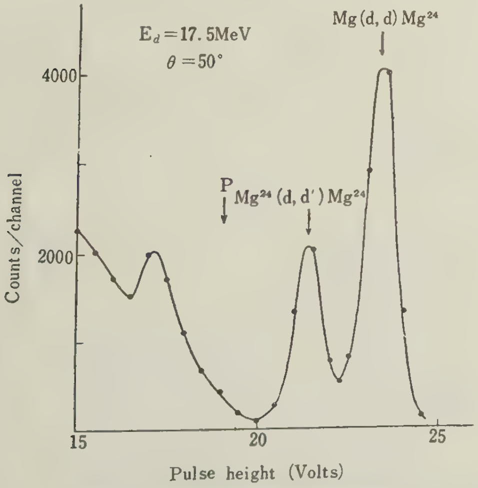

Fig. 3. The pulse height spectra of the charged particles resulting from the deuteron bombardment on Mg^{24} with E_d=17.5 MeV at 50°.

Figs. 1 to 5. Arrows *P* in Figs. 1 to 5 indicate the maximum pulse heights of protons obtained in the CsI scintillators used in the detection of deuterons. In the case of C^{12} the elastically scattered deuterons passed through the CsI crystal. As shown in Figs. 1 and 2, in which we compared the energy spectra resulting from carbon target with those from polyethylene, our carbon target is thought to contain a little amount of hydrogen, and at 20° the energy of an inelastically scatter-

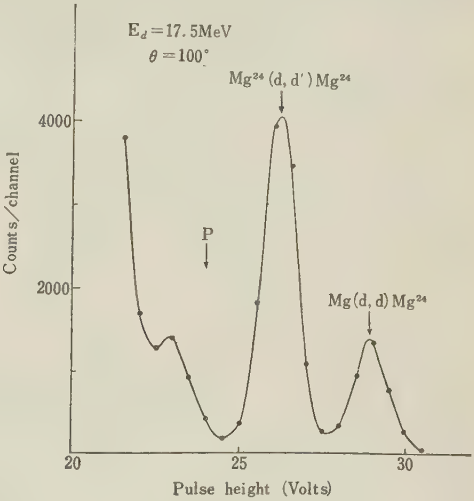

Fig. 4. The pulse height spectra of the charged particles resulting from the deuteron bombardment on Mg^{24} with E_d=17.5 MeV at 100°.

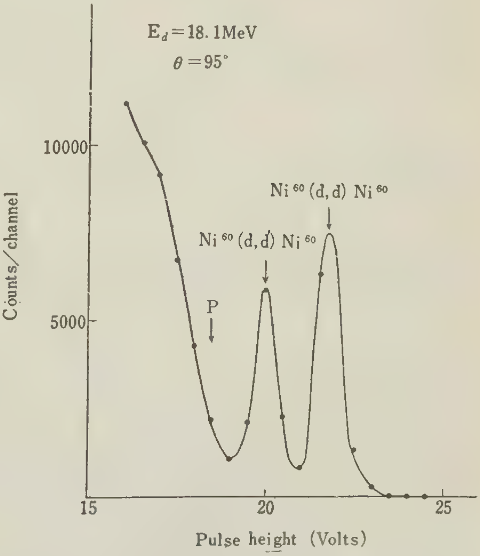

Fig. 5. The pulse height spectra of the charged particles resulting from the deutron bombardment on Ni^{60} with E_d=18.1 MeV at 95°.

ed deuteron from C^{12} leading to the first excited state nearly agrees to that of an elastically scattered deuteron from hydrogen at our bombarding energies. We can not resolve these two deutrons. Therefore, we deduced the angular distribution of deuterons elastically scattered by hydrogen from our data measured at angles of 10°, 15° and 25°, with reference to other experiments.[18)–19)] Then, we could obtain the cross section of inelastically scattered deuterons from C^{12} at 20° by subtraction.

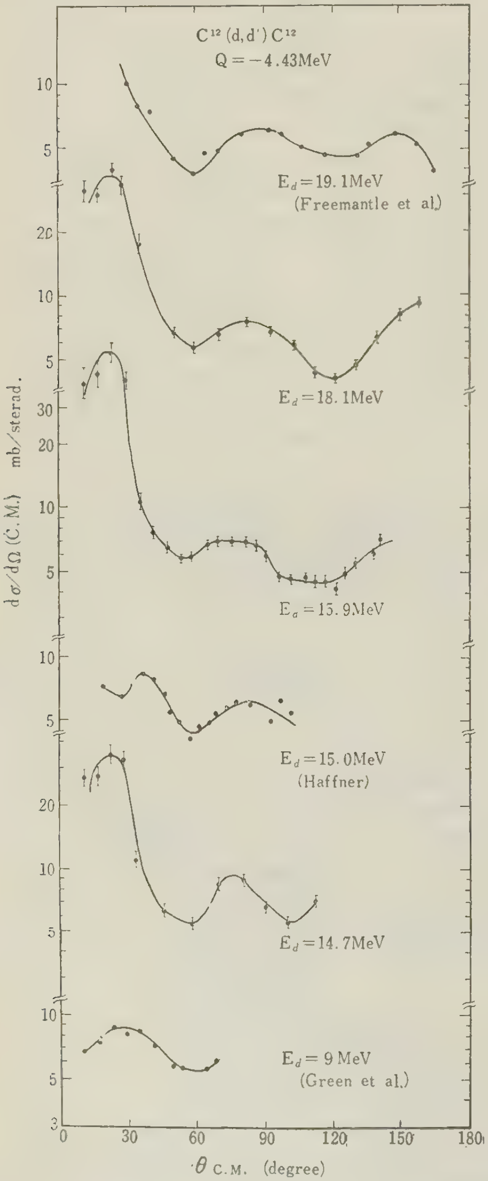

Fig. 6. Angular distributions of the inelastically scattered deuterons from C^{12} leading to the 4.43 MeV state at various bombarding energies.

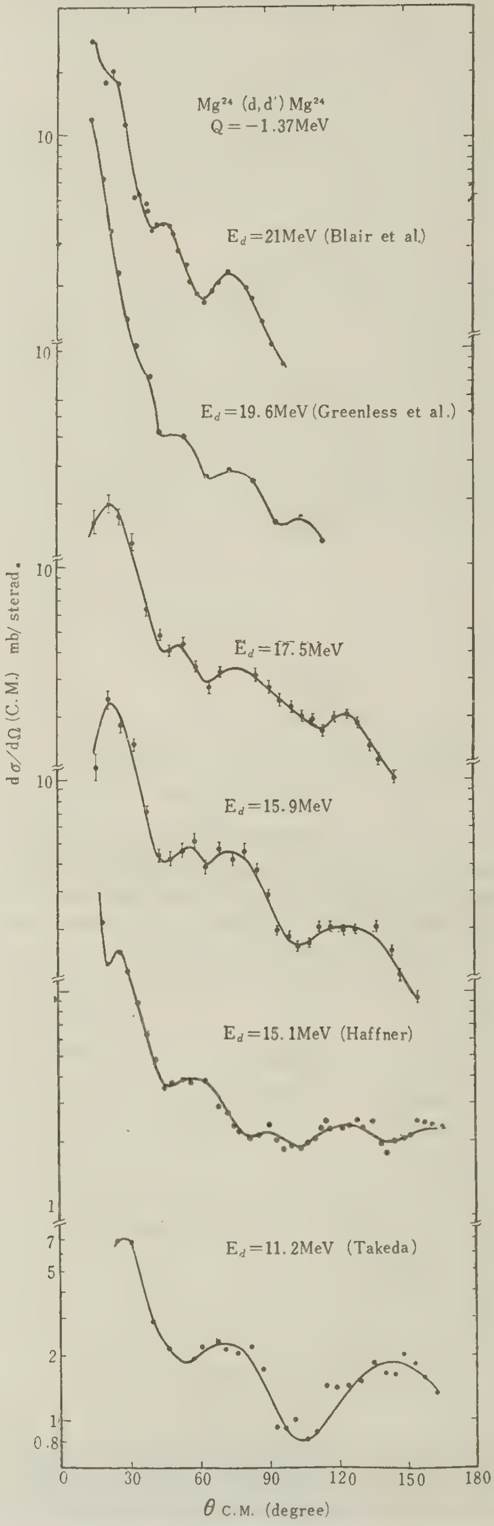

Fig. 7. Angular distributions of the inelastically scattered deuterons from Mg^{24} leading to the 1.37 MeV state at various bombarding energies.

§ 3. Results and Discussions

Angular distributions of the inelastic scattering leading to the 4.43 MeV state of C^{12} were obtained at the incident deuteron energies E_d=14.7, 15.9 and 18.1 MeV. In Fig. 6, we show the results together with those obtained by other authors at different energies. The curves obtained by us are very similar with one another, however not so similar to the quoted data, and have a forward peak at the angle near to 25°.

The angular distributions of inelastically scattered deuterons from Mg^{24} leading to the 1.37 MeV state are shown in Fig. 7. The curves at E_d=15.9 and 17.5 MeV were obtained in this experiment. The curves have a forward peak near to 22°.

The electric interaction theory, given by Mullin and Guth, assumes the interaction potential

$$V=\sum_{n=1}^{Z}\frac{ze^2}{|\mathbf{r}-\mathbf{R}_n|}, \quad \text{for } r\geq r_0 ,$$

$$=0 , \quad \text{for } r\leq r_0$$

where $\mathbf{r}$=the distance of the incident deuteron from the center of the target nucleus, Z, z are the atomic number of the scattering nucleus and the projectile, the sum of their radii is taken as r_0 and $\mathbf{R}_n$ is the coordinate of the n-th particle in the nucleus.

The important factor determining the angular distribution for electric quadrupole transition is

$$\frac{d\sigma}{d\Omega}\propto\left[\frac{j_1(Kr_0)}{Kr_0}\right]^2,$$

where $K=|\mathbf{K}_1-\mathbf{K}_2|$ is the difference between the wave numbers of the initial and the final deuteron, and $j_1(Kr_0)$=spherical Bessel function. This theory predicts a maximum in the forward direction for our cases concerned here.

According to the present experimental results obtained for C^{12} and Mg^{24}, the cross section decreases in the extremely forward direction. Therefore, we can conclude that in the inelastic scattering of a deuteron, the electric interaction process between a deuteron and a nucleus has scarcely any contribution to the cross section.

Fig. 8 shows the angular distribution of inelastically scattered deuterons from Ni^{60} to the 1.33 MeV state. The curve shows a typical diffraction pattern.

One of the characteristic features of the present angular distributions is the increase of the number of diffraction oscillations with atomic mass. The ratio of the cross sections at the forward to backward angles increases with increasing energy and atomic mass.

From all the curves shown in Fig. 6, we see that all the first minima (in the case of Haffner, second minimum) appear at the same angle of 60°, and the second peak shifts a little to larger angles, and broadens out when the energy of bombardment increases from 14 to 20 MeV.

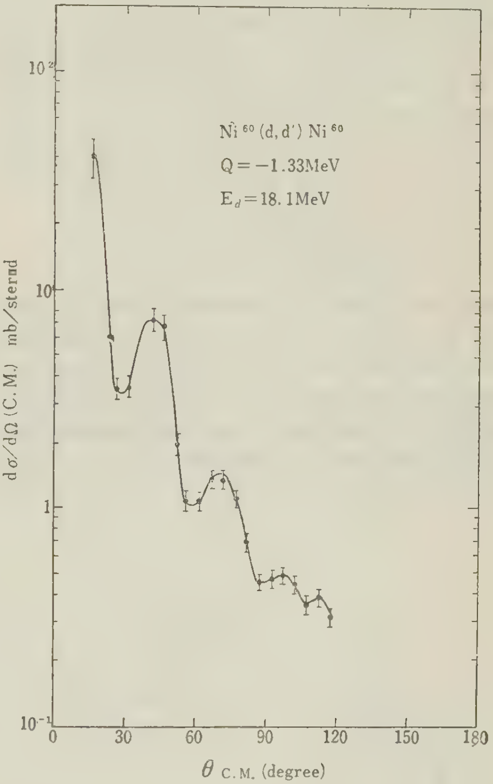

Fig. 8. Angular distribution of the inelastically scattered deuterons from Ni^{60} leading to the 1.33 MeV state.

Fig. 7 shows that the first maximum and the first minimum shift by small amounts to the forward direction with a large increase of the incident energy. The second peak of the curve obtained at E_d=11.2 MeV splits into two peaks, which we call peaks A and B, as the bombarding energy increases. Peak A is much larger than Peak B at E_d= 15.1 MeV. Then, A moves to the forward angle and its amount decrases gradually with increasing energy, and B grows up suddenly at $E_d=15.9$ MeV largely shifting to smaller angles. B decreases gradually with increasing energy from $E_d=15.9$ MeV. These characters do not appear in the case of elastic scattering of deuterons at the same range of the energy in our other experiments.[20]

As mentioned in § 1, compound-nucleus process does not contribute to the cross section. Huby and Newns have developed the direct interaction theory for the inelastic scattering of deuterons in somewhat analogous way to the (d, p) theories of Butler and others.[21] The angular distribution was derived in the plane-wave Born approximation.

We compared our results with the theory of Huby and Newns, in which the differential cross section is of the form

$$\frac{d\sigma(\theta)}{d\Omega}=\sum|A_l|^2\left\{\left[\frac{4\alpha}{K}\cdot\tan^{-1}\left(\frac{K}{4\alpha}\right)\right]\cdot\left(\frac{\pi}{2K\alpha}\right)^{1/2}J_{l+1/2}(Ka)\right\}^2$$

where $\alpha=(1/\hbar)\times(M_p\times\text{deuteron binding energy})^{1/2}=0.23\times10^{13}\ \mathrm{cm}^{-1}$, K is the difference of wave numbers of the deuteron before and after the collision; $K=|\mathbf{K}_i-\mathbf{K}_f|$, $a=$the interaction radius, and $J_{l+1/2}(Ka)=$Bessel functions of the half-integral order. The A_ls are constants suitably chosen. The most important factor determining the angular distribution is $[J_{l+1/2}(Ka)]^2/Ka$. This theory predicts the drop in the forward direction except for the case where $l=0$.

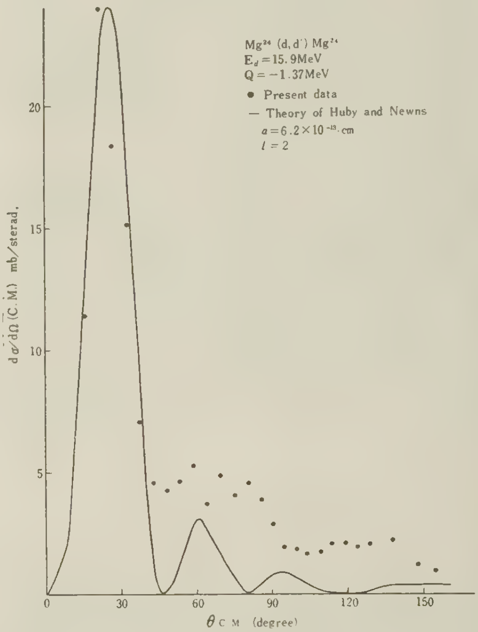

Fig. 10. Comparison of the $Mg^{24}(d, d')Mg^{24}$ angular distribution at $E_d=15.9$ MeV with the nuclear interaction theory of Huby and Newns.

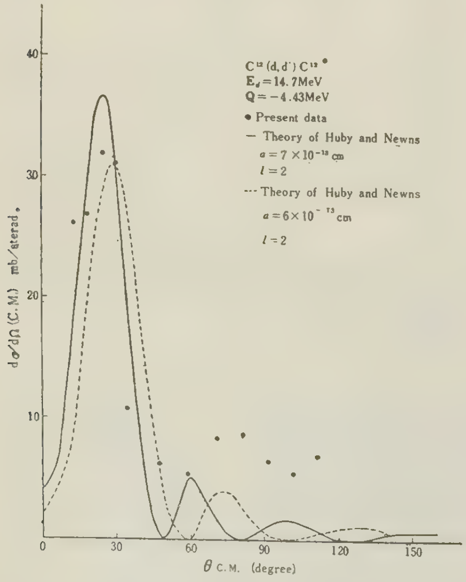

Fig. 9. Comparison of the $C^{12}(d, d')C^{12}$ angular distribution at $E_d=14.7$ MeV with the nuclear interaction theory of Huby and Newns.

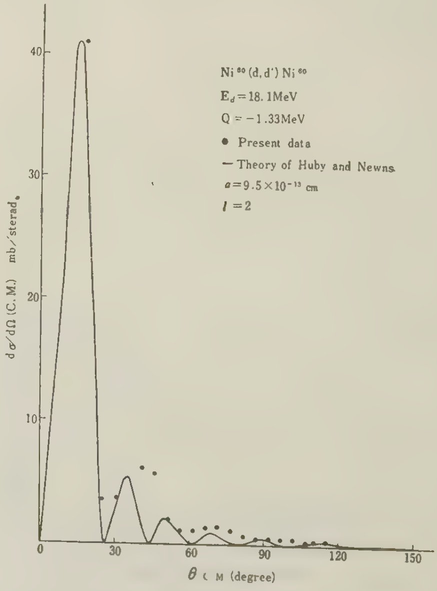

Fig. 11. Comparison of the $Ni^{60}(d, d')Ni^{60}$ angular distribution at $E_d=18.1$ MeV with the nuclear interaction theory of Huby and Newns.

In Figs. 9 to 11 results are shown in the cases of C^{12}, Mg^{24} and Ni^{60} at $E_d=14.7$, 15.9 and 18.1 MeV, respectively. The characteristic features are rather well reproduced by the theory except that the interaction radius of C^{12} for deuteron is too large.

If theoretical values are normalized to fit the experiment at the forward peak, however, theoretical cross sections are so much small at rather large angles. The data at forward angles were also analysed in terms of the diffraction scattering formula of Blair,[22] in which the cross section of inelastic scattering by quadrupole surface excitation of an even-even nucleus is expressed as

$$\frac{d\sigma(\theta)}{d\Omega}(0\rightarrow 2)=(ka^2)^2\left(\frac{5}{4\pi}\right)\cdot\left(\frac{\hbar\omega_2}{2C_2}\right)\cdot\left\{\frac{1}{4}\,[J_0(ka\theta)]^2+\frac{3}{4}[J_2(ka\theta)]^2\right\},$$

where $\hbar\omega_2$ is the excitation energy of the final nucleus and C_2 is the surface tension parameter.

Some results are given in Figs. 12 and 13. The values of a in the Figs. 12 and 13 are those that fit the data of the elastic scattering obtained in our other experiment.[20]

In order to explain the present experiments by direct nuclear interaction process at all angles, it seems to be necessary to calculate with a distorted wave approximation, using a proper optical potential. However, it is uncertain if the strong dependence on energy in the angular distributions for Mg^{24} can be explained with the optical potential having a large imaginary part. Further measurements of the angular distributions seem to be

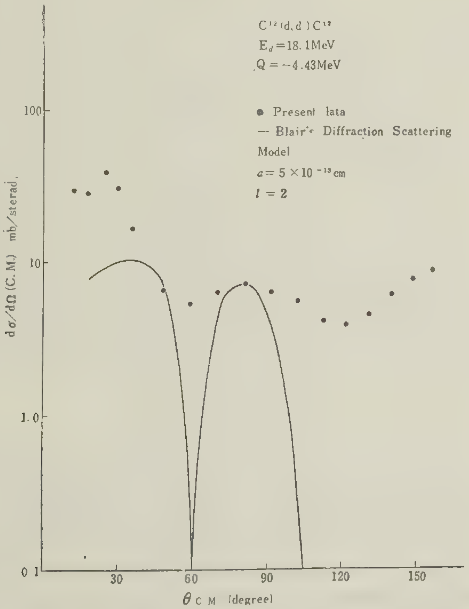

Fig. 12. Comparison of the $C^{12}(d, d')C^{12}$ angular distribution at $E_d=18.1$ MeV with Blair's diffraction scattering model.

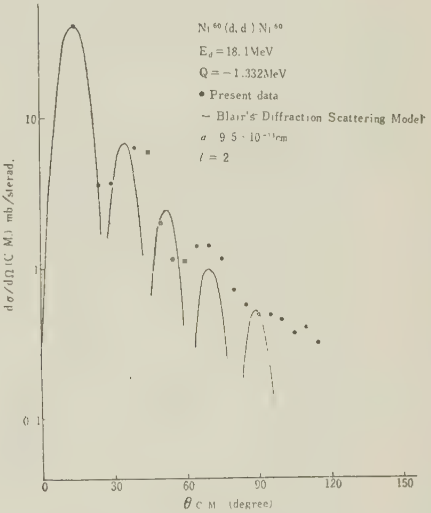

Fig. 13. Comparison of the $Ni^{60}(d, d')Ni^{60}$ angular distribution at $E_d=18.1$ MeV with Blair's diffraction scattering model.

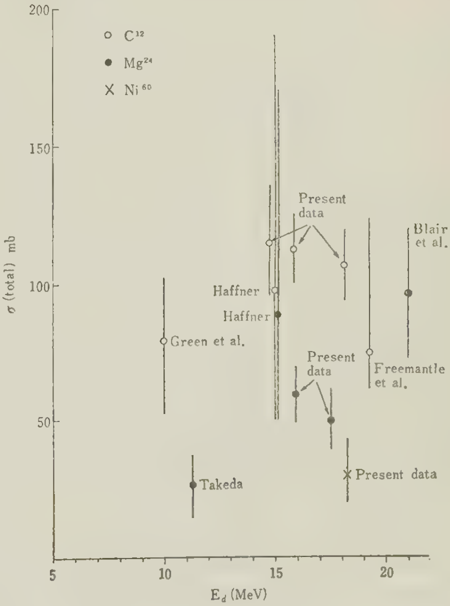

Fig. 14. The total cross sections for inelastic scattering leading to the 1st excited states of C^{12}, Mg^{24} and Ni^{60}.

desirable with smaller changes of the incident energy in order to clarify what is responsible for such a strong dependence.

Fig. 14 gives the total cross sections for the inelastic scattering leading to the first excited states of C^{12}, Mg^{24} and Ni^{60} at the various deuteron energies. All the values are calculated from the absolute differential cross sections reported here, except for the value given by Haffner. The error shown in Fig. 14 comes from an uncertainty in estimating the total cross section from the given differential cross section.

The total cross sections for C^{12} and Mg^{24} seem to increase up to about 14 MeV incident energy, and then decrease gradually with increasing energy. The values for the deuterons are about 2/3 times those for the protons in the case of C^{12}, about 1/2 in Mg^{24} and nearly 2/3 in Ni^{60}, in the measurements at nearly equal deuteron and proton energies.[23)]

In the general form, the differential cross section for the direct process is given by

$$\frac{d\sigma(\theta)}{d\Omega}=\frac{K_f}{K_i}\cdot\left(\frac{M_i}{2\pi\hbar^2}\right)^2\cdot\frac{1}{2I_i+1}\cdot\sum_{i,f}|\langle f\,|V|i\rangle|^2\,,$$

where K=the wave number, i and f indicate the initial and final state respectively, M_i= the mass of the incident particle, I_i=the total spin of the target nucleus in the initial state and V=the interaction potential. If we measure the cross sections of inelastic scattering of a deuteron and a proton of the same wave number, the geometrical factor of the cross section shows that the cross section for a deuteron is four times the cross section for a proton. When the energy of the incident beam is much larger than the absolute Q value, K_f/K_i is nearly equal to 1. Therefore, the ratio of the total cross section for a deuteron to that for a proton may be estimated as about 4 for the same target and Q value, provided that transition matrix elements are also same. However, these ratios in our measurements for C^{12} ($Q=-4.43$ MeV), Mg^{24} ($Q=-1.37$ MeV) and Ni^{60} ($Q=-1.33$ MeV) are nearly equal to 1/2. This suggests that the matrix element for deuteron is about one-third to that for protons. The reduction of the transition probability for a deuteron is infered to be due to large imaginary part of optical potential for a deuteron than that for a proton.[24)]

In the collective model of a nucleus, the interaction between a incident particle and a nucleus is approximated to occur mainly on the nuclear surface. The target nuclei used in this experiment have some evidence of the collective nature.

The transition probability from the first excited state with 2^+ spin to the ground state with 0^+ spin gives a useful information on the structure of the nucleus. The Table II shows the measured mean lives and the ratios of theoretical and experimental values of the nuclear transitions concerned here.

Table II. Measured mean lives of $2^+ \to 0^+$ transitions and the ratios of theoretical and experimental values.

Nucleus	Mean life τ	ratio $\tau_{exp.}/\tau_{theo.}$
C^{12}	2.6×10^{-14} sec	22
Mg^{24}	2.5×10^{-11}	0.32
Ni^{60}	1×10^{-12}	5.1

Data are taken from references 27)~29).

Here the theoretical values of the mean lives are calculated on the basis of the single particle model. As can be seen from the table, the ratios are remarkably large in C^{12} and Ni^{60}. These large values are probably due to the contribution from the collective excitations in these nuclei. In case of nucleus with closed shell, the effect of the collective excitation may be smaller, but can not be neglected, as shown in the analysis by Kisslinger and Sorensen on Sn^{120}, for which the ratio is 4.4.[25),26)] The small value of the ratio in Mg^{24} is hard to be understood and might be due to mistake of the measurement or some selection rule which makes the collective excitation improbable. We think that the study of nuclear reaction gives frequently useful informations on the structure of nuclei.

Acknowledgement

The author wishes to thank Professor I. Nonaka for continuous encouragement. His thanks are also expressed to Drs. T. Ishimatsu, T. Nakamura, Y. Nakano, Y. Saji and S. Yasumi for their helps through this experiment. He thanks Drs. M. Sano, S. Okai and R. Eisberg for discussion and comments to the manuscript. His thanks are due to Mr. T. Karasawa and other operating crew of the cyclotron, and Mr. Y. Yoshimura for the preparation of the electronic circuits.

Anomalies in the Scattering of Alpha Particles by Carbon

By Takashi Mikumo

Institute for Nuclear Study, University of Tokyo,
Tanashi-machi, Kitatama-gun, Tokyo, Japan

(Received February 4, 1961)

Angular distributions of elastic and inelastic scattering ($Q=-4.43$ MeV) of alpha particles by the carbon nucleus have been measured at eight different alpha particle energies between 27.0 and 35.5 MeV. These data are discussed together with those reported previously in this journal and with those of other authors.

Angular distributions for both elastic and inelastic alphas show remarkable variation with bombarding energy and cannot be explained with simple direct interaction theories. There appear anomalies in the angular distributions for E_α in the neighbourhood of 30 MeV. Also in the excitation energy near 30 MeV in the compound system, some resonances were found in the elastic excitation function and in the integrated cross section for the inelastic scattering ($Q=-4.43$ MeV). Even at such high excitation energies the effect of the compound system seems to be important.

§ 1. Introduction

In the course of our experiments, previously done in this Institute[1], angular distributions of alpha particles scattered elastically and inelastically ($Q=-4.43$ MeV) by the carbon nucleus were measured at incident alpha particle energies 33.4, 30.7 ahd 28.2 MeV.* (At the last energy, angular distributions of inelastic alpha groups corresponding to $Q=-7.66$, -9.63 and $\simeq -12.7$ MeV were also measured.) In that paper it was reported that some features for the elastic and the inelastic scattering ($Q=-4.43$ MeV) at forward angles seemed to reflect an important contribution of diffraction scattering mechanism such as that discussed by Blair[2]: for example, sharp diffraction patterns in both elastic and inelastic angular distributions; the general out-of-phase relation between both angular distributions; and the large absolute cross sections for the inelastic scattering. On the other hand, the following characteristics were not likely to be explained by Blair theory: the remarkable changes of cross sections and angular distributions with energy in both scattering; the rise of the cross sections at backward angles, especially for the inelastic scattering; the change of the value of the interaction radius R_0 wifh incident alpha energy E_α for the elastic scattering, as calculated after Blair theory, especially the sudden change of R_0 for E_α around 30 MeV.

In addition, Watters[3] had found an anomaly in the elastic angular distribution at 31.5 MeV, which appeared as a plateau at $\theta_{\text{c.m.}} \simeq 60°$. Such an anomaly cannot be understood with the current theories. Nobody else,[4)–12)] however, found such an anomaly at this angular region. Many circumstances for $E_\alpha < 30$ MeV seemed different from those for $E_\alpha > 30$ MeV, for example, the number of the peaks in the angular distributions appeared smaller at $E_\alpha < 30$ MeV than at higher energies. In the energy region, $E_\alpha \simeq 30$ MeV, however, there were very few data published.

Even if the separate data of $\alpha' - \gamma$ angular correlation[13] and some of the angular distributions[14] seemed compatible with the predictions of direct interaction theories, the ensemble of the data reflected the complicated character of the scattering mechanism. In order to elucidate the mechanism it was considered to be necessary to obtain more data, especially to know behaviours around 30 MeV. So, in the present experiment, angular distributions of elastic and inelastic scattering were measured at eight more incident alpha energies ranging from 27.0 to 35.5 MeV. For the study of such an energy-sensitive behaviour the variable-energy cyclotron of this Institute is particularly suitable.

---

* Energy values quoted here are slightly smaller than those reported in ref. 1. This is due to the different references from which range-energy relation are taken. See discussions in § 2B.

The data obtained here show several anomalies for $E_\alpha \simeq 30$ MeV: reproduction of Watters' plateau at somewhat different energy; disappearance of a peak in the angular distributions for both scattering found at higher energies; large value of R_0 compared with that obtained at other energies; some resonance phenomena in the elastic excitation function and in the integrated cross section σ_t for the inelastic scattering.

These facts, together with similar phenomena recently found in this Institute with oxygen and nitrogen, may throw some light on the study of the reaction mechanism and the structure of light nuclei.

§ 2. Experimental Produce

A. *Experimental apparatus*

Details of the 160 cm INS (Tokyo) variable-energy cyclotron[15], the beam focussing system[15] and the scattering apparatus[1],[16] were reported previously. Several modifications were made which are described in the following:

i) In order to see the change of angular distributions of scattered alpha particles with a slight change of beam energy, the target was made as thin as possible. A self-supporting carbon target 1.37 mg/cm² thick was made by the method described in refs. 1 and 16. This corresponds to energy loss of 200 to 300 keV at the relevant alpha particle energies. With this target much better resolution in the histogram was obtained even at backward angles:

ii) Three detectors were placed on the turntable in the 100 cm scattering chamber, instead of two. They were called "extreme-forward," "forward" and "backward" detectors; the last two were 180° apart and the first was on the same side as the third with regards to the beam direction and made an angle of 45° with each other. Fig. 1 shows the arrangement in the scattering chamber. The defining slits for the three detectors were of 2 mm, 3 mm and 6 mm diameter, respectively. Thus we could obtain data at small angles without unduly diminishing the beam intensity. In doing so, however, the minimum laboratory angle attainable was as large as

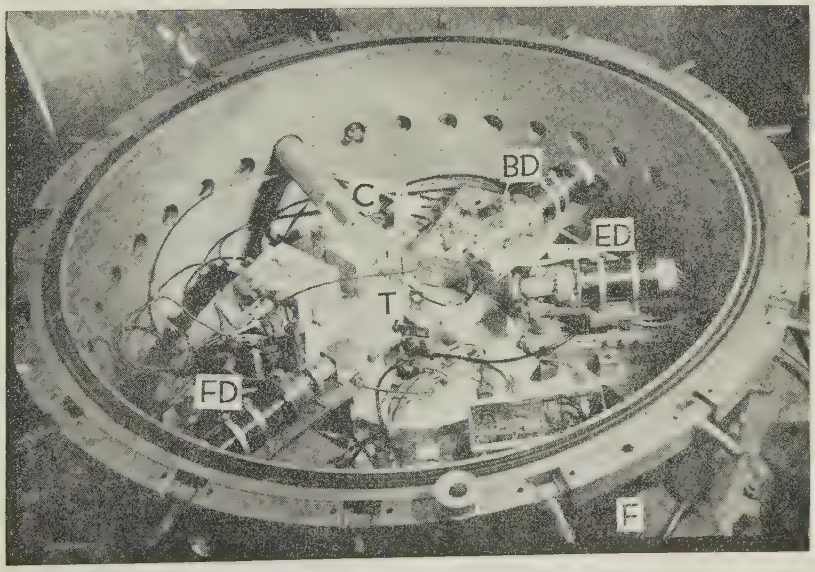

Fig. 1. Arrangement of detectors in the scattering chamber.

C : Beam collimator.
F : Faraday cup.
T : Target holder.
FD: Forward detector (Proportional counter not used is seen between defining slit and scintillation counter).
BD: Backward detector.
ED: Extreme-forward detector.

20°; the lack of data at extremely small angles was somewhat of a handicap in making the analysis.

The angular resolutions for three detectors were about, 0.5°, 0.8° and 1.7° (full angles).

The extreme-forward detector took data between 20° and 35°, the forward detector between 30° and 100°, the backward detector between 85° and 150°, the last two took data simultaneously.

iii) A proportional counter-scintillation counter telescope was used only as the backward detector; each of the other two detectors consisted of only a scintillation counter. During the course of earlier experiments[1)], we had confirmed that it is not necessary to employ proportional counters for α_0 (elastic alphas) and α_1 (inelastic alphas, $Q=-4.43$ MeV) for the small angles, (In Fig. 1 a proportional counter not used is shown in front of the forward scintillation counter.) The proportional counter for the backward detector contained about 30 cm Hg of Argon-CO_2 mixture (5% CO_2). Pulses from the proportional counter, amplified and biased adequately so as not to miss elastic alphas but to discriminate out singly charged particles, opened the gate for pulses from the scintillation counter into multi-channel pulse height analysers.

iv) The CsI(Tl) crystals used for scintillation counters were made as thin as possible. The thicknesses of crystals for three detectors were 0.45 mm, 0.45 mm and 0.3 mm, respectively. At the highest energies an aluminium absorber was inserted in front of the extreme-forward detector in order to stop elastic alphas in the crystal.

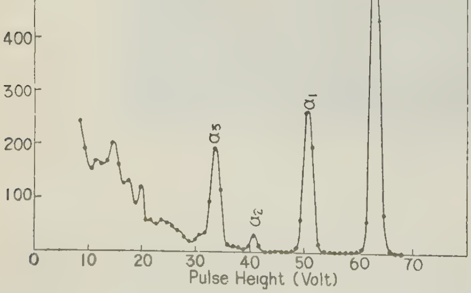

Fig. 2. Typical histogram obtained with extreme-forward detector at $\Theta_{lab}=35°$ and $E_\alpha=35.5$ MeV.

A typical histogram obtained with the forward detector is shown in Fig. 2.

B. *Beam energy measurement*

The energy of the alpha particle beam was determined with the same apparatus as was used in refs. 1 and 16, i.e., a device consisting of aluminium absorbers and an ionisation chamber placed just behind the rear flange of the Faraday cup of the scattering chamber, at the centre of which was a small window of an aluminium foil. Changing the thickness of absorbers one could obtain a Bragg curve and the mean energy of incident alpha beam was determined. At the beginning and/or at the end of each energy run the energy was measured. In refs. 1 and 16 we used range-energy relations of protons in aluminium, carbon and air after Aron et al.[17)] and converted them to alpha particles. This time range-energy relations of protons in aluminium after Bichsel et al.[18)] were used. For carbon and air we were obliged to make use of those of Aron et al. With the aid of these relations, effective energies were estimated to be 35.5, 34.5, 30.7, 30.2, 30.0, 29.8, 29.6 and 27.0 MeV. In order to get the last energy, an aluminium absorber was inserted in front of the beam collimator at the entrance of the scattering chamber.

The beam energies reported in refs. 1 and 16 are higher than would be calculated with Bichsel's relation, according to which the mean alpha particle energies used in 1 were 33.4, 30.7 and 28.7 MeV. In the following discussions these corrected energy values will be used.

C. *Errors*

The width of beam energy was estimated, using a beam analysing magnet (whose momentum resolution being less than 0.1%), to be around 0.5%[19)]. The drift of beam energy in the course of an energy run is due to drifts of the magnetic field of the cyclotron and the focusing magnet, of oscillation frequency, and of dee voltage. The drift of mean energy due to these causes was estimated to be less than 0.5%. This slight drift of energy introduced, however, as will be mentioned below, a considerable change in the differential cross sections of elastic scattering in some angular region at $E_\alpha \simeq 29.8$ MeV.

Uncertainty in the absolute value of each energy was within 300 keV or so, but that in the relative value was much less.

At higher energies ($E_\alpha = 35.5$, 3.45 and 31.4 MeV), because of an improper path, the focused beam did not hit the target at the centre. This caused a disagreement in reading of about 1° between the extreme-forward and forward detectors at a corresponding angle, as these two detectors viewed the beam from oposite sides. Corrections to the angles were therefore made. At lower energies the beam passed through the centre of the target and the readings of angles with three detectors were very consistent. (Uncertainty in the scattering angles: ±0.2°)

The errors in the solid angles of three detectors were estimated to be less than a few per cent. Absolute cross sections obtained with the forward and backward detectors showed, however, disagreements as high as 20% at some corresponding angles, particularly when the overlapping angles corresponded to steep sides of angular distributions. The backward cross sections were normalized to the corresponding forward ones.

The uncertainty in target thickness, mainly due to its inhomogeneity, was estimated to be less than 10%.

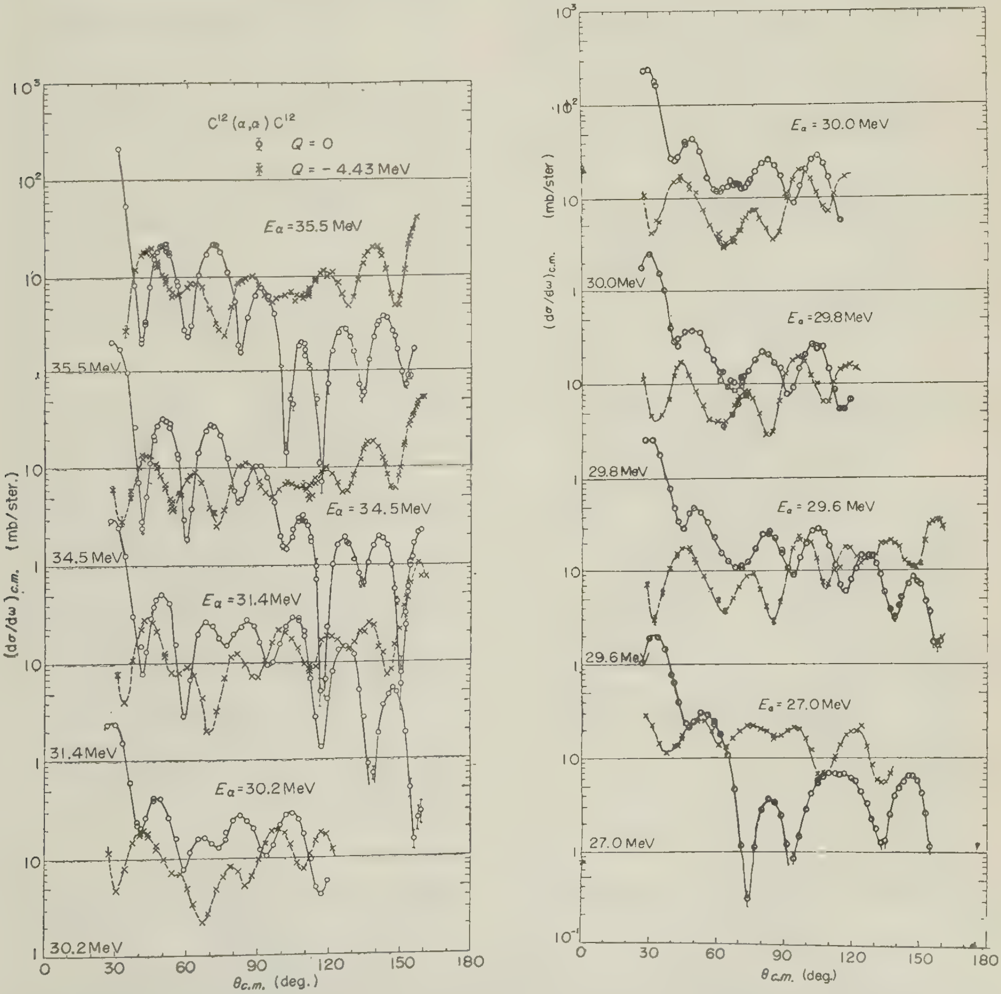

Fig. 3. Angular distributions for both elastic and inelastic (α_0) scattering (α_1) obtained at eight alpha particle energies.

Statistical errors ranged from less than 1% to about 20% depending on the angular position.

Errors due to background subtraction were small, except for α_1 at backward angles at the lowest energy (27.0 MeV), where these errors were sometimes as large as 20%.

The absolute values of cross sections were estimated to be correct to within 20 to 30%.

§ 3. Experimental Results

Differential cross sections for both elastic and inelastic scattering ($Q=-4.43$ MeV) obtained at eight alpha-particle energies are shown in Fig. 3.

Angular distributions for α_0 expressed as ratios to Rutherford cross sections are in Fig. 4, where data of our previous experiments at 33.4, 30.7 and 28.2 MeV* and those

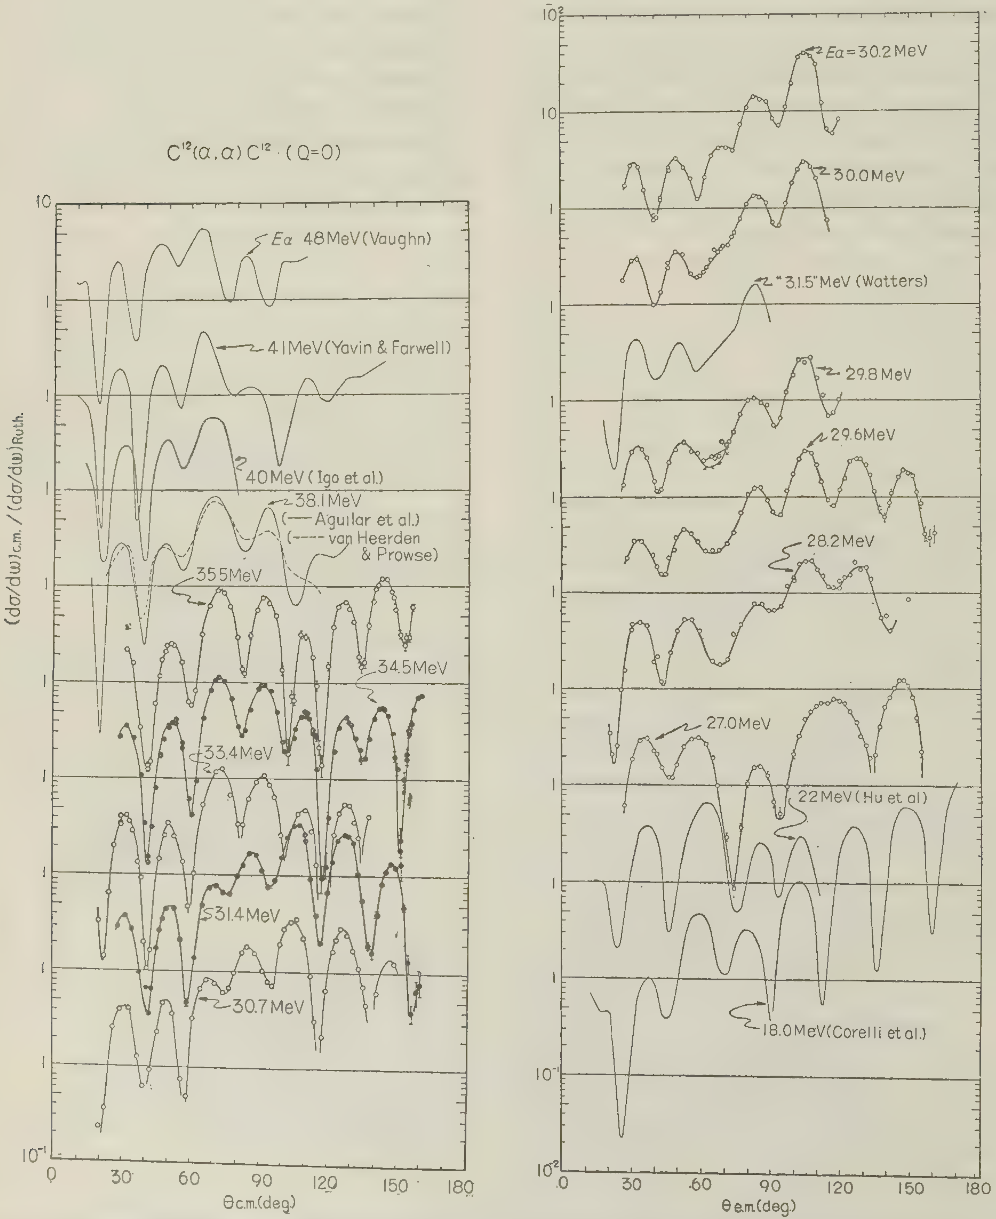

Fig. 4. Angular distributions for α_0 expressed as ratios to Rutherford cross sections. Points × show the change of angular distribution at $E_\alpha \simeq 29.8$ MeV with non-measurable variation of cyclotron energy.

---

* See caption of p. 2 and Sec. 2B.

published by many authors are also presented.

Angular distributions for α_1 are shown in Fig. 5, together with our previous data and those of other authors.

At first sight, angular distributions for both α_0 and α_1 show striking diffraction patterns. It is very difficult to find any systematic variation of the angular distributions with energy. In general the out-of-phase relation between the α_0 and α_1 angular distributions are roughly satisfied, except at several singular points. Elastic scattering and inelastic scattering are therefore closely correlated, but the peak cross sections do not decrease monotonically with increasing angles as Blair's diffraction theory[2] predicts.

The energy variation of the α_0 and α_1 angular distributions is very complicated, nevertheless we may point out some of its characteristics.

i) *Elastic scattering* (α_0)

There are some very deep minima in the angular distributions, especially at $\theta_{c.m.} \simeq 115°$ for $35.5\text{ MeV} \geq E_{\alpha(\text{lab.})} \geq 30.7\text{ MeV}$, and at some other angles. There is also a deep first minimum at extremely forward angles, where our new data are lacking. The ratio $(d\sigma/d\omega)_{c.m.}/(d\sigma/d\omega)_{\text{Ruth.}}$ oscillates and becomes higher at larger angles, especially for the lowest energies. This ratio is extremely high around the fourth and fifth maxima in the energy region of 29 to 32 MeV. This feature

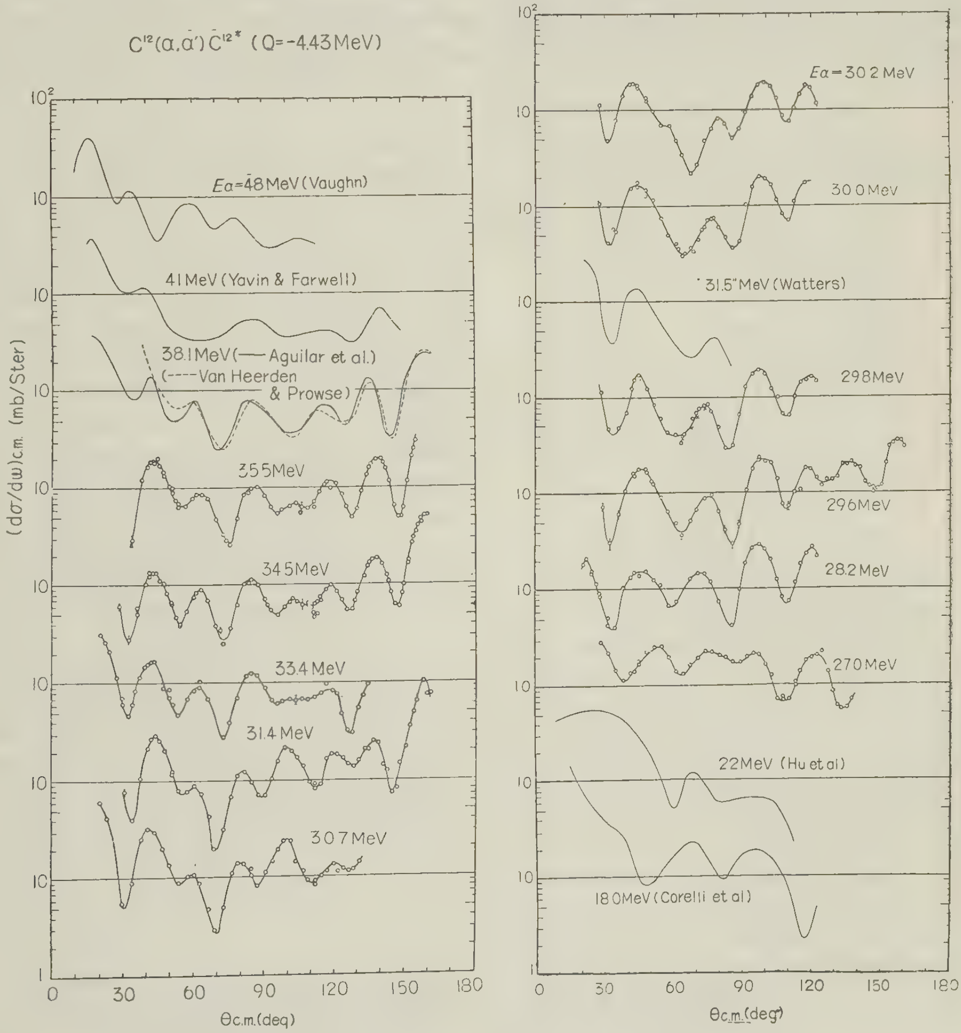

Fig. 5. Angular distribution for α_1.
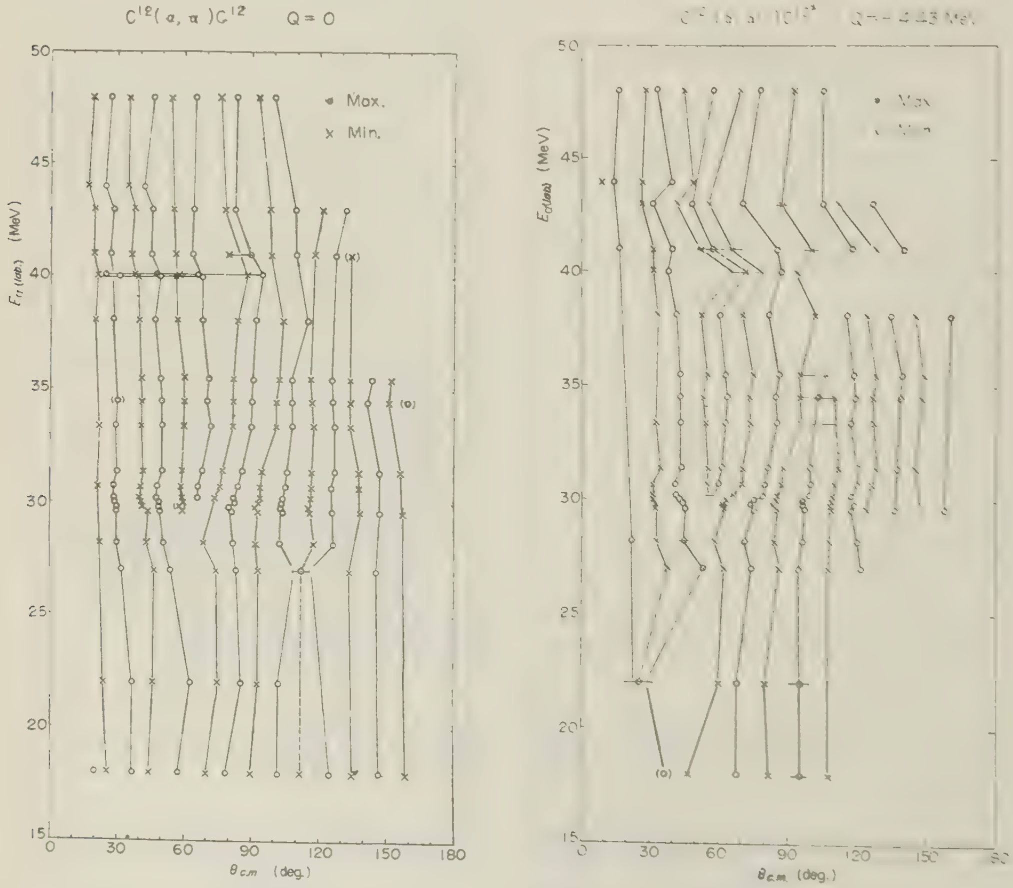
Points × show the change of angular distribution at $E_\alpha \simeq 29.8$ MeV with non-measurable variation of cyclotron energy.

will be discussed in more detail.

The most dramatic phenomenon is the behaviour around 60° to 70°. There is a strong peak for $E_{\alpha} \geq 33.4$ MeV (the third maximum). This peak decreases with energy and it disappears at $E_{\alpha} \simeq 30.0$ MeV. For lower energies, it becomes hidden in a valley (the third minimum) which becomes deeper as E_{α} becomes lower.

In order to investigate this behaviour we made measurement of cross sections at every 200 keV between 29.6 and 30.2 MeV in the forward angular region. As the cyclotron beam has an energy spread of about 0.5% (See Sec. 2 C), this change corresponds to about the width of the beam. The cross sections and angular distributions changed, however, remarkably with slight variations of the mean energy of cyclotron. At $E_{\alpha}=29.8$ MeV, a non-measurable variation of cyclotron energy changed the shape of angular distribution in the angular region in question. This behaviour is shown in Fig. 4 with the points χ. The energy spread of the beam being taken into account, the change of the angular distributions must be considered as more energy-sensitive than is shown in Fig. 4. This strange behaviour appearing as a plateau in the angular distribution had been found by Watters at E_{α}="31.5" MeV. His angular distribution agrees very well with ours at $E_{\alpha}=30.0$ MeV. The effective energy at the centre of his target is not precisely known because of the lack of information concerning the target thickness. (He used carbon targets between 0.2 and 1 mil thick. The last target would have reduced $E_{\alpha\text{eff}}$ to about 30.6 MeV,



(a) (b)

Fig. 6 (a). Angular positions of maxima and minima in α_0 angular distributions plotted against E_{α} (lab).
(b). Angular positions of maxima and minima in α_1 angular distributions plotted against E_{α} (lab).

which is still higher than our energy.* His rather thick target would have caused him to observe some average behaviour in this energy region.) The energy-sensitive behaviour just mentioned may not be explained by simple diffraction theories, nor by direct reaction theories. Whether this anomaly can be attributed to a resonance in a compound system will be discussed later.

In Fig. 6 (a) the angular positions of maxima and minima are plotted against E_α, where the anomalous behaviour in the region around 30 to 31 MeV is clearly shown.

Another singular phenomenon is observed around 110° at $E_\alpha=27.0$ MeV. A very broad peak is observed in this region, which is split into two peaks for both higher and lower energies. Unfortunately we have not made measurement at either slightly higher or lower energies, nevertheless the singularity is clearly shown also in Fig. 6 (a).

ii) *Inelastic scattering* (α_1, $Q=-4.43$ MeV)

From Figs. 3 and 5, we can point out some of the characteristics in the angular distributions.

At $E_\alpha \simeq 30$ MeV, there appears a similar phenomenon to that found in the elastic scattering case. Here a valley and a peak, observed around 50° to 60° at higher energies, disappear. This valley and peak corresponds to the peak and valley in the α_0 angular distributions discussed in Sec. 3 i). This fact reflects a close correlation between α_0 and α_1, although the out-of-phase relation is violated in the angular region in question.

There are some plateaus around 100° for $33.4\text{ MeV} \leq E_\alpha \leq 35.5\text{ MeV}$ and for $E_\alpha=41$ MeV.

Another remarkable feature is the rise of the cross sections at backward angles ($\theta \gtrsim 150°$). This rise, especially remarkable at $E_\alpha=31.4$ MeV, reminds us of the rise of the backward cross sections observed in the reaction $C^{12}(\alpha, p_0)N^{15}$ ($Q=-4.96$ MeV)[16] for $E_\alpha \lesssim 31$ MeV. This point will be discussed later more fully.

§4. Discussion

i) *Elastic scattering*

As is seen in Fig. 6 (a), angular positions of minima and maxima do not shift systematically towards the smaller angles with an increase of energy as diffraction theories predict. According to these theories, in order that the interaction radius R_0 between a carbon nucleus and an alpha particle be constant, $\theta_{\text{c.m.}}$ for corresponding maxima and minima must decrease as $1/k$, where k is the c.m. wave number of the incident alpha particles. The angular positions of the first minimum and maximum being almost constant, the interaction radius R_0 calculated by diffraction theories (e.g. Blair theory) would decrease as $1/k$, as shown in the previous paper[1]. The reason for this fact is not yet clear. The larger value of R_0 around 30 MeV, shown in ref. 1, seems also established with the aid of the present data. The relation between R_0 and E_α based upon the diffraction model is shown in Fig. 7. (R_0 was obtained from angular positions of second maximum and minimum, because the data of the first ones are lacking in the present results.)

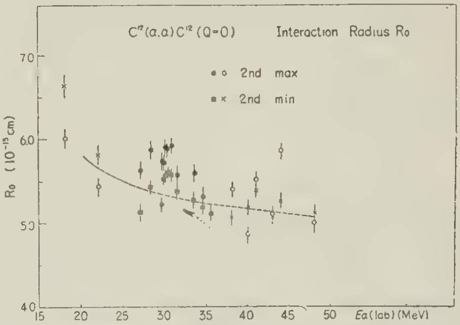


Fig. 7. Interaction radius R_0 obtained from simple diffraction theory plotted against $E_{\alpha(\text{lab})}$.

Aside from the forward angular region where Coulomb scattering must be important, the excitation function for elastic scattering is shown in Fig. 8 at every ten degrees from 70° to 150° (c.m.). This function was obtained from the data of angular distributions. At all these angles, there appears a broad peak (or two narrow peaks) for $E_{\alpha(\text{lab.})}$ around 30 MeV. At other energies less well established peaks are also observed. Unfortunately the behaviour around $E_\alpha \lesssim 27$ MeV is obscured because of the lack of data.

The resonance at $E_\alpha \simeq 30$ MeV corresponds to an excitation energy E_{ex} in the O^{16} nucleus of around 30 MeV. It is surprising that such a resonance exists, and it is not likely that this resonance be attributed to a "compound nucleus" resonance, in the ordinary sense. It seems, however, that in addition to the shape elastic and the diffraction scattering, some particular states in the compound system $C^{12}+\alpha$, which have a large alpha-particle width, contribute to the elastic scattering, even at such a high excitation energy. Interferences among these modes would make the phenomena very complicated.

---

* According to N. S. Wall (private communication), Watters' energy measurements were off by about 1 MeV, and at the centre of his target the effective energy would be about 30.2 MeV which agrees with ours.

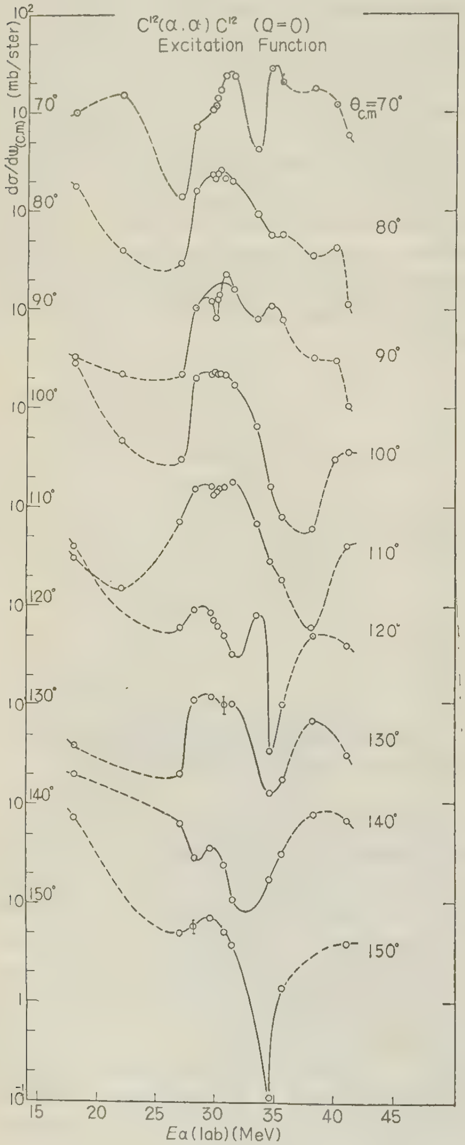

Fig. 8. Excitation function for elastic scattering at every ten degrees from 70° to 150° (c.m.), obtained from angular distribution data.

It is not yet clear whether the Watters' plateau, found in this energy region, is attributed to this resonance or it is nothing else than a transient phenomenon, in which contributions of certain waves of high l-values increase gradually with energy. Optical model calculations would be a powerful tool to solve this problem.

ii) *Inelastic scattering*

Angular positions of the maxima and minima of the angular distributions are shown in Fig. 6 (b). Still less systematic shifts of angular positions with energy were obtained than in the case of elastic scattering, nevertheless singularities at $E_\alpha \simeq 30$ MeV and $E_\alpha \simeq 27$ MeV are observed.

In Fig. 9 is shown the integrated cross section σ_t for α_1 as a function of $E_{\alpha(\text{lab.})}$ and $E_{\text{ex}}(O^{16*})$. σ_t was obtained by integrating the observed differential cross sections by extraporation to 0° and th 180°. (Absolute value of σ_t is not shown, but the values in the coordinate may roughly be read as mb.) σ_t decreases, in general, as the increase of E_α, which is not expected from Blair theory. Although the errors in σ_t are large, especially at energies where data at small or large angles are absent, two peaks at $E_\alpha \simeq 31.5$ MeV and at $E_\alpha \simeq 27$ MeV are observed. For comparison, σ_t for the reaction $C^{12}(\alpha, p_0)N^{15}$ ($Q=-4.96$ MeV)[16),20),21)] is also shown in Fig. 9. (The energy scale is corrected in our present scale.) While it was concluded in ref. 16 that σ_t decreased monotonically as the increase of energy, there appear a peak at $E_\alpha \simeq 25$ MeV and a bump at $E_\alpha \simeq 31$ MeV.

The resonance for α_1 at $E_\alpha \simeq 31.5$ MeV corresponding to $E_{\text{ex}}(O^{16*}) \simeq 31$ MeV has a width of less than 2 MeV. It is surprising that such a resonance (the actual width seems to be narrower, the width of beam energy being taken into account) does exist in such a high excitation of nucleus. It is difficult to consider it to be a "compound nucleus" resonance, since the evaporation mechanism can hardly explain why $\sigma_t(\alpha_1)$ exceeds 10 to 20% of geometrical cross section. ($\pi R_0^2 \simeq 80 \sim 100$ mb)

It is interesting that the energy position where the peak around 60° disappears in the α_0 and α_1 angular distributions turns out to be just at the valley between two peaks in σ_t vs. E_α curve.

In Fig. 9 the energy levels of O^{16} known from the reactions $N^{14}(d, n)$, $C^{13}(He^3, p)$ and $O^{16}(\gamma, 4\alpha)$ are also shown for comparison[22]. Whether the resonances found here correspond to some of these levels is left for future investigation.

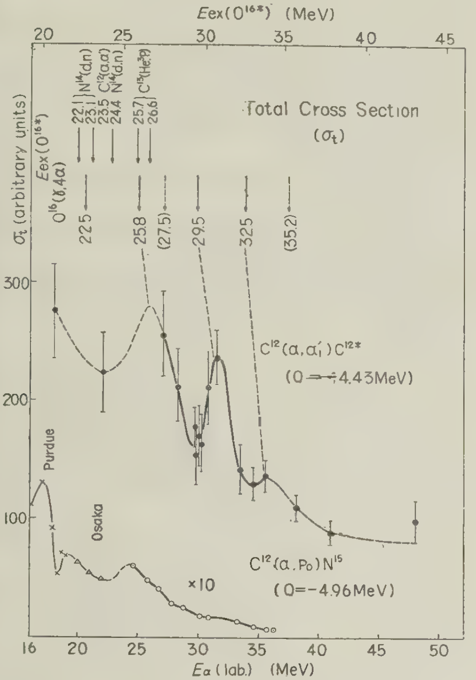

Fig. 9. Integrated cross section σ_t for α_1 plotted against $E_{\alpha(\text{lab})}$ and $E_{\text{ex}}(O^{16*})$.
Energy levels in O^{16*} are taken from the paper of Ajzenberg-Selove and Lauritsen: Nucl. Phys. **11** (1959) 1.

A comparison among the reactions $C^{12}(\alpha, \alpha')C^{12*}$, $C^{12}(\alpha, p)N^{15}$, $C^{12}(\alpha, d)N^{14}$, etc. would elucidate the behaviour of the entrance channel, while a comparison among the reactions initiated by $N^{15}+p$, $N^{14}+d$ and $C^{12}+\alpha$ would be helpful to determine whether the resonant or singular phenomena are open to different entrance channels. The angular distributions of $N^{14}(d, \alpha_0)C^{12}$ and $N^{14}(d, \alpha_1)C^{12*}$ [23] show sharp diffraction patterns and strong energy dependence. At some energies there is a pronounced rise in the cross sections at backward angles and $(d\sigma/d\omega)_{\alpha_1}$ is larger than $(d\sigma/d\omega)_{\alpha_0}$. These features are similar to those in the case of $C^{12}(\alpha, \alpha_0)$ and $C^{12}(\alpha, \alpha_1)$. (At backward angles inelastic cross sections are larger than elastic cross sections. See Fig. 3.) Angular distributions of $N^{14}(d, p_0)N^{15}$ obtained in this Institute by Kyushu University group[24] at $E_d=14\sim16$ MeV resemble those of $C^{12}(\alpha, p_0)N^{15}$ data[16] near the same O^{16} energy. These similarities might be a reflection of the fact that the compound system plays an important role in these scattering and reactions.

In the study of $Mg^{24}(\alpha, \alpha_0)Mg^{24}$ and $Mg^{24}(\alpha, \alpha_1)Mg^{24*}$ ($Q=-1.37$ MeV), Blair et al.[25] found a systematic variation of angular distributions (experiments were done only in the forward angular region), both in size and in shape and in the angular positions of maxima and minima, and they could obtain a " universal " curve in the relation $1/k^2\, d\sigma/d\omega$ *vs.* $2kR_0 \sin\theta/2$. It was impossible to obtain such a curve even in the extremely forward angular region with carbon. We have recently studied $O^{16}(\alpha, \alpha_0)O^{16}$, $O^{16}(\alpha, \alpha')O^{16*}$, $N^{14}(\alpha, \alpha_0)N^{14}$ and $N^{14}(\alpha, \alpha')N^{14*}$ and and found energy variation of angular distributions similar to those found in the case of carbon[26]. The resonance energies in the elastic excitation function for oxygen and the energies where the third peak in the elastic angular distributions disappear for both oxygen and nitrogen are found to be in the region of E_{ex} between 25 and 30 MeV. It is not clear whether these anomalies occur with every light nucleus or are accentuated with nuclei of $n\alpha$-type on the one hand, and for what mass numbers and excitation energies it is possible to obtain " universal " curves on the other hand.

It is also to be investigated whether the same resonances are observed with different incident particles and to compare with the case of alpha scattering. In elastic and inelastic scattering of protons many resonances were observed, by Matsuda et al., with many nuclei, including carbon, corresponding to $E_{\text{ex}}=10\sim30$ MeV[27], on the contrary Ishizaki et al.[28] found no significant anomalies in their study of $C^{12}(d, d_0)C^{12}$ and $C^{12}(d, d_1)C^{12*}$ at $E_d=15$, 16 and 18 MeV ($E_{\text{ex}}(N^{14*})=22\sim25$ MeV). It is also of interest to compare these resonances with those found by Bromley et al. in carbon-carbon elastic scattering[29] and carbon-carbon reactions[30].

Acknowledgement

The author wishes to express his appreciation of the valuable counsel of Professor I. Nonaka during the course of this investigation. He is also very grateful to Dr. H. Yamaguchi for his continual collaboration and discussions, and to the research staff of I.N.S. (Tokyo). Sincere appreciation is extented to Messrs. S. Hitaka, T. Maki, M. Mukae and T. Nakashima for their collaboration during this investigation. Sincere thanks are due to the cyclotron crew of I.N.S. especially to Messrs. A. Suzuki and T. Yamada.

He^3-Alpha Scattering

Ren CHIBA*, Homer E. CONZETT**, Haruhiko MORINAGA***,
Naoshi MUTSURO, Katsufusa SHODA and Motoharu KIMURA
Department of Physics, Tohoku University, Sendai, Japan

(Received February 9, 1961)

Differential cross sections for scattering of He^4 by He^3 have been measured at E_α=27.7, 28.5, 29.4, 30.0, 32.0, 33.4, 34.7, 36.5, 38.4, 41.0 MeV using a scintillation counter spectrometer, at the center of mass angles from ~30° to ~150°. Three distinct minima were found at about 45°, 100°, and 140°. The absolute cross-section and the pattern of the angular distribution showed no appreciable change in the energy range investigated: thus, there was found no sharp resonance in the He^3+He^4 system corresponding to an excited state of Be^7 between 13.4 and 19.2 MeV.

Differential cross-sections of the protons from $He^3(\alpha, p)Li^6\ Li^{6*}$ were observed. Differential cross-sections of alpha-alpha scattering were also measured at E_α=33.5 and 35.5 MeV.

§1. Introduction

Elastic scattering of He^4 by He^3 has not been extensively studied, but is an interesting problem. The scattering mechanism should be quite similar to that of alpha-alpha scattering of which a considerable amount of work has been accumulated making a very fine analysis possible[1]. There are, however, many fundamental differences between those two cases since for alpha-alpha scattering both incident and target particles are identical and have spin zero but in the latter case they are different and have different spins. Moreover, in the energy range of our experiment, reaction other than the elastic scattering can take place. These possibilities will make a phase-shift analysis similar to the case of alpha-alpha scattering difficult but still many interesting features should reveal themselves in the scattering cross-sections.

One of the most interesting things and the major motive of the present experiment is the investigation of the excited states of Be^7. The lower states of Be^7 or Li^7 are known from various experiments[2], and the four low lying odd-parity states have been successfully explained by the intermediate coupling shell model[3),4)]. However, a striking thing is that these states are also explained quantitatively applying the wave functions given by Nilsson[5]. Namely, the moment of inertia and the decoupling factor derived from the experimental energy of the ground, 1st, and the 3rd excited states, assuming that these are the rotational band of $K=\frac{1}{2}^-$ intrinsic states are, in good agreement with the values expected from Nilsson's theory and the 2nd excited state of $7/2^-$ comes very close to the calculated energy. Such a fit may be theoretically expected under certain condition as proved by Elliott[6]. It is extremely interesting to see if this is of the nature discussed by the latter author or if Nilsson's simple theory actually applies.

If Nilsson's theory is applicable, one can expect $9/2^-$ and $11/2^-$ states at around 13 to 15 MeV excitation as a continuation of the low-lying rotational states. The Elliott's theory does not assure this, since such a rotational character is of a pseudo nature.

One support for the rotational nature of these lower states may be attributed to the experimental results of the 3 to 5 MeV He^3-alpha scattering involving the $7/2^-$ state of Be^7[7]. The scattering cross-section is very close to that of Wigner's sum rule limit indicating that this state is made of He^4 and He^3. This may also imply that this state is of the "rotating cigar" type.

The situation is quite similar to that of Be^8. Here, the ground state is probably of the dumbbell type and this is expected from Nilsson's theory, too. Experimentally, the 0–2–4 series seems[1] to represent the rotational spectrum of such a dumbbell. However, such a 0–2–4 series can also be obtained from the intermediate coupling shell model. A dumbbell model predicts a 6^+ state in the energy range investigated, but so far no indication of such a state has been seen[8],[9]. The intermediate coupling shell model will not uniquely predict such a state.

*** Present Address: Department of Physics, University of Tokyo, Motofuji-cho, Bunkyo-ku, Tokyo.

From the cyclotron at the Institute for Nuclear Study of the University of Tokyo, alpha-particles with energies from 28 to 42 MeV are obtained. These alphas incident on He^3 correspond to Be^7 excitations of 13.4 and 19.2 MeV, which are about the region where a $9/2^-$ or $11/2^-$ state with a width close to the Wigner limit should be observed if Nilsson's simple theory applies. Such states would show up as resonances with $l=5$. However our experimental results seems to have disproved the existance of such a simple Nilsson state in Be^7. This is agreement with the present theoretical interpretation of the rotational spectra in light nuclei[4].

In our energy range a reaction,

$$He^4+He^3 \longrightarrow Li^{6(*)}+p$$

can take place[10]. This reaction is well worth studying since many states involved are of a well-known nature. Therefore, it could be used to test various simple theories about these states and the reaction mechanism involved.

§ 2. Experimental Arrangement

The alpha-particle beam, furnished by the variable energy cyclotron was successively passed through a deflectihg magnet, Q magnets and led into a scattering chamber.

The beam entered through a collimeter of 5 mm diameter and passed through a gas target chamber and was collected in a Faraday cup. A detailed description of the apparatus may be found elsewhere[11].

The target chamber, 8.5 cm in diameter, was mounted at the center of the scattering chamber and was filled with 98% He^3 to a pressure of 10–15 cm Hg. Both incoming and outgoing windows of the target chamber were sealed by 25-micron aluminum foils. A small mercury manometer mounted on the target chamber made it possible to monitor the He^3 gas pressure during the experiment.

In order to get the pulse height distributions at various angles, a counter and a slit system were mounted on a movable disc which could be rotated about the center of the scattering chamber in vacuum. The detecter consisted of a thin CsI(TI) crystal mounted on a multiplier phototube. A proportional counter was mounted in some cases in front of the scintillation counter to separate proton groups from double charged particles by determing the dE/dX of the particles.

A multiple slit system of 1 mm aperture was used for the scintilllation counter and a system of 2 mm was employed for the proportional and scintillation counter assembly. The angular resolution of these slits was about 2 degrees and 4 degrees respectively in the center of mass coordinate.

Another scintillation counter and slit system, mounted at a fixed position (20 or 30 degrees) on the wall of the scattering chamber was used as a monitor.

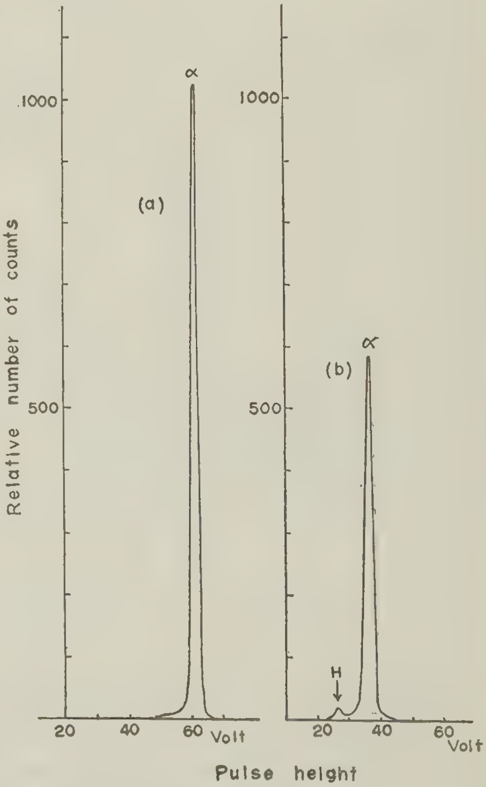

Fig. 1. Scintillation counter spectrum of alpha-alpha scattering in multichannel pulsle height analyzer. $E_\alpha=32.5$ MeV
(a): at 21°, (b): at 41° lab. angle. H indicate recoil proton from hydrogen impurity.

§ 3. Alpha-Alpha Scattering

In order to check the apparatus and experimental arrangement, the scattering of Alpha-particles by helium was investigated at two different energies; 32.5 MeV and 35.5 MeV.

The apparatus used was the same as that for the He^3-alpha scattering, except that the gas filling system and manometer were mounted outside the scattering chamber. The spectrum of the scintillation counter showed a clear alpha-particle peak with an energy resolution of about 4%. A small peak of protons due to hydrogen impurity was observed at some angles. (Fig. 1)

The differential cross-sections as a function of scattering angle are shown in Fig. 2. The angular resolution due to the finite size of the slit system was about 4 degrees in the center of mass system. The angular distribution of alpha-alpha scattering changes appreciably with energy in this energy range. The present result is in good agreement with that of Birmingham group$^{8)}$.

§ 4. He^3-Alpha-Scattering

Experimental procedure

In the present He^3-alpha scattering experiment the bombarding energies of the alpha-particles were 27.5±0.5, 28.5±0.5, 29.4±0.4, 30.0±0.5, 32.0±0.5, 33.4±0.5, 34.7±0.5, 36.5±0.5, 38.4±0.5, 41.0±1.0 MeV at the scattering portion of the gas target.

Since the incident particle is heavier than the target particle, the transformation from tne center of mass to the laboratory system reveals a somewhat unusual behavior in the scattered particle. The scattered particle loses its energy more rapidly than He^3 as the scattering angle increases and appears only up to a critical angle, 48°35′. Actually, from 0° to this critical angle, the energy of alpha-particle is double valued. (Fig. 3) The lower energy corresponds to back scattering in the center of mass system. This low energy particle usually did not pass through the aluminum foil of the scattering chamber or did not give a large enough pulse to be distin-

guished from the gamma and neutron background from the cyclotron in the scintillation-counter spectrum. In the pulse height spectrum, several peaks were observed as shown in Fig. 4. The identification of these peaks was rather complicated since the scintillation-counter does not distinguish alpha, He^3 and proton (at small angles, Li^6 is also expected).

In order to identify these peaks, the pulse heights of these peaks were plotted at every 2 degrees (Fig. 5) The energy-pulse height curves of alpha-particles, He^3 and protons were obtained at those angles where the spectra were comparatively simple, and identification of the peaks was made by comparing the diagram (Fig. 5) with the calculated energy curve.

The pulse height of He^3 is higher than that of alpha-particle of the same energy. At small angles, the He^3 energy is lower than that of the alpha, but the pulse height was higher over the measured angular range. Also, alpha-particles doubly scattered from the entrance and exit foils of the target chamber, and alpha-particles scattered by impurity gases (O_2, N_2) have higher energies, and these are intense at small angles. The intensity of doubly-scattered alpha-particles is proportional to $1/(\sin\theta/4)^3$ if coulomb scattering is assumed.

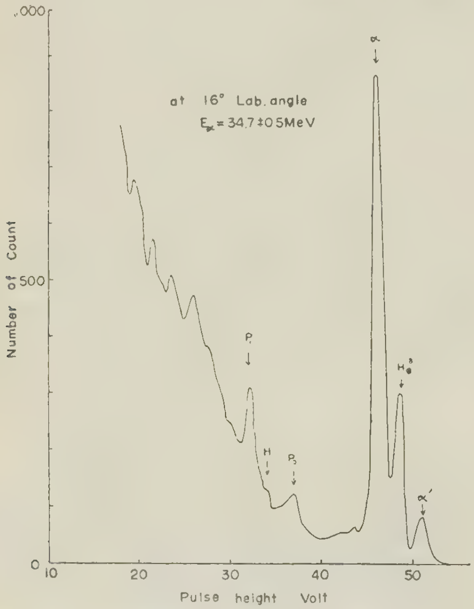

Fig. 4. Pulse height spectrum observed at a lab. angle of 16° in the He^3-alpha scattering in the CsI scintillation counter.

α' : alpha-particles scattered by impurity heavy gas (O_2, N_2) and that of doubly scattered by aluminum windows.
He^3: recoil He^3-particles
α : alpha-particles scattered by He^3
P_0 : protons from $He^3(\alpha, p)Li^6$ gnd.
P_1 : protons from $He^3(\alpha, p)Li^{6*}$ 1st excited state
H : recoil protons from hydrogen impurity

Since the energies of these three groups of alpha's and He^3 are close together at small angles, there is some ambiguity in the cross-section due to imperfect separtion of these groups in the spectra.

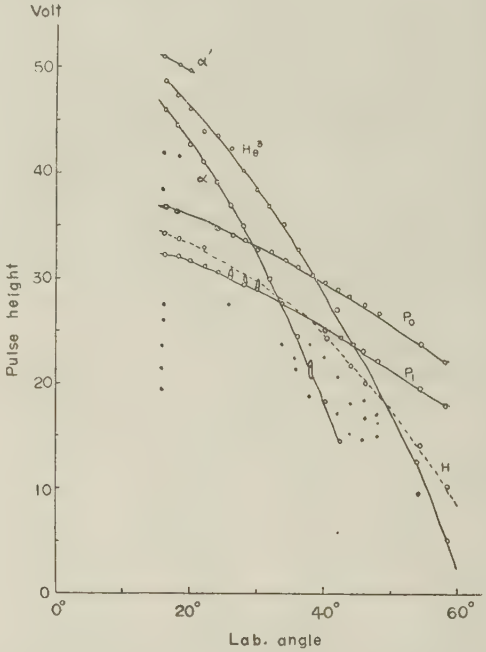

Fig. 5. Pulse height of peaks of various charged particles with scintillation counter spectra were plotted as a function of lab. angle. (E_α=34.4 MeV). Same notations as Fig. 4 were used for identified particles.

Besides alpha-particles and He^3, protons from $He^3(\alpha, p)Li^6$ (to the ground and 1st excited states) and from the impurity hydrogen recoil were observed and separated at larger angles. However, quite frequently these peaks were not completely resolved. For example, around 30 degrees, a proton peak overlapped the alpha's. In order to separate these particles, a proportional counter was used in coincidence with the scintillation counter in the measurements at 33.4 MeV and 41 MeV. The different energy losses of protons and alphas in the proportional counter made it possible to separate these particles with the same pulse height in the scintillation counter spectrum. Because of the poorer resolution of the proportional counter, however, both groups were not very well separated (Fig. 7). Thus the errors between 70–100 degrees (center of mass system) due to overlap of protons and alphas were reduced but not completely eliminated. Near 40 degrees (laboratory angle), the intensities of alpha-particles and He^3 were very low, and overlapping protons were not negligible. Also the rapid decrease of the alpha and He^3 energy with increasing angle made it more difficult to separate the peaks from background as the angle increased. The background subtraction and the finite resolution of the measuring instrument always led to some ambiguity in determing the number of counts in the spectrum. The determination was made from symmetry considerations of the peaks. The errors include both the uncertainty due to separation of the peaks and statistics.

The discriminater level of monitor counter was set at a minimum of the spectrum, to count known groups of particles; the statistical uncertainty was 2–3%. However, in the measurements at 27.5 MeV, 29.4 MeV and 32.0 MeV, the fluctuation of the monitor counts was larger than the statistics. This was caused by a leak of the beam current integrator. It was difficult to correct for the effect of this leak, since it depended strongly on the fluctuation of the beam intensity. In these cases, a plot of the monitor counts v.s. run time was extrapolated to zero run time and the value at zero was accepted as a normalization factor corresponding to a correct integrated charge.

The uncertainty in the absolute scale of the whole angular distribution for each energy was estimated to be 5%. This arises from the uncertainties in the measurement of solid angle, normalization by monitor counts or integrated beam current, alignment of beam

and slit system, and measurement of target gas pressure.

To obtain the full angular distribution curves, the cross-sections for the forward angle in the center of mass system was obtained from the forward scattered alpha-particles and that for the backward was deduced from the forward scattered He^3.

§ 5. Results and Discussion

The differential cross-sections of elastic scattering of He^3-alpha are shown in Figs. 8 and 9. No significant change in the angular distribution was observed between E=32 MeV

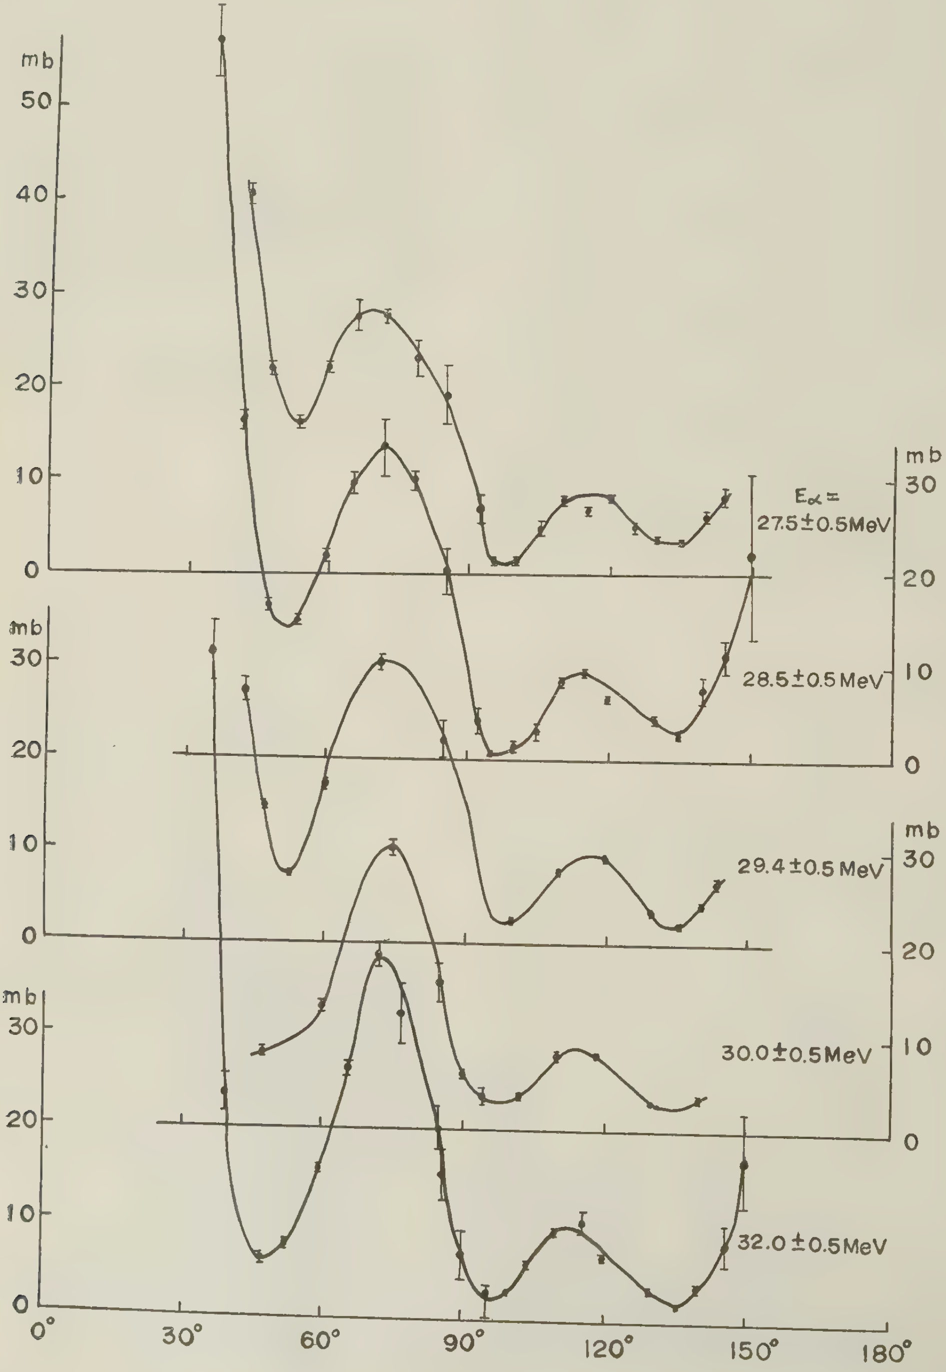

Fig. 8.

and 41 MeV, within the experimental accuracy. The results are consistent with the angular distribution measured by the Birmingham group at 16.6 MeV (center of mass energy[10]).

The whole range of the angular distribution may be fitted approximately by a broad 1=3 resonance. The phase shift analysis of experimental results is difficult since at these energy high 1 values contribute to the scat-

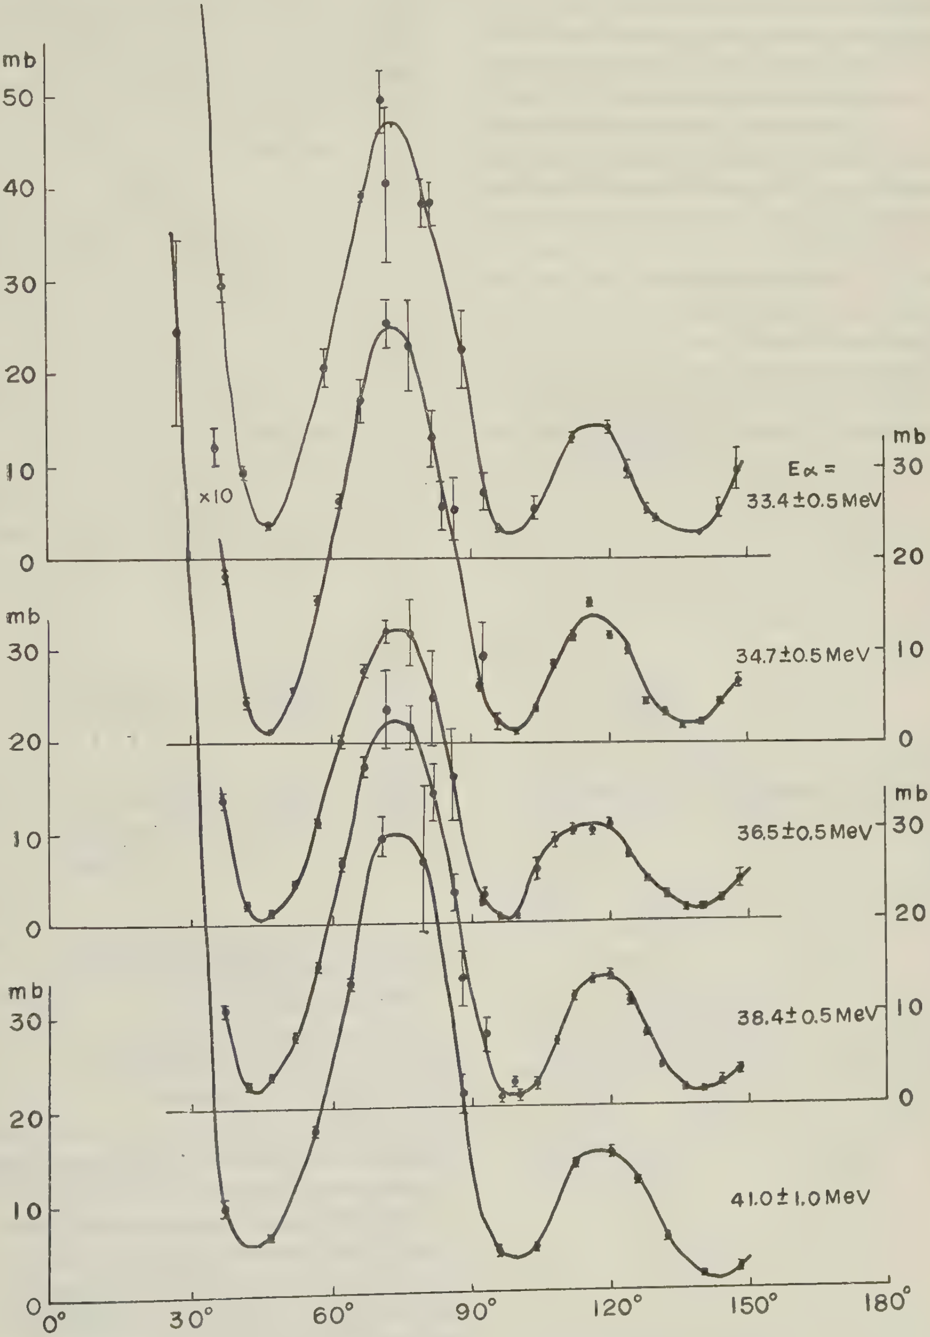

Fig. 9.

Fig. 8 and 9. Angular distributions of He^3-alpha elastic scattering in the center of mass co-ordinate. Energy of alpha-particles indicated are of lab. system. Ordinate are differential cross-section in mb/sterad.

tering. Moreover, it was not possible to estimate the total inelastic cross-section from present experiment which determines the imaginary part of the phase shift. However, it seems to us that the elastic scattering is governed by some mechanism which is slowly energy dependent in these energy range.

The 1=5 resonance which would have been observed was not detected in present experiment. In our experimental region, it is rather difficult to suppose that we have skipped such resonance. It may be that such resonances lie in the energy region different from that was scanned in our experiment because of some other perturbation effect, or may be that they do not exist. It seems to be very interesting to see the result of experiment in broader energy region.

The proton groups from $He^3(\alpha, p)Li^6$ reaction and the large number of unresolved particles below alpha-particles in the spectrum suggest that the reaction cross-sction is not negligible compared with the elastic scattering cross-section (Fig. 4).

The differential cross-sections of the protons from above reaction leading to Li^6 gnd. state ($J=1$, $T=0$) and first excited state ($J=3$, $T=0$, 2.18 MeV) which were resolved at large angles (Fig. 11) were transformed to center of mass system and shown in Fig. 10 a and b. The angular distributions of these two groups of protons were measured by Birmingham group and the cross-sections at about 90° are in agreement with our results$^{10)}$. The intensity of protons to the 2nd excited state ($J=0$, $T=1$, 3.56 MeV) was less than 1/5 of to the gnd. state, or may be less than 1/10 at about 90° of center of mass system if the smooth background was subtracted. It is interesting, however, to point out that not any angular momentum, Parity, nor isotopic spin selection rules imposed on the $He^3+He^4 \longrightarrow Li^{6*}+p$ reaction can suppress the formation of the $Li^{6*}(0^+, T=1)$ state.

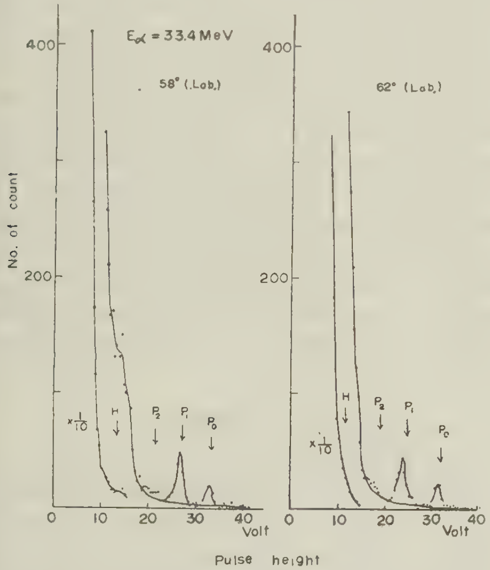

Fig. 11. Pulse height spectrum at large angles. P_0, P_1 and P_2 indicate expected positions of ground, 1st and 2nd excited state protons respectively.

Acknowledgement

This experiment was performed as one of the co-operating project of Institute for Nuclear Study of University of Tokyo. We are grateful to the staff members of the Institute who made it possible for us to use the facilities in this work.

We wish to express our appreciation to the crew of the cyclotron for their assistance during the cyclotron runs.

One of the author (H.E.C.) is grateful to Fulbright grant which made his stay at Institute for Nuclear Study of University of Tokyo possible.

One of the author (H.M.) is grateful to Prof. A Bohr. for the discussions concerning the possibility of applying unified model to Be^7-Li^7 pair and want to take this chance for expressing his sincere gratitude.

Colaborations of graduate students of Tohoku University during the experiments are highly appreciated.

Angular Correlation of the Mo^{95} Gamma-Gamma Cascades

By Atsushi AOKI

Department of Physics, Kyoto Prefectural University, Kyoto

(Received February 10, 1961)

The directional correlation and the polarization-direction correlation of the 838 Kev–204 Kev and 584 Kev–204 Kev gamma-gamma cascades in Mo^{95} have been measured. It is found that the spin of 788 Kev level is 1/2, and that of the 1042 Kev level is either 1/2 or 3/2. The branching ratio of the positron decay is also obtained as 0.4%.

§ 1. Introduction

The 60 days isomer of Tc^{95} decays to Mo^{95} by orbital electron capture competing with weak positron emission. The spin of the ground state of Mo^{95} is established to be 5/2 from the investigation of the paramagnetic resonance by Owen and Ward[1]. In addition, from the angular distribution and the polarization-direction correlation of the 204 Kev gamma ray in Coulomb excitation experiments, McGowan and Stelson have shown that the spin of the first excited state must be 3/2, and the multipolarity of the 204 Kev transition is a mixture of $E2$ and $M1$ with the mixing parameter $\delta=-0.6\pm0.2$[2]. Furthermore, many spectroscopic investigations of the decay of Tc^{95} have been made in the last decade[3–7]. Recently, Unik and Rasmussen reported on the decay of Tc^{95m}[8]. Their work was based principally on the results of high-resolution conversionelectron spectroscopic studies, supplemented by gamma ray scintillation spectroscopy and coincidence experiment. The decay scheme proposed by them are shown in Fig 1. As will be seen in this figure, the spins of the 1042 Kev and the 788 Kev levels are both assigned to be either 1/2 or 3/2. They concluded that the 584 Kev transition is more likely to be $M1$ and the 838 Kev transition $M1$ or $E2$. However, since the conversion coefficients for $E2$ and $M1$ are very similar at this particular atomic number for the energies of 838 Kev and 584 Kev[9], the multipolarity assignment for these gamma rays from the conversion coefficients is very difficult. Therefore it seems worthwhile to remove these ambiguities by measuring the angular correlation of the relevant gamma rays.

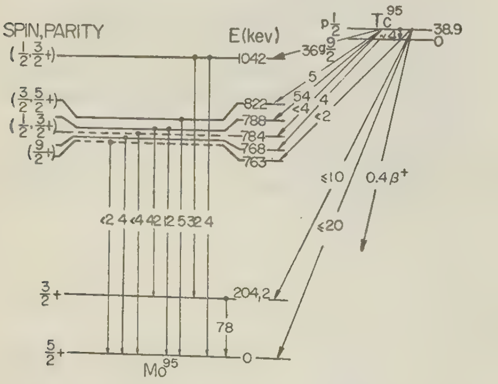

Fig. 1. Decay scheme of Tc^{95m}. Transition intensities are given as percent of total decay. (from Unik and Rasmussen[8]).

§ 2. Experimental Procedure

2.1 *Source preparation*

The Tc^{95m} source was prepared by bombarding the separated Mo^{95} (abundance in enriched element: 94%) as well as the molybdenum metal with 1200 microampere hours of 10 Mev proton particles in the 160 cm cyclotron at the Institute for Nuclear Study of the University of Tokyo, leading to the reaction $Mo^{95}(p, n)Tc^{95,95m}$. The enriched isotope, supplied from Oak Ridge National Laboratory in the chemical form of very volatile MoO_3, was reduced by hydrogen to metallic powder by heating in an electric furnace. The gamma ray from enriched source was measured one month after the bombardment by use of a scintillation spectrometer consisting of a cylindrical NaI (Tl) crystal, 5 in. in diameter and 4 in. high, coupled with a EMI type 6099B photomultiplier tube and a Sunvic 100-channel pulse height analyzer, and the spectrum is presented in Fig. 2. It can be regarded as the gamma ray spectrum following the decay of Tc^{95m} because of the far shorter half-life (20 hr[10]) of Tc^{95}.

Measurements using the sources prepared by natural molybdenum target were started several months after the bombardment to allow the short-lived activities to decay sufficiently. The gamma ray spectra of these sources were in good agreement with the result shown in Fig. 2, except for the contribution from the long-lived (90 days) isomer of Tc^{97}, which has no gamma-gamma cascade[11], and has no significant influence upon the present angular correlation experiments.

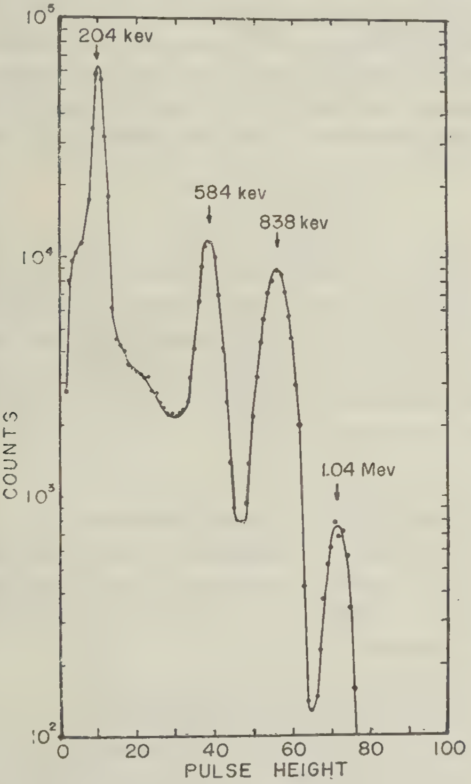

Fig. 2. Gamma ray spectrum of Tc^{95m}.

Thus the sources produced from natural molybdenum were used in the present experiment because of their strong intensity. The part with high activity of the bombarded target of natural molybdenum was peeled off and crushed up to fine powder. Then, the powder, packed in a cylindrical glass container with the inner diameter of 2 mm and depth of 4 mm, was used as the source for the directional correlation experiments. The remaining part of the target was chemically processed[12], and the activities of technetium were then electrodeposited on a thin copper foil[13], which was used for the measurement of the polarization-direction correlation.

2.2 *Directional Correlation Experiments*

The coincidence spectrometer used was the same as reported previously by Hayashi[14], whose detectors consisted of NaI (Tl) crystals of $1\frac{1}{2}$ in. in diameter by 1 in. thick, coupled to RCA-5819 photomultiplier tubes. The measurements of directional correlation were carried out for the 838 Kev–204 Kev gamma-gamma cascade as well as the 584 Kev–204 Kev one. The distance between the source and the front face of each crystal was 7 cm in both cases. If the gamma rays having the energies of 800 Kev or so are scattered backwards by Compton effect in the crystal which is to detect the radiations with energy of 838 Kev or 584 Kev, they give the energy of about 600 Kev to the crystal[15] and some portions of them are counted in the present experimental arrangement. Furthermore, since the back-scattered gamma rays degrade their energy to about 200 Kev, they may be counted in the detector for the 204 Kev radiation. Thus, in order to avoid these undesirable coincidences the front face of the crystal detecting the 838 Kev or 584 Kev gamma rays was covered with a lead disk of 5 mm thick. Besides, the lateral surface of each crystal was surrounded with cylindrical lead shields of 2.5 mm in thickness. The windows of the pulse height analyzers were set so as to pick up the full energy peaks of relevant gamma rays. The results of the directional correlation experiments measured with the metallic source are shown in Figs. 3 and 4. The solid curves drawn in these figures represent the least-squares fit of the experimental data[16], in which the terms up to $P_2(\cos\theta)$ are taken into consideration, owing to the spin value of 3/2 for the 204 Kev level[2]. A deviation of the experimental points at 165° and 180° from the curve appearing in the case of 584 Kev–

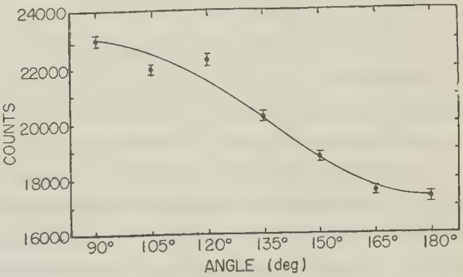

Fig. 3. Directional correlation of the 838 Kev–204 Kev cascade in Mo^{95}. The solid curve represents the least-squares fit of the experimental data.

204 Kev cascade (Fig. 4) can be attributed to the effect of the annihilation gamma rays created at the source position, and these points are omitted in drawing the curve. From these most fitted curves, the measured correlation functions for each case are

$$W'(\theta)=1-(0.178\pm0.005)P_2(\cos\theta)\ ,$$

for the 838 Kev–204 Kev cascade, (1)

and

$$W'(\theta)=1-(0.223\pm0.006)P_2(\cos\theta)\ ,$$

for the 584 Kev–204 Kev cascade. (2)

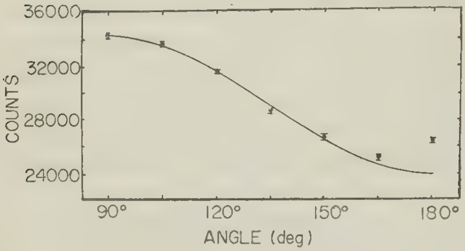

Fig. 4. Directional correlation of the 584 Kev–204 Kev cascade in Mo^{95}. The solid curve represents the least-squares fit of the experimental data obtained by omitting the experimental points at 165° and 180°.

In the case of the 584 Kev–204 Kev cascade, the contribution of the 838 Kev-204 Kev cascade was estimated to be 58% in the present experimental condition. Subtracting this contribution, Eq. (2) becomes

$$W''(\theta)=1-(0.285\pm0.016)P_2(\cos\theta)\ . \quad (3)$$

Then, corrected for finite angular resolution of the detectors[16], Eqs. (1) and (3) give the following equations as the experimentally determined correlation functions.

$$W(\theta)=1-(0.195\pm0.006)P_2(\cos\theta)\ ,$$

for the 838 Kev–204 Kev cascade. (4)

$$W(\theta)=1-(0.321\pm0.017)P_2(\cos\theta)\ ,$$

for the 584 Kev–204 Kev cascade. (5)

2.3 *Polarization-direction correlation*

As will be described in the next section, two possible mixing ratios are obtained for both of the 838 Kev and the 584 Kev gamma rays from the data of the directional correlation experiments. In order to accept alternative, the measurement of the polarization-direction correlation of the gamma-gamma cascades under consideration was carried out. The polarimeter employed was the same as used in the previous experiments[17], and the details of the apparatus were described in the previous paper[18]. The asymmetry ratio R was estimated to be 2.8 and 2.3 for the 548 Kev and the 838 Kev gamma rays, respectively. The mean scattering angle of the polarimeter was adjusted to 80 degree so as to obtain the maximum asymmetry ratio concerning the relevant gamma rays. Since it is difficult to discriminate the 838 Kev and the 584 Kev gamma rays from each other in the polarimeter, there is no other alternative besides measuring the composed polarization-direction correlation for these cascades.

The asymmetry thus obtained in the case of $\theta=90°$ is

$$\frac{N_{\parallel}(\theta)}{N_{\perp}(\theta)}=1.03\pm0.03\ , \quad (6)$$

where $N_{\parallel}(\theta)$ and $N_{\perp}(\theta)$ represent the counting ratios for the cases in which the plane of scattering of the incident gamma ray into the phosphor is parallel, and perpendicular to the plane containing both of the cascade gamma rays, respectively.

§ 3. Analysis and Discussion

In order to analyze the results of the directional correlation experiment, the coefficient of the Legendre polynomial $P_2(\cos\theta)$ in the correlation function, A_2, is calculated for the spin sequence of

$$j_1(Q, D;\ \delta_1)3/2(Q, D;\ \delta_2=-0.6)5/2\ ,$$

where the spin of the initial state, j_1, is 1/2 and 3/2. The results are shown in Fig. 5 as a function of the quadrupole content, which is defined as $\delta_1^2/(1+\delta_1^2)$ by Arns and Wiedenweck[19]. It is readily concluded from Fig. 5 that the spin of 788 Kev level must be

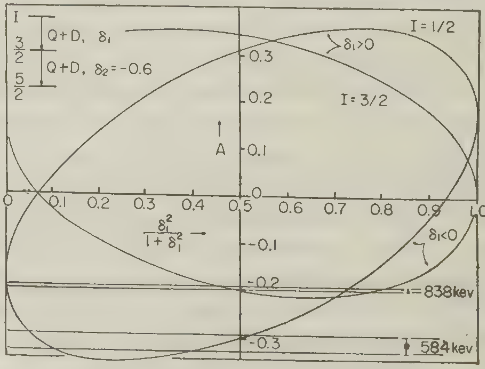

Fig. 5. Analysis of the dipole-quadrupole mixing of 838 Kev and 584 Kev transitions according to Arns and Wiedenweck[19].

1/2, while two possibilities for the spin of the 1042 Kev level are left undecided. The quadrupole contents determined from Fig. 5 for the 838 Kev and the 584 Kev transitions are presented in Table I.

Table I. The quadrupole contents determined from directional correlation experiments. ($\delta_1<0$, $\delta_2<0$)

Level (Kev)	Spin	Gamma ray (Kev)	Quadrupole content (%)
788	1/2	584	8±3 or 48±5
1042	1/2	838	0 or 73±1
1042	3/2	838	44±2 or 78±2

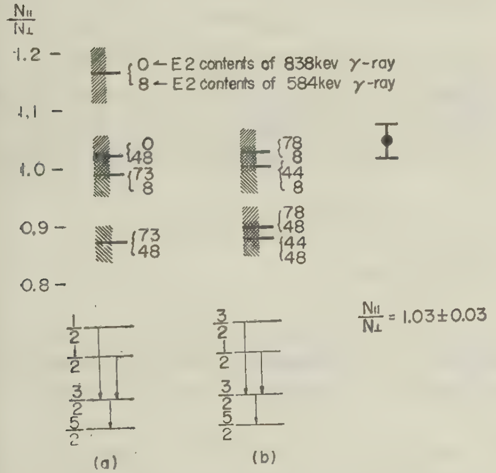

Fig. 6. Expected asymmetry in the polarization-direction correlation experiment for possible combinations of spins and $E2$-$M1$ admixture of the 838 Kev and 584 Kev gamma rays. The shades attached to each line correspond roughly to the error caused by the uncertainty of the experimentally determined A_2.

Under the present experimental condition, the asymmetry expected in the polarization-direction correlation measurements is estimated for these combinations of spins and quadrupole-dipole mixings by using Eq. (2A) in the Appendix, and is shown in Fig. 6 schematically, where (a) and (b) represent the case of $j_1=1/2$ and 3/2, respectively. The shades attached to each line in the figure correspond roughly to the error caused by the uncertainty of the experimentally determined A_2.

Table II below summarizes the results consistent with the angular correlation experiments. The experimental ratios of the K-conversion coefficients for the 584 Kev transition to that of the 838 Kev one, estimated by Unik and Rasmussen[8] and Takazawa *et al.*[20], suggest the small electric quadrupole content for the 548 Kev gamma ray more plausibly. In the above analysis, the quadrupole-dipole mixing parameter of the 204 Kev gamma ray is regarded as −0.6. In paractice, however, since this value includes the error of ±0.2, the quadrupole contents listed in Table II vary about 10% correspondingly.

Table II. The $E2$ contents which are consistent with the angular correlation experiments.

Spin of 788 Kev level	Spin of 1042 Kev level	$E2$ content (%)	
		838 Kev	584 Kev
1/2	1/2	0($M1$ pure)	48±5
1/2	1/2	73±1	8±3
1/2	3/2	78±2	8±3
1/2	3/2	44±2	8±3

In addition to the experiments mentioned above, similar directional correlation experiments with liquid source (TcO_4^- in water) were also put into practice. The measured directional correlation coefficients are 0.166±0.004 and 0.212±0.005 for the case of the 838 Kev–204 Kev and the 584 Kev–204 Kev gamma-gamma cascades, respectively. These coefficients are more attenuated than in the case of the metallic source. The fact suggests the existence of the influence caused by the extranuclear field in the intermediate state. Since the metallic molybdenum has the crystalline structure of the body-centered cubic lattice[21], no attenuation in angular correlation coefficients is expected as far as radio-active technetium atoms sit in the regular lattice sites[22]. Accordingly, the corresponding attenuation factors for the liquid source are evaluated as 0.93±0.03 and 0.95 ±0.03, which are in good agreement whithin their experimental error. Averaging them, we obtain $\bar{G}=0.94\pm0.02$. Recently, Bodenstedt *et al.*[23] observed strong attenuation in measuring the directional correlation of gamma-gamma cascades in W^{184}, following the electron capture of Re^{184}. The half-life of 1.28×10^{-9} sec of the intermediate state in these cascade[23] is comparable with that of 0.76×10^{-9} sec in the case of Mo^{95}.[2] Since they used liquid source containing the activity as ReO_4^-, the situation is considered to be quite similar to the present work. They estimated the attenuation factors as $G_2=0.54$ and $G_4=0.673\pm0.020$. The result of the present work is consistent with these ones if we assume the time-dependent quadrupole interaction[24] as the influence of extranuclear field in both cases and attend to the large quadrupole moment of the intermediate state of W^{184}.

Finally, from the coincidence counts obtained at $\theta=180°$ in the 584 Kev–204 Kev directional correlation measurements, the branching ratio of positron emission is estimated to be 0.4% of the total disintegration. This value is consistent with the results reported in the previous works[6,8,20].

Acknowledgments

The author wishes to express his heartly gratitude to Prof. K. Kimura at Kyoto University for his sustained interest and encouragement throughout the present research. He also expresses his sincere thanks to Prof. T. Hayashi and Dr. M. Kawamura for their many helpful discussions. The helps given by Prof. M. Ishibashi and Mr. M. Koyama at Kyoto University on the chemical separation of the radio-active isotopes are deeply appreciated. His thanks are also due to the cyclotron crew at the Institute for Nuclear Study of the University of Tokyo for their kindly cooperations. This work was partly supported by a grant-in-aid for scientific research of the Ministry of Education.

Appendix

According to Biedenharn and Rose[25], the general formula of the gamma-gamma double correlation concerning the cascade of $j_1(L_1, L_1')j(L_2, L_2')j_2$ is represented as follows:

$$W(\alpha\beta\gamma)\sim\sum(-)^{L_1+L_2}c_{\nu\tau_1}(L_1L_1')c^*_{\nu\tau_2}(L_2L_2')(j_1\|L_1\|j)(j_1\|L_1'\|j)(j_2\|L_2\|j)(j_2\|L_2'\|j)$$
$$\times W(jjL_1L_1';\nu j_1)W(jjL_2L_2';\nu j_2)D(\nu,\tau_2\tau_1;\alpha\beta\gamma),$$

where the notations are the same as those used by Biedenharn and Rose. Now we consider the case that both radiations are mixture of 2^L and $2^{L'}$ pole radiation, and the polarization of the second radiation is to be observed. Then, further calculation of Eq. (1A) yields

$$\begin{aligned}W(\beta,\varphi)\sim&\sum_{\nu\geq0}P_\nu(\cos\theta)\{F_\nu(L_1j_1j)+\delta_1^2F_\nu(L_1'j_1j)+2\delta_1(-)^{j_1-j-1}[(2j+1)(2L_1+1)(2L_1'+1)]^{1/2}G_\nu(L_1L_1'j_1j)\}\\&\times\{F_\nu(L_2j_2j)+\delta_2^2F_\nu(L_2'j_2j)+2\delta_2(-)^{j_2-j-1}[(2j+1)(2L_2+1)(2L_2'+1)]^{1/2}G_\nu(L_2L_2'j_2j)\}\\&+(-)^{\sigma(L_2')}\sum_{\nu\geq2}\{F_\nu(L_1j_1j)+\delta_1^2F_\nu(L_1'j_1j)+2\delta_1(-)^{j_1-j-1}[(2j+1)(2L_1+1)(2L_1'+1)]^{1/2}G_\nu(L_1L_1'j_1j)\}\\&\times\left\{\frac{-2\nu(\nu+1)L_2(L_2+1)}{\nu(\nu+1)-2L_2(L_2+1)}F_\nu(L_2j_2j)+\delta_2^2\frac{2\nu(\nu+1)L_2'(L_2'+1)}{\nu(\nu+1)-2L_2'(L_2'+1)}F_\nu(L_2'j_2j)\right.\\&\left.+2\delta_2(L_2'-L_2)(L_2'+L_2+1)(-)^{j-j_2-1}[(2j+1)(2L_2+1)(2L_2'+1)]^{1/2}G_\nu(L_2L_2'j_2j)\right\}\\&\times\left[\frac{(\nu-2)!}{(\nu+2)!}\right]\cos2\varphi P_\nu^2(\cos\beta),\end{aligned}\tag{2A}$$

provided $L_2+L_2'+\nu$ is an odd integer. Also the parity index $\sigma(L_2')$ is determined by the character of $2^{L_2'}$ pole radiation, that is, $\sigma(L_2')=1$ for magnetic and 0 for electric radiation. In Eq. (2A), φ is the angle between the polarization vector and the normal to the plane determined by the cascade radiations, and P_ν^2 is the associated Legendre polynomial; the first term of Eq. (2A) describes the directional correlation function for the unpolarized radiations.

Angular Distribution of (α, p) Reactions in Some Light Nuclei

By Michiya KONDO, Takashi YAMAZAKI and Shotaro YAMABE

Department of Physics, Faculty of Science, Osaka University, Osaka

(Received February 17, 1961)

The angular distributions of the proton groups corresponding to the lower states of the residual nuclei from the reactions $C^{12}(\alpha, p)N^{15}{}_{\rm gnd}$; $F^{19}(\alpha, p)Ne^{22}{}_{\rm gnd,\ 1.28\ MeV}$; $Al^{27}(\alpha, p)Si^{30}{}_{\rm gnd,\ 2.24\ MeV}$; and $Si^{28}(\alpha, p)P^{31}{}_{\rm gnd,\ 1.27,\ 2.23,\ 3.13\sim3.51\ MeV}$ have been measured using 22.5±0.2 MeV alpha particles. The angular distributions of the $C^{12}(\alpha, p)N^{15}{}_{\rm gnd}$ reaction are energy dependent. At 20.6 MeV steep rise in the forward angles is observed, but at 22.2 MeV the steep rise in the backward angles appears instead of the forward rise. The angular distributions of the $F^{19}(\alpha, p)Ne^{22}$ reaction are both peaked in the backward angles. The angular distributions of the $Al^{27}(\alpha, p)Si^{30}$ and the $Si^{28}(\alpha, p)P^{31}$ reactions show the diffraction-like patterns and they are interpreted with Butler's direct interaction theory.

§1. Introduction

The angular distributions of the (α, p) reactions for light nuclei have been measured at various energies[1-6], and the results for the proton groups corresponding to discrete levels in the residual nucleus have been usually compared with the surface direct interaction theory[7].

The angular distributions of the ground state proton group of the reaction $C^{12}(\alpha, p)N^{15}$ have been measured for alpha particle energies between 16 and 19 MeV[3], and between 25 and 40 MeV[4-6]. The angular distributions at the energies higher than 34 MeV show the diffraction-like patterns expected by the direct interaction mechanism. But the angular distributions at the energies below 30 MeV become energy dependent and show steep backward peaking which is unable to be explained by the simple direct interaction theory[7]. We have measured the angular distributions at the alpha particle energies of 22.2, 21.4 and 20.6 MeV.

The angular distributions of the $F^{19}(\alpha, p)Ne^{22}$ reaction have been measured at alpha particle energies of 18.9 MeV[1], and between 6.0 and 6.55 MeV[5]. At 18.9 MeV the angular distributions of the p_0, p_1 and p_2 proton groups (p_i is the group leaving residual nucleus in its i'th excited state.) are all peaked in the backward angles. We have measured the angular distributions of the p_0 and p_1 groups at the energy of 22.2 MeV.

In the case of the reaction $Al^{27}(\alpha, p)Si^{30}$, the angular distributions of the p_0 and p_1 groups at 30 MeV[6] give qualitative agreement with the calculation of the direct interaction theory. But there are some points of disagreement such as (*a*) the marked filling in the regions between the maxima and (*b*) a much higher degree of forward peaking. This higher degree of forward peaking not expected by the theory is also found in the reaction $C^{12}(\alpha, p)N^{15}$.[2] We have measured the angular distributions of the p_0 and p_1 groups of the reactions $Al^{27}(\alpha, p)Si^{28}$ at the energy of 21.8 MeV, and especially for the p_0 group we have also measured the angular distribution at 22.2 MeV to study the energy dependence of this reaction.

We have also measured the angular distributions of the $Si^{28}(\alpha, p)P^{31}$ reaction corresponding to the lower levels of the residual nucleus at the energy of 22.2 MeV, and compared the results with the direct interaction theory.

2. Experimental Procedures

The general experimental arrangement and procedure are similar to that described in the previous experiment[8].

The beam of 22.5±0.2 MeV alpha particles accelerated by the 44 inch Osaka University Cyclotron was lead to a scattering chamber (Fig. 1). Protons emerged from the target were detected by Ilford C-2 nuclear emulsion, 200 microns thick, and the angular distributions were measured every 7.5° from 7.5° to 165° at the laboratory angles. The angular setting of the plate camera was accurate within 1/2°. The angular resolution was determined by the scanned regions of the plate and was about ±1°. Aluminum and gold foils of suitable thickness were inserted between the target and emulsion to stop the scattered alpha particles and to get suitable lengths of tracks of the emitted protons in the emulsion. The beam current was collected by a Faraday cup connected to a polystyrene condenser and the charge was measured by an electrometer. The beam energy was degraded by aluminum foils placed in front of the collimator system.

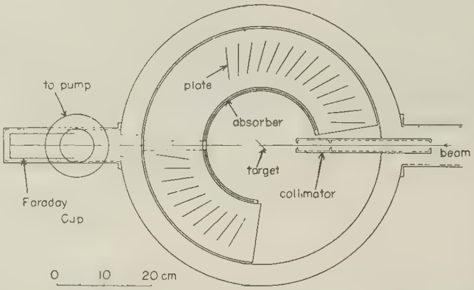

Fig. 1. Schematic diagram of scattering chamber and plate camera.

A thin polyethylene foil of 1.74 mg/cm² thick was used for the carbon target. For the study of fluorine a foil of teflon, 2.1 mg/cm² thick, was prepared. The aluminum target was 1.82 mg/cm² thick. A foil of fused silica, 2.0 mg/cm² thick, was used for silicon experiment. They were all self-supporting and set at 45° with respect to the beam direction.

§ 3. Results

A typical example of the range distribution for the emitted protons is shown in Fig. 2. This is the distribution for $Si^{28}(\alpha, p)P^{31}$ at the laboratory angle of 52.5° induced by 22.5 MeV alpha particles.

The results of the angular distributions for the (α, p) reactions are shown in Fig. 3 to Fig. 6. The energy values shown in the figures are those at the center of target. The errors indicated in these figures are only the statistical ones. The plots in which the errors are not indicated in the figures are due to their smallness. The estimated errors in the absolute differential cross sections are less than 30%, but for teflon target the absolute error is somewhat larger owing to the nonuniformity of the target thickness.

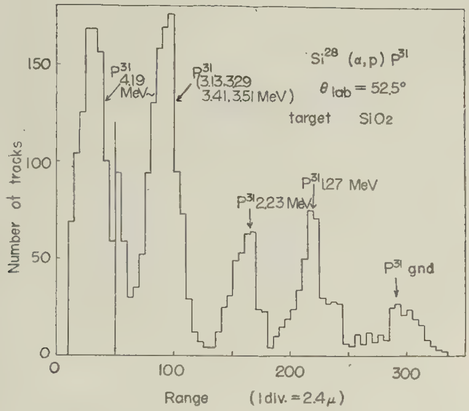

Fig. 2. Range distribution of the protons from the $Si^{28}(\alpha, p)P^{31}$ reaction observed at the laboratory angle of 52.5°. An aluminum foil of 1080 microns was inserted between the target and emulsion.

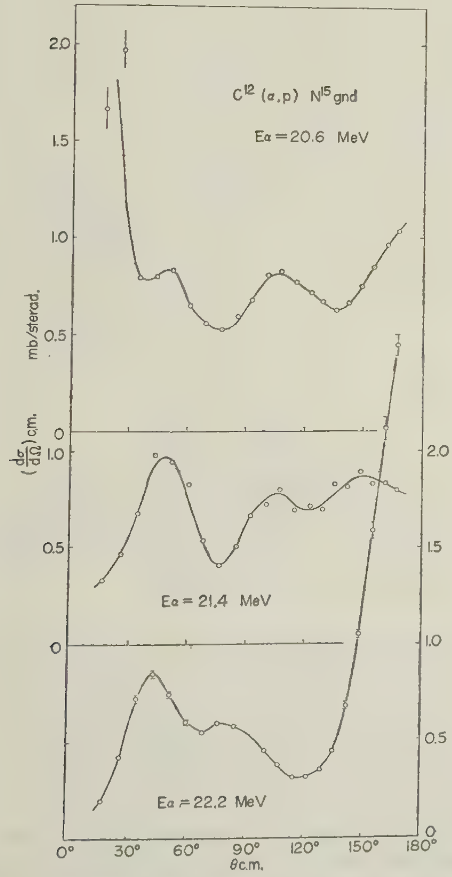

Fig. 3. Angular distributions of protons from the $C^{12}(\alpha, p)N^{15}_{gnd.}$ reaction.

4. Discussion

(i) $C^{12}(\alpha, p)N^{15}$

The angular distributions of the ground state protons from the reaction $C^{12}(\alpha, p)N^{15}$ show remarkable energy dependence. At 22.2 MeV steep rise in the backward angle is observed, at 21.4 MeV the angular distribution shows oscillation without steep rise in both

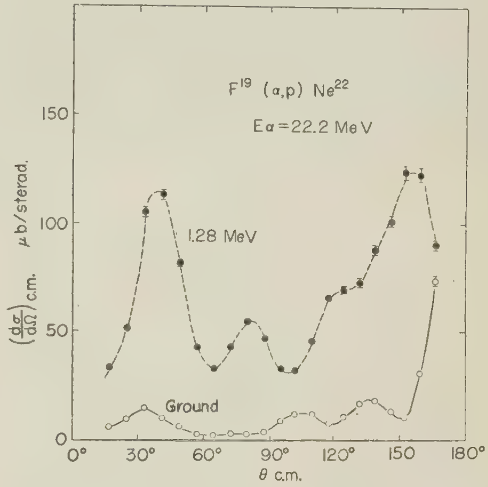

Fig. 4. Angular distributions of protons from the $F^{19}(\alpha, p)Ne^{22}_{gnd, 1.28 MeV}$ reactions.

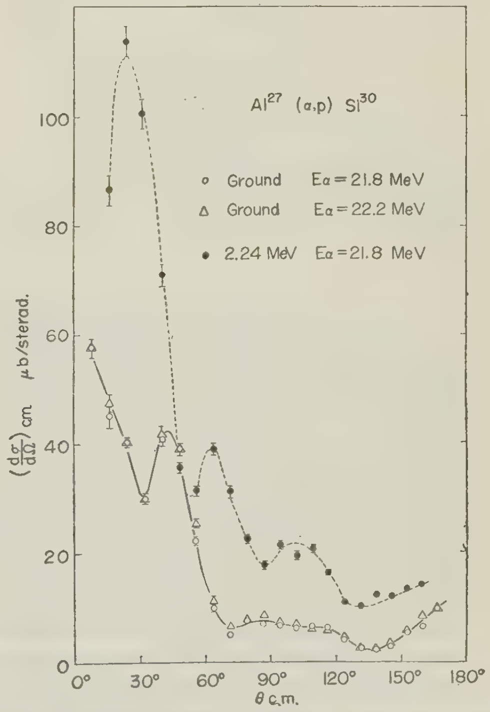

Fig. 5. Angular distributions of protons from the $Al^{27}(\alpha, p)Si^{30}_{gnd, 2.24 MeV}$ reactions.

the forward and backward angles, and at 20.6 MeV the rise in the forward angle appears. The peak near 45° is observed in all of these angular distributions.

The steep backward peak appeared at the alpha particle energy of 22.2 MeV has been observed also at other energies[1),2)]. The excitation curve of this reaction at $\theta_{cm}=165°$ obtained by the interpolation of the angular distributions is shown in Fig. 7. It seems that the backward rise in the angular distributions shows the maximum at about 25 MeV excitation energy of compound nucleus O^{16}, though just at this energy the experimental data are not yet obtained. The steep rise in the backward angle is also observed at 19.2 MeV of the excitation energy of $O^{16}(E_\alpha=16.1\text{ MeV})$[1)]. The backward peak has remarkable energy dependence at the alpha particle energy near 20 MeV, and this behavior may not be explained by the heavy particle stripping[13)] or by the reflection of the outgoing proton waves at the nuclear surface[14)].

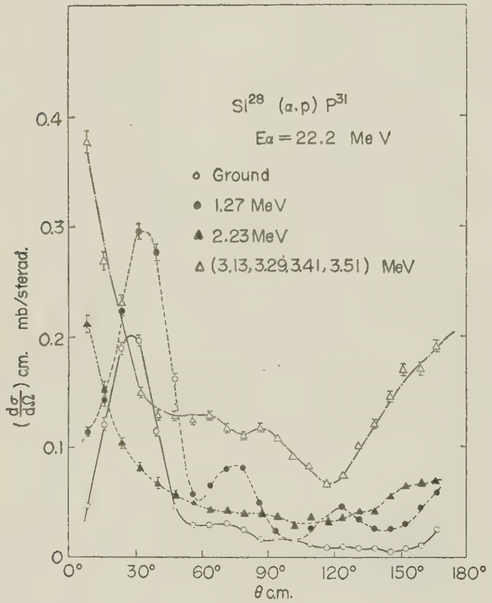

Fig. 6. Angular distributions of protons from the $Si^{28}(\alpha, p)P^{31}_{gnd}$, 1.27 MeV, 2.23 MeV, (3.13, 3.29, 3.41, 3.51 MeV) reactions.

The excitation energy of the compound nucleus O^{16} produced by 21 MeV alpha particle is about 23 MeV, and it is expected that the level density is not so high in this region because O^{16} is a double magic nucleus. In the region higher than 21 MeV in the excitation energy of O^{16} resonances are found in the excitation curves of the reaction $N^{14}(d, n)O^{15}{}_{gnd}$ and the angular distribution of this reaction is energy dependent (Fig. 7)[9)]. Some levels are found in the yield curve of $O^{16}(\gamma, n)O^{15}$.[10)] At the excitation energies of O^{16} between 21 and 26 MeV the excitation curve of $N^{15}(p, \gamma)O^{16}$ is obtained at 90° and shows large resonances at 21.8 and 24.8 MeV (Fig. 7)[11)].

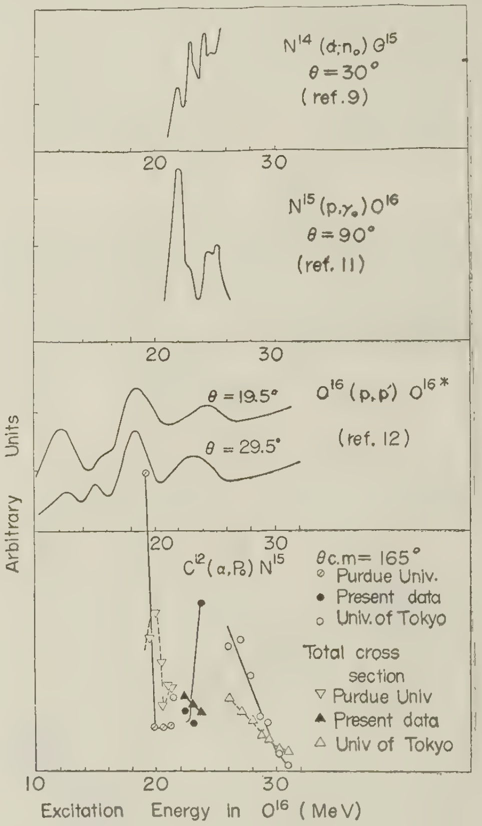

Fig. 7. The integrated cross section and the differential cross section at $\theta_{cm}=165°$ of $C^{12}(\alpha, p)N^{15}$ vs. the excitation energy of the compound nucleus O^{16}. Some other data relating this excitation energy of O^{16} are also shown.

The energy spectra for the inelastic scattering of 185 MeV protons on oxygen[12)] show peaks at 18.5 and 24 MeV of the excitation energy of O^{16} and these peaks roughly coincide in energy with the backward peak of the reaction $C^{12}(\alpha, p)N^{15}{}_{gnd}$ (Fig. 7). The effects of the levels of compound nucleus O^{16} are seen in these reactions and it is probable that similar circumstance exists on the reaction $C^{12}(\alpha, p)N^{15}{}_{gnd}$.

The integrated cross sections of the reaction $C^{12}(\alpha, p)N^{15}{}_{gnd}$ obtained from the angular distributions are shown in Table I. The energy dependence of the integrated cross sections is shown in Fig. 7 together with other results[1),2)]. This shows that the integrated cross section decreases generally as the energy increases though small bumps are observed. The integrated cross section does not show the strong energy dependence though the angular distributions change remarkably as shown in Fig. 3. This is perhaps due to the fact that the amplitude of the compound nucleus formation adds to the amplitude of the direct interaction.

Table I. The integrated cross sections of the reaction $C^{12}(\alpha, p)N^{15}{}_{gnd}$

E_α (MeV)	20.6	21.4	22.2
σ (mb)	6.30	5.50	4.94

(ii) $F^{19}(\alpha, p)Ne^{22}$

The angular distributions of the p_0 and p_1 proton groups from the reaction $F^{19}(\alpha, p)Ne^{22}$ at the alpha particle energy of 22.2 MeV are both peaked in the backward angles. The intensity of the p_1 proton group is greater by a factor of about ten than that of the p_0 proton group. The steep backward peaks of the p_0 and p_1 proton groups observed at 22.2 MeV have been also found at 18.9 MeV[2)]. The angular distribution of p_1 group at 22.2 MeV is very similar to that at 18.9 MeV at the angle larger than 90°, and the difference of these angular distributions is that the forward rise observed at 18.9 MeV is not seen at 22.2 MeV.

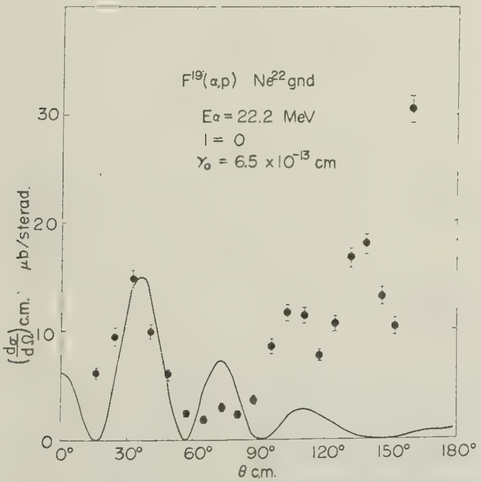

Fig. 8. Theoretical fit to the angular distribution of the $F^{19}(\alpha, p)Ne^{22}{}_{gnd}$ reaction using Butler's formula (Knock on; Eq. 57 of ref. 1) with $l=0$ (uniquely) and $r_0=6.5\times10^{-13}$ cm.

The theoretical fit to the angular distributions of the p_0 and p_1 groups using Butler's formula[1)] are shown in Figs. 8 and 9. For the p_0 and p_1 groups the unique l value of 0 and 2 are allowed, respectively. The interaction radius of 6.0×10^{-13} cm for the p_1 group is larger than that at the other energies[2)]. The fitting of the p_0 group using Butler's formula is rather poor. The steep backward peak of p_0 group and the peak of p_1 group at 155° can not be explained by Butler's theory[7)].

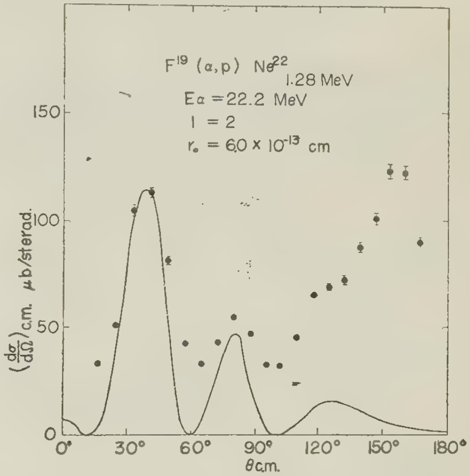

Fig. 9. Theoretical fit to the angular distribution of the $F^{19}(\alpha, p)Ne^{22}{}_{1.28\,MeV}$ reaction using Butler's formula with $l=2$ (uniquely) and $r_0=6.0\times10^{-13}$ cm.

(iii) $Al^{27}(\alpha, p)Si^{30}$

The angular distributions of the p_0 and p_1 proton groups from the reaction $Al^{27}(\alpha, p)Si^{30}$ at the alpha particle energy of 21.8 MeV show the oscillation with forward peaking and no remarkable backward peaking as observed in the reactions $C^{12}(\alpha, p)N^{15}$ and $F^{19}(\alpha, p)Ne^{22}$. The result of the p_0 proton group at 22.2 MeV is similar to that at 21.8 MeV, and therefore it seems that any strong energy dependence does not exist in this energy region. These facts suggest that the direct interaction mechanism plays an important role. The results of fitting Butler's formula[7)] to these data are shown in Figs. 10 and 11.

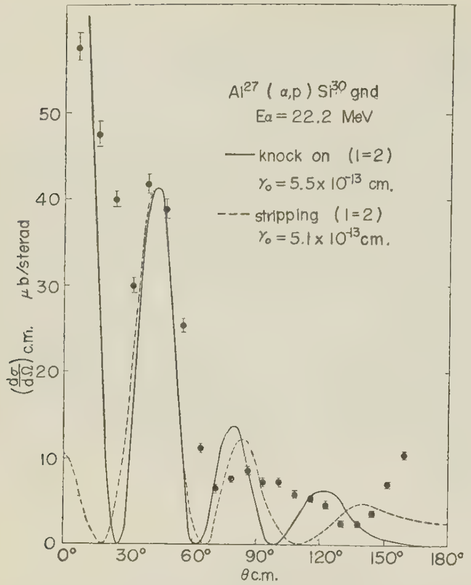

Fig. 10. Theoretical fit to the angular distribution of the $Al^{27}(\alpha, p)Si^{30}_{gnd}$ reaction using the formula of knock-on theory with $l=2$ (uniquely) and $r_0=5.5\times10^{-13}$ cm and the formula of stripping theory with $l=2$ (uniquely) and $r_0=5.1\times10^{-13}$ cm.

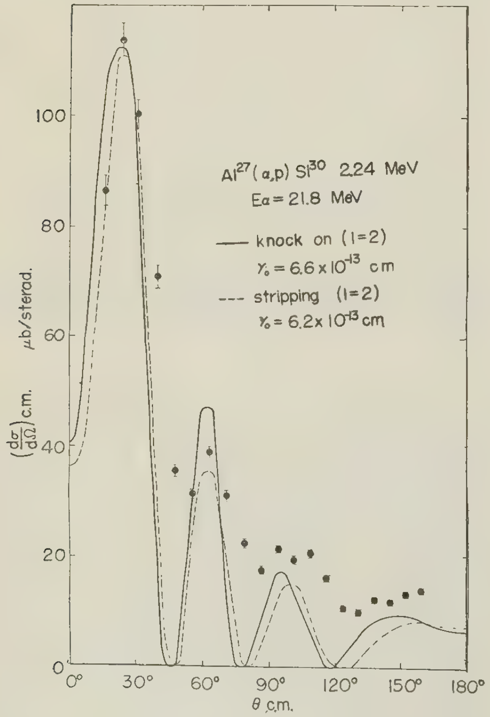

Fig. 11. Theoretical fit to the angular distribution of the $Al^{27}(\alpha, p)Si^{30}_{2.24\,\mathrm{MeV}}$ reaction using the formula of knock-on theory with $l=2$ and $r_0=6.6\times10^{-13}$ cm and the formula of stripping theory with $l=2$ and $r_0=6.2\times10^{-13}$ cm.

At the alpha particle energy of 30.4 MeV[6] the angular distributions of the p_0 and p_1 groups show marked filling in the regions between the maxima. This tendency is also observed in our results, but the filling is not so marked as that of 30.4 MeV[6]. Butler, Austern and Pearson[12] have shown in semi-classical calculation that the filling of minima in the angular distribution is produced by the absorption of either the incident or the emergent particles. This calculation suggests that the difference of the filling of minima at 21.8 MeV and 30.4 MeV is due to the difference of the absorption coefficient of either the incident or the emergent particles.

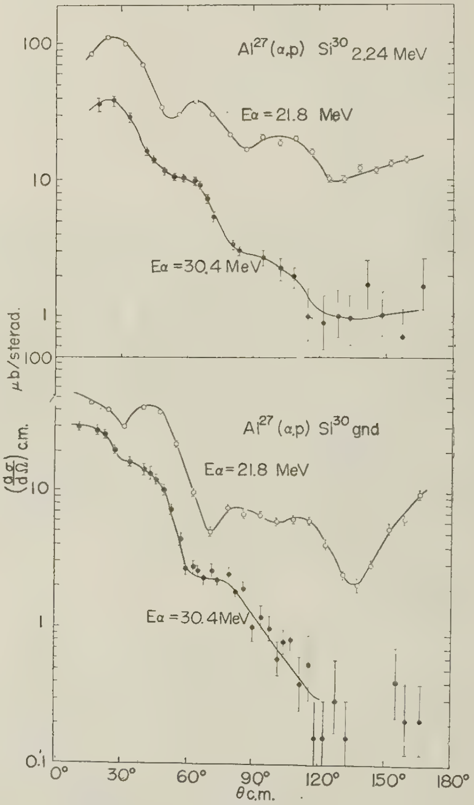

Fig. 12. Differential cross section of $Al^{27}(\alpha, p)Si^{30}_{gnd,\ 2.24\,\mathrm{MeV}}$ at $E_\alpha=21.8$ and 30.4 MeV[7] vs. c.m. scattering angle.

If we assume the interaction radius r_0 is constant in Butler's prediction[7] on direct interaction, the shapes of the differential cross sections plotted against momentum transfer q should be same at different energies. However, as shown in Fig. 12, the positions of maxima and minima in the angular distributions of the $Al^{27}(\alpha, p)Si^{30}_{gnd,\ 2.24\,\mathrm{MeV}}$ reactions at 21.8 MeV are almost same as those at 30.4 MeV, so the positions of maxima and minima will shift at different energies if the differential cross sections are plotted against the momentum transfer q (Fig. 13). Butler's prediction is based on the plane wave assumption, and if we use the distorted waves on the incident and the emergent particles this behavior of the differential cross section may be explained. This independence of the angles of maxima and minima on bombarding energies is also observed in the reaction $C^{12}(\alpha, p)N^{15}{}_{\mathrm{gnd}}$ at the alpha particle energies between 28 and 38 MeV[2] and in some (d, p) reactions at the deuteron energies higher than 10 MeV[15].

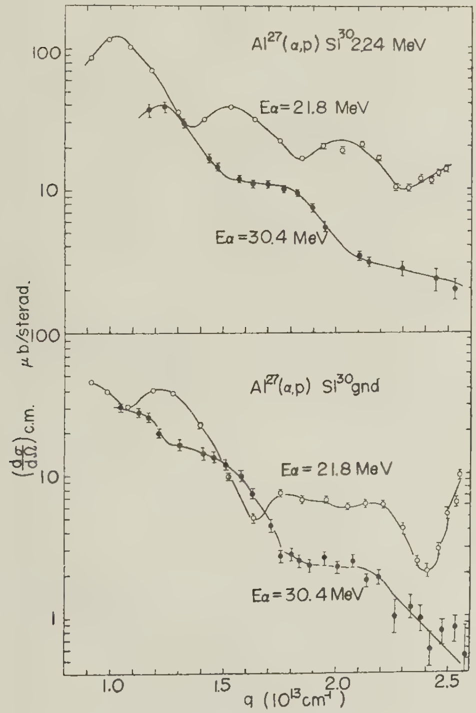

Fig. 13. Differential cross sections of $Al^{27}(\alpha, p)$ $Si^{30}{}_{\mathrm{gnd,\ 2.24\ MeV}}$ at $E_\alpha=21.8$ and 30.4 MeV[7] vs. momentum transfer q.

In the deuteron stripping reaction Satchler[16] has investigated the intrinsic probability of capture of nucleons by nuclei which exhibit collective rotations in addition to an underlying shell structure of independent nuclear orbits. In the case of (α, p) reaction, though we cannot distinguish from the angular distributions only whether the reaction proceeds through knock on or stripping process, we assume stripping for the reaction. Then the probability of triton capture by deformed nuclei is given by

$$\Lambda = \mathrm{const.} \sum_j |C_j|^2 (J_i j K_i \Omega | J_f K_f)^2 ,$$

where (J_i, K_i) and (J_f, K_f) are the angular momenta and their projections along the axis of symmetry of the nucleus for the initial and final states, and (j, Ω) are the corresponding quantities for the added triton. C_j is the probability that the triton has total angular momentum j in the spheroidal potential. In the case of $Al^{27}(\alpha, p)Si^{30}{}_{\mathrm{gnd,\ 2.24\ MeV}}$, if we assume $K_i=5/2$ and $K_f=0$, the addition of s-wave triton $(\Omega=1/2)$ is forbidden. Then only the $d_{5/2}$ triton capture is allowed for both p_0 and p_1 groups, and the ratio of the p_0 and p_1 groups $\Lambda(2^+)/\Lambda(0^+)$ becomes C_j independent,

$$\Lambda(2^+)/\Lambda(0^+) = 1.8 .$$

This explains the experimental result,

$$\Lambda(2.24\ \mathrm{MeV})/\Lambda(\mathrm{gnd}) \cong 3.5 ,$$

qualitatively.

(iv) $\mathbf{Si^{28}(\alpha, p)P^{31}}$

In the $F^{19}(\alpha, p)Ne^{22}$ reaction at 22.2 MeV and the $Al^{27}(\alpha, p)Si^{30}$ reaction at 21.8 MeV, the intensity of the p_1 group is greater than that of the p_0 group, but in the $Si^{28}(\alpha, p)P^{31}$ reaction at 22.2 MeV the intensities of the p_0, p_1 and p_2 groups are almost same. The

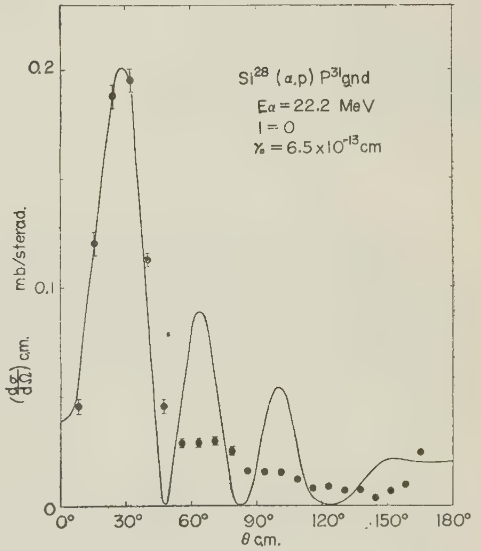

Fig. 14. Theoretical fit to the angular distribution of the $Si^{28}(\alpha, p)P^{31}{}_{\mathrm{gnd}}$ reaction using Butler's formula with $l=0$ (uniquely) and $r_0=6.5\times10^{-13}$ cm.

angular distributions of the p_0 and p_1 proton groups show oscillation, but that of the p_2 proton group does not show such a pattern and has monotonic forward peaking.

For the p_0, p_1 and p_2 groups the unique l values of 0, 2 and 2 are allowed, respectively. Therefore the angular distributions of the p_1 and p_2 groups are expected to be almost same each other in contradiction to our experimental results. The structure of P^{31} is well explained by the Nilsson model by assuming that a proton couples to the deformed Si^{30} core of 0^+.[17] In this model the first and second excited states belong to the different bands, and this circumstance may influence the angular distributions.

The results of fitting Butler's formula[7] to the data are shown in Figs. 14 and 15. The theoretical fittings of these angular distributions are satisfactory. The angular distribution of the protons consisting of unresolved p_3, p_4, p_5 and p_6 groups shows the backward peaking which is not noticeable in the p_0, p_1 and p_2 groups.

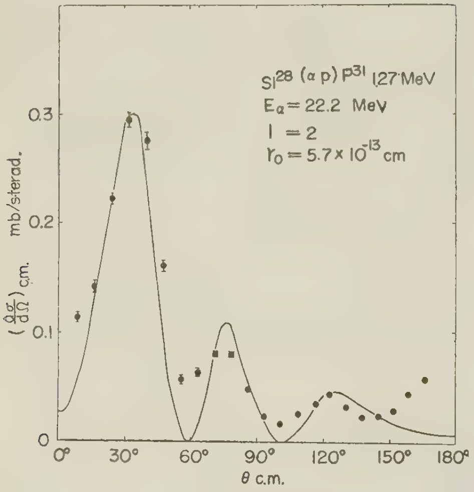

Fig. 15. Theoretical fit to the angular distribution of the $Si^{28}(\alpha, p)P^{31}{}_{1.27\,\mathrm{MeV}}$ reaction using Butler's formula with $l=2$ (uniquely) and $r_0=5.7\times10^{-13}$ cm.

Acknowledgments

The authors are indebted to Professor T. Wakatsuki for his guidance and Miss M. Kitatani for her helps in scanning the nuclear plates. The authors are also grateful to the Nishina Memorial Fundation for its financial support.

A Cloud Chamber Study of High Energy Nuclear Interactions of Cosmic Ray Particles (I)—A Possible Evidence of Successive Collisions in Carbon Nuclei

By Isao KITA

Department of Physics, Kobe University, Kobe, Japan

(Received February 10, 1961)

In an attempt to study the high energy nuclear interactions of cosmic ray particles, a momentum cloud chamber was operated at Mt. Norikura, 2740 meter high above the sea level, and about ten thousand pairs of stereoscopic pictures of the events were taken. Selected showers were transformed to the C.M.S. of the collisions to obtain the intrinsic features of the nuclear interactions. In the energy range around 100 Gev of incident nucleons, the successive collision model in carbon nuclei, rather than the complete collision model, seems to be consistent with the experimental evidences.

§ 1. Introduction

This and the succeeding papers* report the results of the experimental study of the nuclear interactions of cosmic ray particles with energies around 100 GeV. The interactions which occurred in carbon blocks were observed by a momentum cloud chamber. The chamber was operated at the Cosmic Ray Laboratory on Mt. Norikura, 2740 meter high above the sea level.

In the experiments using cloud chambers, to the contrary in the nuclear emulsion technique, the target material can be chosen as is liked and hydrogen[1], berillum[2], carbon[3),4], or other light materials[5),6] have been used to reduce the probability of successive collisions within the same nucleus. Carbon was used as the target material in this experiment because it does not have a too complex nucleus to obtain the informations on the nucleon-nucleon collisions and also is very easy to get in hand. It is expected that the nucleon-nucleon collisions can take place in a pretty large probability by the peripherical collisions of the incoming particles with the nuclei or due to the transparency of the target nuclei. Although the successive collisions can also occur in the carbon nuclei, there is a prospect that these could be treated in some way or other in such a simple nucleus as carbon.

The momentum of the individual charged particles in this chamber can be measured in a magnetic field up to 25 GeV/c. The ionization density of a track can also be estimated. Hence from the knowledge of the momenta, velocities, and the space angles of all charged particles of a shower, the Lorenz transformation to the centre of mass system of the collision can be calculated. Then the momenta and the angles of emission in the C.M.S. of the collision can be deduced, giving the intrinsic informations on the nuclear interactions of cosmic ray particles.

In this experiment it was hoped that the successive collisions within carbon nuclei could be possibly separated from nucleon-nucleon collisions in a more or less unquestionable way. The results on the successive collisions thus obtained are described in this paper and the results on the single collisions of nucleons will be reported in the succeeding paper.

§ 2. The Experimental Procedures

a) *The cloud chamber and the magnet*

The experimental apparatus used in this experiment is shown in Fig. 1. The cloud chamber situated in a magnetic field has the illuminated volume of 64 cm×64 cm×14 cm and is filled with 35 cm of argon, together with a mixture of ethyl alcohol and water. It was surrounded by a thick copper thermal jacket with flattened copper tubings soldered on its outside surface. Water of which the temperature was controlled within ±0.02°C was circulated through these tubings, and the temperature of the chamber, as measured by thermistors at different four places, was proved within±0.1°C. The dead time was 15 minutes after each expansion for repeating slow expansions and achieving the thermal equibrium of the gas in the chamber.

---

* These papers are referred to in the following as Paper I and Paper II respectively.

The illumination was achieved through the storm windows of the jacket by two Xe-filled flash tubes, each with 200 μF at 3500 volts. The stereoscopic camera which was designed in this laboratory was set at f:16 and unperforated 70 mm Fuji X ray film was used to take the pictures of the events in the chamber. The film is very sensitive and the grains of the film were found to be fine enough to be used for the droplet counting technique.

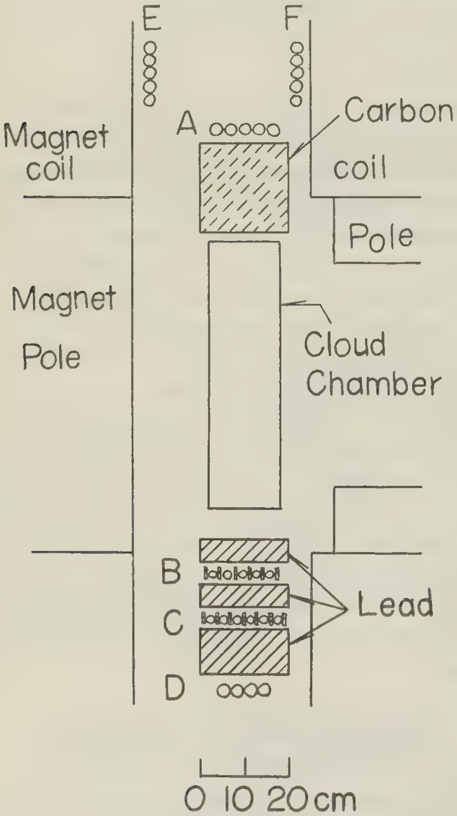

Fig. 1. The experimental arrangements.

The weight of the magnet is about 30 tons in total and the magnetic field of 7350 gausses in the average was yielded by the consumption of 55 kilowatts of power. The gap of the poles is 40 cm wide and there is a hole of 50 cm diameter in a pole for photographing.

b) *Selection of the events*

The simultaneous discharges of at least one counter of the tray A, two of the tray B, two of the tray C, and one of the tray D in Fig. 1 were required to trigger the chamber. In a part of the period of the experiment the E and F were used as anti-coincidence trays to eliminate the dense electron showers or the showers originating in the magnet coils from triggering the cloud chamber.

The photographs were taken at the average rate of 2.3 per hour and about ten thousand stereoscopic pairs of the pictures were taken during the experiment.

The film was scanned by a stereoscopic viewer and the events which were seemed to be nuclear in character were selected. The events which were clearly decided as electron showers were rejected by the visual scanning, and the showers with three or less lightly ionizing tracks were also discarded because it was thought that they were not suitable for finding the velocities of the C.M.S. of the individual events. Thus 277 events which were thought to be prospective for the analysis were picked up from the pictures taken as the first step of the selection procedure. It was realized, however, that all of these events were not fit for the full analysis, and hence more rigorous criteria which will be described later were imposed for the final selection. The analysis was made for each of these events and the results in this and the succeeding paper are mainly based on the analysis of these events.

c) *Measurements of the events*

To obtain the momentum of a charged particle, comparator measurements of the track in both views of the stereoscopic camera were made and a least-square fit was made to each track to calculate the curvature of the track on film. In case that the radius of curvature was smaller than 200 cm, it was measured by fitting the track to the circle of known radius in the full scale projection. The momentum of the particle, p_i, was then determined by applying the magnification factor and the correction of the effect due to the orientation of the track in the magnetic field.

Number of no-field tracks were photographed and the spurious curvatures in the cloud chamber were measured by the same procedures as described above. The maximum detectable momentum, thus obtained, was 25 GeV/c for 40 cm tracks in this chamber. The error in determining the momentum of a particle was assigned using this maximum value of the momentum.

The individual views of the stereoscopic pairs were projected one after the other on a sheet of drawing paper marked with the fiducial lines in full size and the differences of the horizontal coordinates of the track in the both views were measured. Then the side view of the orthogonal projection of the track was constructed, using the numerical table previously prepared. 8% of the linear dilatation was included in this table to account for the expansion of the cloud chamber. Thus the angle of the particle to the vertical line in the side orthogonal projection could be measured. The position of the origin of a shower in the carbon block was then determined from the side orthogonal view. The emission angle of the particle in the front view of the orthogonal projection was obtained, after the effect of the deflection of the particle in the magnetic field was taken into consideration. The space angle of the track was then calculated from the knowledge of the angles in the front and the side views of the orthogonal projections.

As all of the nuclear interactions selected took place in the carbon blocks placed above the chamber and the track of the incoming particle could not be seen in this experiment, the direction of the resultant momentum of the visible particles was assumed to be the axis of the shower. Then θ_i, the angle between a shower particle and the shower axis was calculated. The error in finding the space angle was estimated by repeating the measurements of the angle of a track and was found to be 1.5°.

The ionization of a particle in the cloud chamber was measured by counting the number of the droplet images along the track. Clusters of droplets which had more than 40 drops were rejected in order that the measurement was referred to the primary ionization only. As a fast particle rarely appears actually at the minimum ionization, the minimum level of the ionization was estimated by comparing the measured values with the theoretical ionization curve and the droplet density of the minimum ionization obtained was 18.0±0.6 droplets per cm in the cloud chamber. Once the minimum ionization density was obtained, $I/I_{\text{min.}}$, the ratio of the ionization of a track to the minimum ionization was used to find the velocity of the particle. The image size of a droplet on film was 15 μm.

In some cases of the events observed, however, the droplet counting technique was not available due to the unfavorable condition of the cloud chamber and hence the visual inspection of the ionization was made. In these cases it was estimated that a track could be distinguished from the minimum ionization track if the ratio of its ionization density to the miuimum value, $I/I_{\text{min.}}$ was greater than 2. As $I/I_{\text{min.}}$ exceeds 2 for a charged pion with the momentum less than 105 MeV/c and for a proton with the momentum less than 695 MeV/c, it was considered that pions and protons with the momenta less than the corresponding values given above could be identified by the visual inspection of the ionization. Hence the lightly ionizing particle with the momentum higher than 100 MeV/c was assumed to be a pion, though fast protons might be included in a minor fraction of the presumed pions. All particles below 100 MeV/c with the nearly minimum ionization were considered to be electrons.

d) *Determination of the velocity of the C.M.S.*

The velocity of the C.M.S. of the nuclear collision was determined by finding the frame of reference in which the momenta of the charged particles emitted were balanced in the forward and backward directions. Therefore the events in which the momenta of all charged particles could be measured were picked up for this analysis.

For each particle the value of the momentum p_i and its angle of emission θ_i were measured and the energy E_i was calculated by assigning the mass of the particle in the L.S. According to the Lorenz transformation, the longitudinal component $p_ic\cos\theta_i$ in the C.M.S. is given by

$$p_ic\cos\theta_i^*=\gamma_c(p_ic\cos\theta_i-\beta_cE_i)\ . \qquad (1)$$

In the C.M.S. the sum of the longitudinal components of the momenta is zero if the summation is made over all particles, charged and neutral. It was assumed, however, that the balance of the momenta should hold independently for charged and neutral particles. Hence for the charged particles measured,

$$\sum\gamma_c(p_ic\cos\theta_i-\beta_bE)=\sum p_i^*c\cos\theta_i^*=0\ . \qquad (2)$$

Thus

$$\beta_c = \frac{\sum p_i c \cos\theta_i}{\sum E_i}, \qquad (3)$$

and

$$\gamma_c = \frac{1}{\sqrt{1-\beta_c^2}}.$$

The equation (2) or (3) is rigorously true for any kind of colliding particles when the collision is considered as a single process, and is not restricted to the necleon-nucleon collisions. In fact the incoming particle can be a pion in calculating the γ_c from the equation (3). However, when the interactions are more complex, such as nucleon-nucleus collisions, the significance of γ_c, if any, depends upon the phenomenological model that is used to describe the interactions. If two or more nucleons were hit inside the target nucleus, the value of γ_c calculated in the same way as above can hardly have a definite physical meaning.

The γ_c which was obtained in the present analysis is liable to be smaller than the true value for the very high energy events. The reason for this and also the reason for the fact that the measured highest momentum is much less than the assigned energy of the incident particles is that the maximum detectable momentum of this chamber is 25 GeV/c in the present experiment. Thus one of the particles which should retain the considerable fraction of the incident energy due to the elasticity of the collision will not give the measured momentum of higher than 25 GeV/c. If a neutral particle of very high energy was emitted in the collision, it can only give the same consequence as above. On the other hand if a neutral particle whose value of $pc \cos\theta/E$ is smaller than β_c of the equation (3) is produced in the collision, this will give the larger apparent value of γ_c than the true transformation factor. There is also an error due to the statistical fluctuation by an unfavorable sharing of the momenta among the charged and neutral particles in the collision, which is inevitably introduced in calculating the velocity of the C.M.S. of the individual event.

In spite of these situations, it is presumably believed that the velocity of the C.M.S. thus calculated will give the most reliable value which can be obtained from the experimental measurements. The over-all errors in evaluating γ_c are estimated to be less than 50%.

§ 3. Nature of the Nuclear Collisions Observed

In Fig. 2 the distribution of the multiplicties of 277 events selected was plotted. This multiplicity, n_s, was defined as the number of the particles which appeared to be lightly ionizing and had the momentum of higher than 100 MeV/c. The lightly ionizing particles with the momenta of less than 100 MeV/c were considered to be electrons, as described before. The mean multiplicity calculated from the spectrum in Fig. 2 is 5.1.

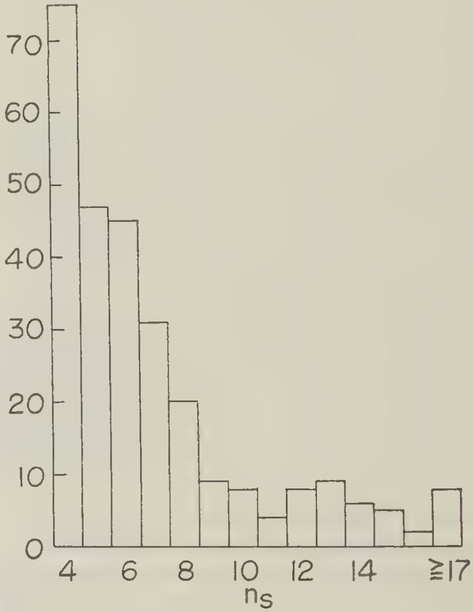

Fig. 2. The histgram of multiplicities of 277 penetrating showers selected.

It was found, however, that more rigorous criteria had to be assigned in order that the full analysis for the individual shower could be made successfully. The criteria used here are the following.

(i) The number of the nearly minimum ionizing nuclear particles with the momenta of >100 MeV/c, n_s, must be four or more, and the momenta of all of them can be measured within the admittable experimental errors.

(ii) The resultant momentum of the charged secondary particles must be 10 GeV/c or more, or three or more particles must have the momenta of >1 GeV/c.

(iii) Each of n_s tracks must be longer than 30 cm, so that a precise measurement of the momentum of the track can be made. This criterion does also confirm that all the particles are located in the well-illuminated region of the chamber.

(iv) When the front and the side views were constructed, all of the tracks must concentrate into a common origin of the shower in the carbon block within the experimental error.

Among 277 events selected above, 32 events were finally found to satisfy these criteria.

With respect to the angular distribution of the secondary particles in the C.M.S. of the collision, as will be reported in Paper II, there was a slight anisotropy with concentrations of particles in the forward and backward directions, but it was thought that the distribution could not be distinctly distinguished from an isotropy when the error in evaluating the transformation factor was taken into account. In fact the angular distribution was not appreciably different from an isotropy for each of the showers in many cases of the events analysed. These showers were designated as the *n-n* group. In the same energy range of cosmic ray interactions, an isotropic distribution in the C.M.S. of emitted particles has been reported by several authors[3),7),8)].

In some cases of showers named the *n-N* group, however, a considerably remarked anisotropy of the angular distribution with quite sharp peaks in the forward and the backward directions was observed. In these showers 80% of the secondary particles of the individual shower were included in the range of $|\cos\theta^*|>0.8$ in the C.M.S., whereas 30% of the emitted particles was included in the same range in the showers of the *n-n* group. There were nine showers of the *n-N* group.

The showers of the *n-N* group can not be regarded as the evidence of the anisotropic distribution of the secondary particles observed in the extremely high energy jet events, because the average γ_c of these showers, if calculated conventionally, is as small as 4.38, whereas the corresponding value of the showers of the *n-n* group is 9.61 as will be reported in Paper II. A possible interpretation of this small value of γ_c in the *n-N* group is that these events were produced by successive collisions of the incoming or emitted particles inside the target nucleus. In fact, if two collisions took place inside a carbon nucleus and if the emitted particles in these collisions were superposed, an apparent anisotropic angular distribution could be resulted by a Lorenz transformation of the collision in which all emitted particles of the two collisions were supposedly included. This is what is expected to occur in case that a simple nucleus like carbon was used as the target of the nuclear collisions. If the successive collisions occurred in a heavier nucleus like bromine or silver in nuclear emulsion, the interaction would be too complex to give such a simple interpretation as above.

On the other hand, the showers of the *n-n* group which showed nearly isotropic angular distributions of the emitted particles were regarded to have been produced by the nucleon-nucleon collisions of the cosmic ray particles. The events of the *n-N* group which were attributed to the successive collisions inside carbon nuclei will be discussed in the following in some detail.

§ 4. Successive Collision in Carbon Nuclei

In considering the shower events using the equation (2), the fundamental assumption was that the secondary particles were emitted in a single process of the collision of two elementary particles. It is very likely, however, that nucleon-nucleus collisions do exist among the events observed[9)], and in such an interaction two or more nucleons can be hit by the incident nucleon or by the emitted particles in the first collision. Attempts have been made to establish the interpretation of such an event in two different ways: the successive collisions[10)] and the composite collision[11)].

A picture of the successive collisions is to assume that an incoming nucleon has an interaction with a nucleon inside a nucleus and then the emitted pions or the nucleons which were concerned in the collision collide with the other nucleons in the same nucleus. Hence in this kind of collisions, the time needed to emit the pions must be shorter than the time interval between the first collision and the second. Thus

$$\frac{\hbar}{E^*} > \frac{\varLambda}{\gamma_c c}, \tag{4}$$

where E^* is the average energy of the pions produced in the C.M.S. of the first collision and Λ is the mean distance between two nucleons in a nucleus in the L.S. Λ is assumed to be of the order of the Compton wave length of a pion and E^* is taken to be 350 MeV from the result of Paper II. Then the equation (4) stands for the value of γ_c which is smaller than 15.

In a model of the composite collision, the pions are not emitted from the excited state of nucleons in the first collision before the succeeding collision takes place inside the target nucleus, or a more reasonable picture is to assume that the incident nucleon interacts with a lump of n nucleons in the nucleus as a whole. In order that this model is accepted, $\Lambda/\gamma_c c$ must be smaller than $\hbar/E^*$ instead of the equation (4): that is $\gamma_c>15$.

As the equation (4) and the corresponding equation for the composite model stand just in the order of magnitude, neither of these two models can be excluded in the energy range of this experiment from the consideration of the time sequence of the collision.

In the nine examples of the showers presented here, it was assumed that an incoming nucleon collided with a nucleon in a carbon nucleus and some ten particles were emitted isotropically in the C.M.S. of the interaction. One or more of these particles collided successively with another nucleon in the target nucleus and several particles were created with an isotropic angular distribution in the C.M.S. of the second interaction.

As the transformation factor γ_1 of the first collision is, as a matter of course, larger than that of the second collisirn γ_2, the apparent γ_{1+2} calculated by taking all the particles involved should be just between γ_1 and γ_2. Hence, if all the particles of this events were transformed by the factor γ_{1+2}, the particles produced in the first collision should show the forward peak and the particles of the second collision should be peaked in the backward direction in this supposed frame of reference. The apparent angular distribution obtained by Lorenz transformations using the wrong values of γ_c will be discussed in Paper II in detail. Therefore the particles in the forward peak were assumed to have been emitted in the first collision and the transformation factor γ_1 was calculated just in the same way as before by taking these particles into account. The vectorial resultant of the momenta of the particles in the backward peak was included in the calculation of γ_1 as one of the constituent of the collision. In the similar way γ_2 was calculated as the transformation factor of the particles in the backward peak and γ_{1+2} taking all the particles was also calculated, though it hardly has a definite physical meaning. Their average values are given below respectively.

$$\gamma_1 = 12.03 \pm 3.5\ ,$$
$$\gamma_2 = 2.22 \pm 0.5\ ,$$
$$\gamma_{1+2} = 4.38 \pm 1.6\ .$$

The second terms assigned are the root mean deviations of γ's of the events adopted. It is quite plain that the γ_{1+2} presented above is too low to be regarded as the transformation factor of the very high energy jet with a peaked anisotropic angular distribution in the C.M.S. of the collision. The average value of γ_1 is a little higher than but is pretty close to the average value of the γ_c's, 9.61, of the events of the n-n group which were attributed to the nucleon-nucleon collisions. This should be naturally accepted, because the γ_1 refers to the energy of the incoming nucleon, just as the γ_c of the nucleon-nucleon collision does so.

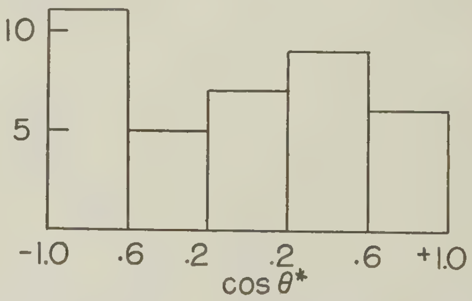

Fig. 3. The angular distribution in the C.M.S. of the emitted particles in the first interactions of the successive collisions.

In Fig. 3 the angular distribution in the C.M.S. of the emitted particles in the first collisions was plotted, which is essentially isotropic within rather poor statistics. This probably means that the first interactions of the successive collisions can be interpretated as the pure nucleon-nucleon collisions of the incoming particles in nature.

The relation between the multiplicities of the all emitted particles in the successive collisions and their corresponding values of γ_1 of the first collisions for the n-N group were plotted in Fig. 4. For comparison the multiplicities of the events of the *n-n* group which were considered as of nucleon-nucleon collision were also presented. As seen in the figure, the multiplicity of each event suffers from a large fluctuation from event to event, but if considered in the average, the multiplicities of the events of successive collisions are appreciably larger than those in nucleon-nucleon collisions. The average values are

$n_s = 7.4 \pm 2.7$ for nucleon-nucleon collisions,

$n_s = 10.6 \pm 2.3$ for successive collisions,

respectively. The difference should be interpretated as the average number of emitted particles of the second interactions in the target nuclei.

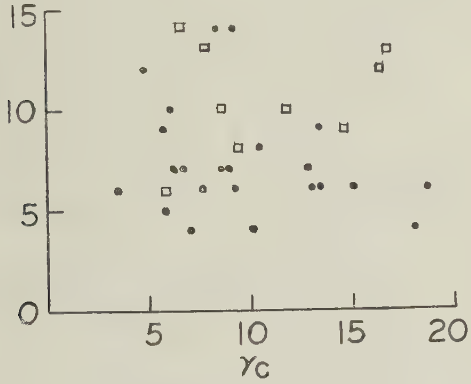

Fig. 4. Multiplicities versus transformation factors. Successive collisions are shown by squares and single collisions by solid circles.

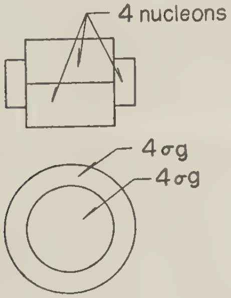

Fig. 5. A static model of carbon 12 nucleus.

In order to treat the successive collisions in more detail, a static model of a carbon nucleus was considered. As the mean free path length through a carbon 12 nucleus is 1.50 times the nucleon diameter, which was just geomertrically calculated, it was assumed that a carbon nucleus was consisted of three layers, each of which included four nucleons. This is shown in Fig. 5, which gives the nucleus a more or less spherical shape and also implys that the incoming fast nucleon can not collide with more than two nucleons in succession. If each nucleon in the target nucleus has the geometrical nuclear cross section, σ_g, and hence, if each layer is opaque for the incoming nucleon, the rate of the occurrence of nucleon-nucleon collisions should be the same as that of successive collisions. If, however, these layers have the transparency of η, the ratio of the rate of the successive collision to that of single collisions is calculated to be

$$R_n = \frac{4\sigma_g(1-\eta)(1-\eta^n)}{4\sigma_g(1-\eta)(1+\eta+\eta^n)} = \frac{1-\eta^n}{1+\eta+\eta^n}, \qquad (5)$$

where n is the number of the particles which were produced in the first collision and could give rise three or more pions in the succeeding collision, so that the backward peak could be noticed. n was assumed to be one third of the multiplicity of the first interaction. As there is no definite information on η of the incident nucleon or of the produced pions in such high energy nucler interactions, the transparencies were assumed to be the same for the successive two interactions in the target nucleus.

In Fig. 6 the calculated curves of R_n are shown for the values of n of 2, 3, 4, and 5. As seen in the figure the curves of R_n are not too sensitive to the variation of n. As the average multiplicity of nucleon-nucleon

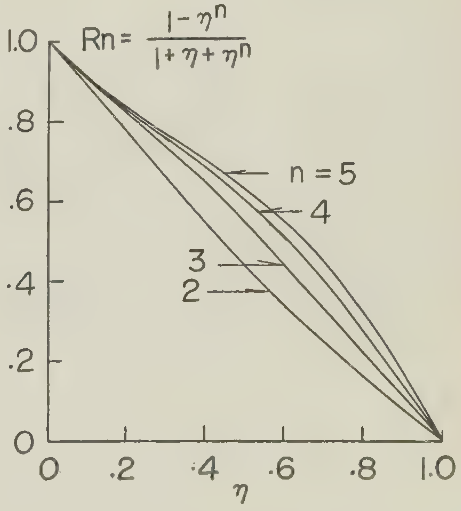

Fig. 6. Calculated curves for the ratios of the cross section for the successive collisions to that of the single collisions.

interactions in this experiment was 11.1, taking the contribution of the neutral pions into account, the value of n adopted was 3.7. There probably is an error due to the uncertainty in identifying the events of the n-N group, which was estimated to be ±3. Then the observed ratio of R_n is $9 \pm 4/23 \pm 6 = 0.39 \pm 0.19$. Thus from the curves in Fig. 6, the transparency η was estimated to be 0.68 ± 0.16. Therefore, if the geometrical nuclear cross section of a nucleon was taken to be 60 mb, the nuclear interaction cross section of a nuclear particle in a carbon nucleus is evaluated to be 19±9 mb. This is in a pretty good agreement with the results obtained in the experiments using the protons or pions of accelerators[12),13)].

When it is accepted that $n = 3.7$ and $\eta = 0.68$, the number of the secondary particles which collide with another nucleon in the carbon nucleus in succession is quite close to one. As this particle is most probably a pion which was emitted in the forward direction in the first interaction, the energy of the particle in the L.S. is calculated to be $E = 8.1$ GeV, using the Lorenz factor of the first collision $\gamma_1 = 12.03$ and the average energy of the pion $E^* = 350$ MeV in the C.M.S. The Lorentz transformation factor between the L.S. and the C.M.S. of the succeeding collision of this particle is calculated from the equation

$$E_\pi = M_N\{\gamma_2\sqrt{\gamma_2^2 - 1 + (M_\pi/M_N)^2} + \gamma_2^2 - 1\}\,, \tag{6}$$

resulting $\gamma_2 = 2.30$, which is in a fairy good agreement with the average value of $\gamma_2 = 2.22$ observed. This is probably another possible evidence of the succession collision model.

In conclusion, from the results of analysis presented above, it might be difficult to treat the successive collisions inside the target nucleus too quantitatively, but it is very plausible that the successive collision model is valid in the nucleon-nucleus collisions in the energy range of this experiment around 100 GeV/c.

Finally the author wishes to express his gratitudes to Professor O. Minakawa for his interest and discussions on this experiment. Thanks go also to Mr. C. Yokoyama, without whose help this work would not have been possible. Dr. Y. Toyoda and Mr. T. Maeda helped the mountain observation. He is indebted to the authorities of Cosmic Lay Laboratory for offering him the facilities for making the experiment on Mt. Norikura. This work was done in collaboration with Professor G. Fujioka.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 16, No. 6, JUNE, 1961

A Cloud Chamber Study of High Energy Nuclear Interactions of Cosmic Ray Particles. (II)—Results of Single Nucleon-Nucleon Interactions

By Goro FUJIOKA

Department of Physics, Kobe University, Kobe, Japan

(Received February 10, 1961)

30 possible nucleon-nucleon interactions of primary energies around 100 GeV observed in a magnet cloud chamber were analyzed in their center of mass systems. The angular distribution of secondary particles was nearly isotropic. The average values of E^* and p_T were 350 MeV and 220 MeV/c, respectively, the R.M.S. deviations about mean values being 225 MeV and 160 MeV/c. The energy spectrum can be represented as $E^{*-2}dE^*$. The inelasticity of interactions had a tendency to decrease with increasing primary energies. The average inelasticity in the center of mass system was 0.27 ± 0.05. All interactions had almost equal number of shower particles in the foreward and backward directions in the center of mass system.

§ 1. Introduction

The production of secondary π-mesons in a single nucleon-nucleon collision at the range of primary energies above those obtained by accelerators is a very important problem and has been investigated by various authors with cloud chambers[1)-5)] and nuclear emulsion[6)] utilizing cosmic ray particles.

From nuclear interactions in a carbon block caused by cosmic ray particles with energies around 100 GeV observed at Mt. Norikura (alt. 2740 m) in a magnet cloud chamber, 30 events which can be attributed to a single collision have been treated in this article. The apparatus and the procedure of measurements were reported in the preceding paper (hereafter referred to as Paper I).

The primary energy of the collision was calculated from momenta and angles of emission of shower particles in the laboratory system, assuming that the collision was nucleon-nucleon, and the analysis of the interaction in its center of mass system was presented. It is considered that about a quarter of events observed was caused by charged π-mesons, but results obtained can be regarded as those of nucleon-nucleon collisions without giving any appreciable error.

The analysed events were confined to those in which momenta of all particles could be measured, that is, no momentum of shower particles should exceed our M.D.M., 25 GeV/c, and in which four or more shower particles should be included. These criteria were necessary because the calculation of the primary energy needed momenta of all particles, and because fluctuation of calculated values might be fairly large, if number of particles considered was too small. Other conditions of selection of events were that the total visible momentum should exceed 10 GeV/c or three or more particles should have momenta greater than 1 GeV/c, and that the convergence of shower particles on the origin should be good enough.

§ 2. The Nature of the Collision and the Primary Energy

As described in Paper I, the shower axis, i.e. the direction of the primary particle, was determined from the balance of the transverse momenta of shower particles, and then the Lorentz transformation factor γ_c of the C.M.S. was obtained from the balance of the longitudinal momenta in that system assigning appropriate masses for secondaries.

As carbon was chosen as the target material in this experiment, there were some cases in which the target was not a single nucleon. The method to estimate the number of target nucleons participated to the interaction was also given in Paper I. If the angular distribution of secondaries in the C.M.S. transformed by the above-obtained γ_c showed too much concentration in the forward and backward directions, it seemed reasonable to interprete that more than two nucleons took part in this collision. Those events in which more than 80% of particles were included in the region of angle, where $|\cos\theta^*|>0.8$, were classified as n-N group. The other events were assumed to be with the only one nucleon of the target carbon nucleus in this analysis, and were classified as n-n group.

In n-N group, particles in the forward hemisphere in the frame transformed by the above-obtained γ_c were considered to be emitted from the first collision with a single nucleon, and the same procedure was applied to calculate γ_c for this first collision. It was found that the features of collisions in the C.M.S. thus obtained were similar to those of collisions in n-n group, and therefore those two types of 30 collisions (23 events of n-n group and 7 first collisions of n-N group) were included in the next analysis. In two cases of n-N group, the number of particles of first collisions was three, and such events were discarded.

The primary particles responsible to the interactions are protons and π-mesons. At this altitude and in this energy-region the ratio of the number of charged π-mesons to the number of protons is less than 40%.7) Assuming that these two types of particles have the same cross sections and that interactions were caused by charged particles as expected from our triggering counter system, about 30% of our interactions might be caused by charged π-mesons. There is some possibility that interactions caused by neutrons were included, as accompanying charged particles could hit the upper counter tray. Therefore the fraction of intractions caused by charged π-mesons may be slightly lower. The rough estimate from the positive excess (1.0 per interaction) assuming the same number for primary positive and negative π-mesons gave the value of 25% for the fraction of π-meson induced interactions.

Though this fraction is not negligibly small, we have considered that our results were those of nucleon-nucleon interactions, because we did not find any peculiar features in individual cases, and because jet showers in nuclear emulsion showed not much difference, whether they were produced by the singly charged primary cosmic-ray particles (which were mainly nucleons at the balloon altitude) or by the singly charged secondary particles from the jets (mainly π-mesons).8) If the interactions caused by nucleons and charged π-mesons are slightly different in character, this postulation will not give important errors in interpreting the results.

Thus 30 nucleon-nucleon collisions were analysed in the C.M.S.. γ_c's range from 3.5 to 18.9, and the mean value is 10.2.

When the target is a single nucleon, the energy of the primary particle in the L.S. is approximately

$$2\gamma_c^2 M_N \qquad \text{for } \gamma_c^2 \gg 1,$$

where M_N is the rest energy of the nucleon, and is nearly independent of the mass of the primary particle. The distribution of primary energies is given in Fig. 1.

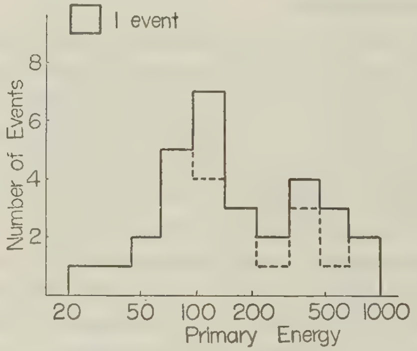

Fig. 1. The distribution of primary energies of nucleon-nucleon interactions. Events above broken lines are of n-N group.

§ 3. The Angular Distribution of Shower Particles in the C.M.S.

The angle of emission of the shower particle in the C.M.S. was calculated by the usual transformation formula,

$$\tan\theta_i^* = \frac{\sin\theta_i}{\gamma_c(\cos\theta_i - \beta_c/\beta_i)}\,. \tag{1}$$

The angular distribution of secondary pions in the C.M.S. thus obtained is shown in Fig. 2. It shows a little peak in the forward direction and a fairly sharp peak in the backward direction.

The average of $|\cos\theta_i^*|$ for each shower was also calculated, and the histogram of this quantity is shown in Fig. 3. The mean value for all events is 0.58 ± 0.03. If the distribution is isotropic, this average should be

0.5, and if the distribution is $|\cos\theta^*|d(\cos\theta^*)$, this should be 0.61, for $\beta_c/\beta^*=1$.

To determine whether the distribution is anisotropic or not, the systematic error caused by the wrongly assigned value of γ_c can not be overlooked. If we use a wrong value γ_c' for the transformation, the solid angle element in the true C.M.S. is transformed in this assigned C.M.S. by the formula,

$$\sin\theta^* d\theta^* = \frac{4\alpha^2}{[(1+\cos\theta^{*\prime})+\alpha^2(1-\cos\theta^{*\prime}]^2}\sin\theta^{*\prime}d\theta^{*\prime}\,, \qquad (2)$$

where $\alpha=\gamma_c/\gamma_c'$, and the assumption that $\beta_c/\beta^*=\beta_c'/\beta^{*\prime}$ is made. The curves of $\sin\theta^* d\theta^*/\sin\theta^{*\prime}d\theta^{*\prime}$ are shown in Fig. 4 for various α values. They are the angular distributions, which we shall obtain due to the erroneous estimate of the primary energy, when the distribution in the true C.M.S. is isotropic. Thus the error in γ_c gives the obtained distribution an apparent an isotropy; it also makes the average of $\langle|\cos\theta^*|\rangle$ larger than 0.5 as shown in Fig. 5, even if the true distribution is isotropic.

There are two sources of error in estimating γ_c that should be considered. The first is the fluctuation on account of the neglection of unseen particles, and perhaps this gives the average error of about 30%. The second is the plural interaction in the nucleus. As shown in Paper I some events

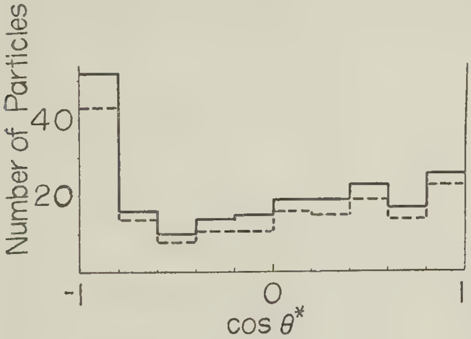

Fig. 2. The angular distribution of shower particles in the C.M.S.. Particles above broken line are of n-N group.

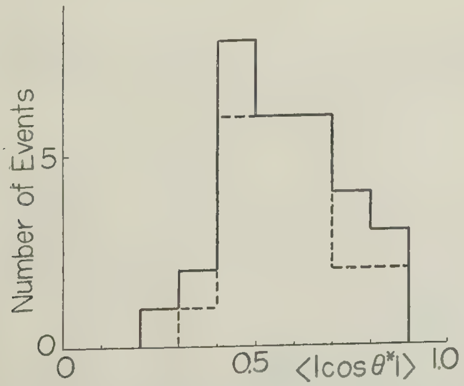

Fig. 3. The distribution of $\langle|\cos\theta_i^*|\rangle$. Events above broken lines are of n-N group.

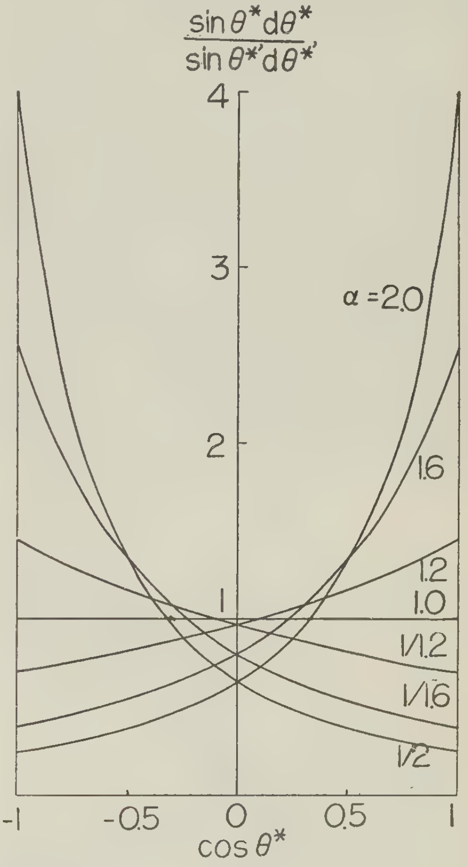

Fig. 4. $\sin\theta^* d\theta^*/\sin\theta^{*\prime}d\theta^{*\prime}$ for various α values, assuming $\beta_c/\beta^*=\beta_c'/\beta^{*\prime}$.

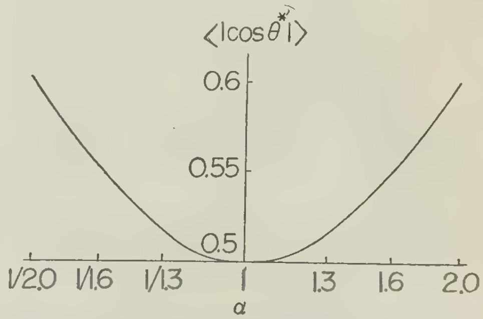

Fig. 5. $\langle|\cos\theta^{*\prime}|\rangle$ *vs.* α, when the distribution in the C.M.S. is isotropic, for $\beta_c'/\beta^{*\prime}=1$.

were interpreted as such and they were discarded from this analysis as stated in § 2. But if the multiplicity of the interaction in the same nucleus caused by the secondary particle emitted from the first interaction was small, or if the energy of the shower particle responsible to this second interaction was not far smaller than that of the primary which had caused the first interaction, such events would not show remarkable separate peaks and might be included in the *n-n* group in this analysis. As $\gamma_1/\gamma_{1+2}\sim 2$ for *n-N* group as shown in Paper I, this source of error will not give the error over 50%.

Considering the effect of the error in γ_c, Figs. 2 and 3 can not be considered as the definite evidence for the anisotropic distribution. But we may go too far if we attribute this anisotropy only to the apparent effect due to the error in γ_c. Our conclusion is that the angular distribution of secondaries in the C.M.S. is not far from isotropy in this range of primary energy.

As the another approach to this problem the indirect but widely used so-called *F*-plot[9] was also considered. To treat all events as a whole, each value of $\tan\theta_i$ was multiplied by γ_c. This means that $\log(F/1-F)$ versus $\log(\gamma_c\tan\theta)$ should be the straight line with the gradient 2 crossing the abscissa at $\gamma_c\tan\cdot\theta=1$ when the distribution is isotropic and β_c/β^* is 1, because

$$\log(F/1-F)=\log(\gamma_c\tan\theta)^2$$

in this case. The *F*-plot constructed from 208 particles is shown in Fig. 6, together with the expected curves for isotropic distribution with $\beta_c/\beta^*=1.0$ and 1.09 (which is the average value in our case). The experimental points can be approximated by these curves if all γ_c values are multiplied by 1.35. This horizontal displacement of *F*-plot is hard to explain but may reflect the fact that the energy estimate from the angular distribution gives high values systematically.[10] Thus the *F*-plot also shows that the angular distribution in the C.M.S. is nearly isotropic.

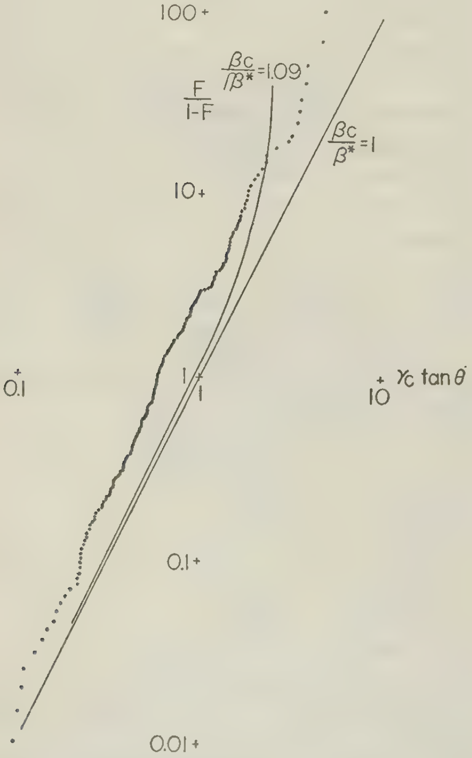

Fig. 6. The normalized *F*-plot constructed from 208 particles of 30 showers.

§ 4. The Energy of Secondaries in the C.M.S.

The energy of secondary pions was calculated according to the usual formula,

$$E_i^*=\gamma_cE_i-\sqrt{\gamma_c^2-1}\,p_ic\cos\theta_i\,. \tag{3}$$

At first, we consider the effect of the error in γ_c. Differentiating (3) by γ_c,

$$\frac{\partial E_i^*}{\partial\gamma_c}=E_i-\frac{\gamma_c}{\sqrt{\gamma_c^2-1}}\,p_ic\cos\theta_i\,. \tag{4}$$

Therefore, if $\Delta\gamma_c$ is not large,

$$\begin{aligned}\frac{\Delta E_i^*}{E_i^*}&=\frac{\Delta\gamma_c}{\gamma_c}\Big[E_i-\frac{\gamma_c}{\sqrt{\gamma_c^2-1}}\,p_ic\cos\theta_i\\&\qquad\Big/E_i-\frac{\sqrt{\gamma_c^2-1}}{\gamma_c}\,p_ic\cos\theta_i\Big]\\&=\frac{\Delta\gamma_c}{\gamma_c}[\beta_cE_i-p_ic\cos\theta_i\\&\qquad/\beta_cE_i-\beta_c^2p_ic\cos\theta_i]\,.\end{aligned} \tag{5}$$

The absolute value of the term in the bracket of (5) is smaller than 1, if

$$\cos\theta_i<\frac{E_i}{p_ic}\;\frac{2\gamma_c\sqrt{\gamma_c^2-1}}{2\gamma_c^2-1}\,, \tag{6}$$

which in many cases holds. Therefore the error in E_i^* introduced by the error in γ_c is in many cases smaller than that of γ_c in percentage and its sign is the same with the sign of the error of γ_c, if the particle is in the backward hemisphere, and the opposite if in the forward hemisphere.

Thus the error in γ_c does not give the systematic error to the energy distribution in the C.M.S., not as in the case of the angular distribution.

The energy distribution is given in Fig. 7. The mean energy was 350 MeV, and the R.M.S. deviation about the mean was 225 MeV. This distribution is expressed fairly well by the formula $1/E^{*2}$ as shown in the figure.

To see if there is any correlation between the energy and the emitted angle, the average energies of particles emitted in given ranges of angles are plotted against the angle of emission in the C.M.S. in Fig. 8. It can be considered as constant, though there are some fluctuations; this shows that there is little dependence of the energy upon the emitted angle in the C.M.S.

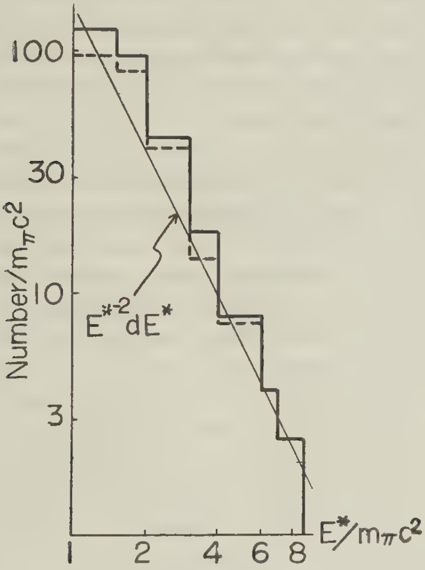

Fig. 7. The energy distribution of secondary π-mesons in the C.M.S.. Particles above broken lines are of n-N group.

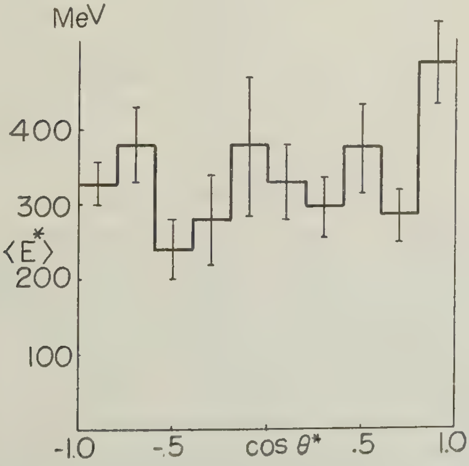

Fig. 8. The average π-meson energy vs. the emitted angle in the C.M.S..

§ 5. The Transverse Momentum of Secondary Particles

The transverse momentum is, of course, Lorentz invariant and independent of γ_c. The distribution of transverse momentum obtained in this experiment is shown in Fig. 9. The average value was 220 MeV/c, and the R.M.S. deviation about the mean was 160 MeV/c.

As the direction of primary particles was determined from the balance of transverse momenta, the transverse momenta were slightly underestimated as pointed out by Minakawa et al.[11] They presented a statistical treatment to obtain the $2n$-th moment of the true distribution of transverse momenta from the observed one. By this method the second moment of the true distribution was calculated. This was $(9.3\pm1.6)\times10^4(\mathrm{MeV/c})^2$, whereas the observed second moment was the

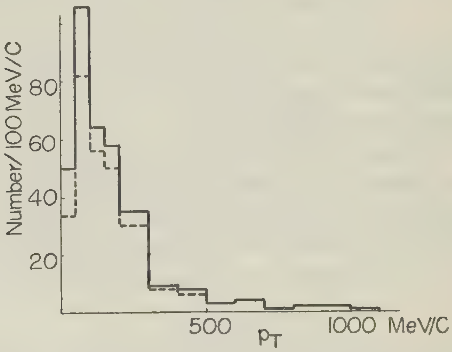

Fig. 9. The distribution of transverse momentum. Particles above broken lines are of n-N group.

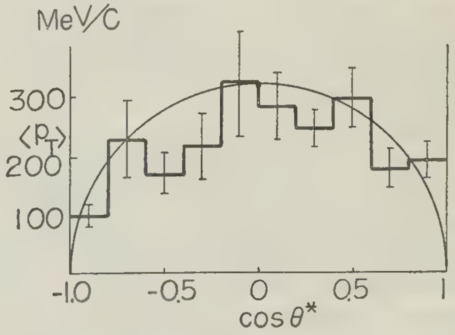

Fig. 10. The average transverse momentum vs. the emitted angle in the C.M.S..

$(7.5\pm1.4)\times10^4(\mathrm{MeV/c})^2$. This shows that the obtained distribution does not differ appreciably from the true one and that the error of determining the primary direction in this analysis is not important.

As it is interesting to see the angular dependence of p_T, the average transverse momentum of pions emitted in given ranges of angles in the C.M.S. is also shown in Fig. 10, though this is not independent of the similar graph for the C.M.S. energy. If there is little correlation between E^* and θ^*, as shown in § 4, p_T should be represented as $\langle p^*\rangle \sin\theta^*$. This curve is drawn in Fig. 10, where $\langle p^*\rangle$ corresponds to $\langle E^*\rangle=350$ MeV. The obtained histogram is rather better approximated by this curve than constant p_T, suggesting again that E^* has little correlation with θ^*.

§ 6. Inelasticity of Collisons

The inelasticity K, that is, the fraction of energy carried out by created particles, was considered in the C.M.S.. This is defined by

$$K=\frac{\sum E_i^*}{2(\gamma_c-1)M_N}, \qquad (7)$$

for the nucleon-nucleon collision, where the summation should be taken over all particles, charged and neutral.

If the primary particle is a π-meson, the velocities of the primary and the target are not the same in the C.M.S.. Putting the suffix π for quantities of the primary π-meson in this system, by the definition of the C.M.S.,

$$\beta_\pi\gamma_\pi M_\pi=\beta_c\gamma_c M_N\,. \qquad (8)$$

The available energy in the C.M.S. including the primary rest mass is

$$\gamma_\pi M_\pi+(\gamma_c-1)M_N\approx(2\gamma_c-1)M_N\,,$$

because $\beta_c\approx\beta_\pi\approx1$. Therefore, in this case K is overestimated if we calculate it from (7), but the error seldom exceeds 10% in our range of γ_c.

If the most energetic positive particle had an energy two times greater than that of any other particle in the L.S., this particle was assumed to be a proton and was not summed up in the numerator of (7). If this particle were a π-meson, K would be underestimated by about 0.2. This was estimated assuming a pion mass for this particle.

To take account the unseen π^0-mesons, the sum for all charged secondaries assuming pion masses was multiplied by 1.5 and was used as $\sum E_i^*$ in (7).

The assumption of all secondaries with momenta greater than 110 MeV/c as π-mesons gives an underestimate of the inelasticity, if K-mesons are produced in that event. The error introduced by this assumption was estimated in each case, assuming that the charged particle, which had the momentum in the L.S. higher than and nearest to 410 MeV/c, was a K-meson and that the neutral K had the same energy with it. This assumption is the very extreme one which gives the highest inelasticity, but was adopted to see the limit of the error. This error seldom exceeded 0.2 under this extreme assumption in our cases.

Thus our value of K assuming that all secondaries are π-mesons and the neutral π-mesons carry half of the energy of all charged π-mesons is correct within the error or 0.2 in the average. K's are plotted against γ_c in Fig. 11. The mean value of K was 0.27 ± 0.05, where the error cited was the standard deviation.

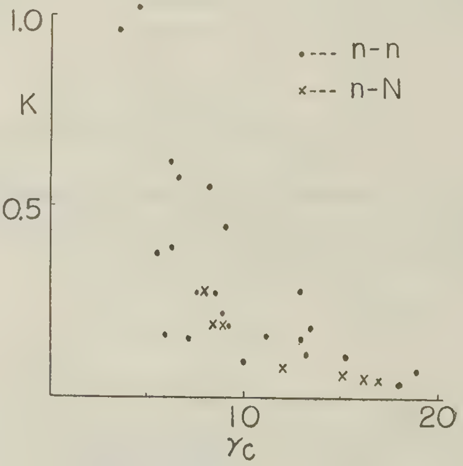

Fig. 11. The inelasticity K *vs.* γ_c.

There is a tendency that K decreases with increasing γ_c. This is not to be taken literally, because many of the high K events with high γ_c might contain too many particles to be analysed or might contain π-mesons with the momentum higher than 25 GeV/c, and those were excluded from this analysis. But the lower limit of K shows the same tendency with increasing γ_c, and, therefore, this is perhaps the true effect.

§ 7. Comparison with Other Results and Discussions

The angular distribution of secondary pions in the C.M.S. is similar to those obtained by Hansen and Fretter,[1] and by Montanet et al.,[2] and shows a slight anisotropy. Kaneko et al.[6] obtained a nearly isotropic distribution in the region of a little lower primary energies. This difference may be due to the difference of altitudes, because at mountain altitudes about one fourth of interactions are caused by charged π-mesons as described in § 2. But considering the systematic error introduced by the fluctuation of γ_c and by the secondary interactions in the nucleus, the discrepancies seem not serious. Though the possibility that there are some events with a weak anisotropy can not be excluded, the angular distribution is not very far from isotropy in the average at this range of primary energies.

The distributions of energy in the C.M.S. and of the transverse momentum are similar between those experiments and ours. Our mean values of E^* and p_T are somewhat lower than those of other authors, but the differences are not significant. $E^{*-2}dE^*$ spectrum seems to hold rather well. This spectrum is just the same with that assigned by Heisenberg[12] in his theory. But this only one point should not be trusted too much as the evidence to support his theory. The independence of the energy and the angle of emission of secondary pions in the C.M.S. shown in § 4 and 5 may favour the statistical model.[13] Perhaps at $\gamma_c \sim 10$ any theory at present can hardly explain satisfactorily all features of interactions.

The tendency that the inelasticity decreases with increasing primary energy was also pointed out by Hansen and Fretter. The average values of K obtained by several authors lie around 0.3 and agree well with ours.

In this analysis we found no example of assymmetric emission of secondaries found by Dobrotin et al.[5] Such assymmetric events, if they exist, contain a high energy particle in many cases, and we might exclude such events as we analysed events in which the momentum of no particle exceeded 25 GeV/c. But assymmetric events with a high energy backward proton in the C.M.S. should be included in this analysis. Even in such cases longitudinal momenta of charged particles should nearly balance in the C.M.S., as it is very implausible that one neutral particle carries an extraordinary momentum in these cases of the presence of one high energy backward proton in the C.M.S.. Our method of estimating γ_c did not depend on the symmetricity of the emission of secondary particles in the forward and backward directions in the C.M.S., but utilized the balance of longitudinal momenta. Therefore it is very unlikely that our calculated γ_c is mistaken by a factor of more than 2, even if we assumed these protons as π-mesons in such cases. Thus we can not find any reason, except the fluctuation of the occurence, why we found no such cases.

We can not say much about the fraction of assymmetric interactions, if any, but our results hold for the symmetric emission of secondaries.

The author wishes to thank Prof. O. Minakawa for his valuable suggestions and discussions. The collaboration with Prof. I. Kita and Mr. C. Yokoyama throughout this work and with Mr. S. Hozumi at the earlier stage of this work was extremely pleasant. Dr. Y. Toyoda and Mr. T. Maeda helped the mountain observation. We are indebted to the Director of Norikura Cosmic Ray Laboratory and his staff, who made this experiment possible. The work was partly supported by the Scientific Research Expenditure of the Ministry of Education.

Effects of *s–d* Exchange Interaction and Temperature-Independent Paramagnetism on Susceptibilities of Nickel, Palladium and Platium

By Masao SHIMIZU

Department of Physics, Faculty of Science, Tokyo Metropolitan University, Tokyo

(Received September 9, 1960)

The well-known discrepancy between the number of the Bohr magneton obtained from the saturation magnetization at 0°K and that obtained from paramagnetic susceptibilities for Ni is explained by taking into account the s–d exchange interaction, instead of the s–d electron transfer, and the temperature-independent paramagnetism due to the orbital moments of d electrons. The similar discrepancy between the number of magnetic carriers obtained from the paramagnetic susceptibility measurement at lower temperatures and that at higher temperatures for Pd is explained in the same way. The same discussion is applicable to Pt. It is concluded that the temperature-independent paramagnetism is important to understand the temperature variations of susceptibilities of transition metals. The paramagnetic susceptibilities for Ni, Pd, and Pt at higher temperatures are expressed in the form, $C/(T-\theta_p)+\chi_0$. The temperature-independent susceptibility, χ_0, is the sum of the paramagnetic susceptibility of the conduction electron (or s electron) spins and that due to the orbital moment of d electrons.

§1. Introduction

It is well-known that the numbers of the Bohr magneton obtained from the saturation magnetization at 0°K for ferromagnetic iron-group metals are different from those numbers estimated from the paramagnetic susceptibility above the Curie temperature¹⁾.

There are two ways at present to obtain the number of the Bohr magneton from the experimental measurements of the paramagnetic susceptibility above the Curie temperature. One is to use the Curie-Weiss law and the other is to use the $1/\chi-T^2$ law where the variation of $1/\chi$ with T^2 is linear.

Using a modified electron gas model, we have attempted to explain the temperature variations of paramagnetic susceptibilities of the iron-group metals above the Curie temperature, but a satisfactory quantitative agreement between the experimental results and our theoretical results for the susceptibilities has not been obtained.[2]

Especially, the variation with temperature of $1/\chi$ for Ni follows neither the Curie-Weiss law nor the $1/\chi - T^2$ law. At higher temperatures the curve $1/\chi$ vs. T follows the Curie-Weiss law apparently. Also, for Pd the curve $1/\chi$ vs. T follows the Curie-Weiss law apparently at higher temperatures. However, the numbers of the Bohr magnetons obtained from these Curie constants for Ni and Pd at higher temperature regions are also larger than the numbers which are obtained from the experimental results at lower temperatures.

Then, it seems that a new mechanism is necessary to explain the temperature variation of the susceptibilities above the Curie temperature for the ferromagnetic iron-group metals, especially for Ni, and that of Pd.

On the other hand these discrepancies have so far been studied by Watanabe[3], Wohlfarth[4], and Krinchik[5], introducing the mechanism of electron transfer between s and d bands, and by Vonsovskii and Vlasov[6] introducing the s–d exchange interaction. Especially Wohlfarth has examined the effect of the s–d transfer on the paramagnetic susceptibilities for pure Ni and Ni–Cu alloys in detail. He has concluded that an increase, with temperature, of the number of holes in the $3d$ band accounts for the major part of the down-ward curvature of the $1/\chi - T$ curves at higher temperatures, but it does not suffice to explain the whole of it.

Moreover, Wohlfarth has found that the electronic specific heat of the $3d$ band increases at higher temperatures because of the increase of the number of holes in the $3d$ band. It seems, however, that experimental results for the specific heat of Ni at higher temperatures do not show the same increase as the one that Wohlfarth has obtained theoretically, although the experimental results at higher temperatures are not absolutely certain. The specific heats at higher temperatures for Ni, Pd, and Pt are discussed in § 4.

Then, consistently to explain the temperature variation of the susceptibilities and the specific heats at higher temperatures for the ferromagnetic iron-group metals, especially for Ni, and Pd, it seems that a new mechanism besides the electron transfer between s and d bands is necessary.

In this paper we take into account the exchange interaction between s and d electrons and examine the effect on the paramagnetic susceptibilities for Ni, Pd, and Pt (§ 2). We assume that the s–d exchange interactions for these metals are ferromagnetic but we do not think that the ferromagnetism of Ni is caused entirely by this s–d exchange interaction. The exchange interaction between d electrons is assumed to be larger than the s–d interaction. By the modified electron gas model we can ascertain this fact (§ 3).

If we take into account the temperature-independent paramagnetic susceptibility which is expected to derive from the contribution of the orbital moment of d electrons to the total magnetic moment, we can satisfactorily explain the temperature variations of the paramagnetic susceptibility for Ni and Pd.

§ 2. Effect of Exchange Interaction between s and d Electrons on Paramagnetic Susceptibility of Transition Metals

In order to consider the s–d exchange interaction in transition metals, we use the approximation of tight-binding for d and s electrons. Let the spin operators for d and s electrons be $\boldsymbol{s}_k$ and $\boldsymbol{\sigma}_{k'}$ respectively. The s–d exchange energy is $-2\sum_{k,k'} J_{kk'}\boldsymbol{s}_k\cdot\boldsymbol{\sigma}_{k'}$. $J_{kk'}$ is an exchange integral between d electron with wave vector k and s electron with wave vector k', and is nearly equal to J/N, where J is an atomic s–d exchange integral and N is the total number of lattice points.

The mean value of the s–d exchange energy becomes

$$-2\sum_{k,k'} J_{kk'}\langle \boldsymbol{s}_k\cdot\boldsymbol{\sigma}_{k'}\rangle_{\mathrm{AV}} = -2JN^{-1}\boldsymbol{M}_s\cdot\boldsymbol{M}_d/(g_s g_d \mu_B{}^2)\,, \tag{2.1}$$

where

$$\left.\begin{aligned} \boldsymbol{M}_d &= N_d g_d \mu_B \langle \boldsymbol{s}_k\rangle_{\mathrm{AV}}\,,\\ \boldsymbol{M}_s &= N_s g_s \mu_B \langle \boldsymbol{\sigma}_{k'}\rangle_{\mathrm{AV}}\,, \end{aligned}\right\} \tag{2.2}$$

and N_d and N_s are the numbers of d holes and s electrons respectively.

From (2.1), the effective fields for d holes and s electrons become respectively, as shown by Owen et al.[7],

$$\left.\begin{aligned} \boldsymbol{H}_d &= \lambda \boldsymbol{M}_s\,,\\ \boldsymbol{H}_s &= \lambda \boldsymbol{M}_d\,, \end{aligned}\right\} \tag{2.3}$$

where

$$\lambda=2J/(Ng_s g_d \mu_B^2)\ . \tag{2.4}$$

Let the paramagnetic susceptibility of the d holes above the Curie temperature and that of the s electrons be χ_d and χ_s respectively. The magnetizations of d holes and s electrons are given by

$$\left.\begin{aligned} M_d&=\chi_d(H_0+\lambda M_s)\ ,\\ M_s&=\chi_s(H_0+\lambda M_d)\ , \end{aligned}\right\} \tag{2.5}$$

where H_0 is an external magnetic field.

Then, the total magnetic susceptibility χ is given by

$$\chi=(M_d+M_s)/H_0=\chi_d\frac{(1+\lambda\chi_s)^2}{1-\lambda^2\chi_s\chi_d}+\chi_s\ . \tag{2.6}$$

If there is a contribution from the orbital moment of d electrons to the total magnetic moment, we must take into account the temperature independent paramagnetic susceptibility[8], $\chi_{d,\mathrm{orbit}}$, and this should be added to the susceptibility given by (2.6). Kubo and Obata have pointed out that this is important in paramagnetic metals with partly filled non-s bands[8]. Then in this case we have for the paramagnetic susceptibility of transition metals,

$$\chi=\chi_d\frac{(1+\lambda\chi_s)^2}{1-\lambda^2\chi_s\chi_d}+\chi_s+\chi_{d,\mathrm{orbit}}\ , \tag{2.7}$$

where we neglect the diamagnetic susceptibility of atomic core. $\chi_{d,\mathrm{orbit}}$ and g_d are estimated roughly as follows: $\chi_{d,\mathrm{orbit}}\simeq N_d\mu_B^2/\Delta\mathcal{E}$, and $\Delta g_d=g_d-2\simeq\xi/\Delta\mathcal{E}$, where ξ is the coefficient of spin-orbit interaction and $\Delta\mathcal{E}$ is the mean of the separations of energy levels in the d band.

For Ni, Pd, and Pt, the numbers of d holes are few and the widths of d bands are narrow, so that the degeneracy temperatures of these metals are relatively low. If the temperature is so high that the d holes, as a gas, are not degenerate, the paramagnetic susceptibility due to the d hole spins follows the Curie-Weiss law[2),9)], and is given by

$$\left.\begin{aligned} \chi_d&=C_d/(T-\theta)\ ,\\ C_d&=N_d g_d^2\mu_B^2/(4k)\ . \end{aligned}\right\} \tag{2.8}$$

In this case, from (2.7) and (2.8), we have

$$\chi=\frac{C}{T-\theta_p}+\chi_c\ , \tag{2.9}$$

where

$$\left.\begin{aligned} \theta_p&=\theta+C_d\chi_s\lambda^2\ ,\\ C&=C_d(1+\lambda\chi_s)^2\\ &=N_d(g_d/2)^2\mu_B^2(1+\lambda\chi_s)^2/k\ ,\\ \chi_c&=\chi_s+\chi_{d,\mathrm{orbit}}\ . \end{aligned}\right\} \tag{2.10}$$

The formula of this type, (2.9), was already proposed by Néel[10] for Ni alloys.

In the ferromagnetic state and at 0°K, the spontaneous magnetization is given by

$$\begin{aligned} M&=M_d+M_s=(1+\lambda\chi_s)M_d\\ &=N_d(g_d/2)(1+\lambda\chi_s)\mu_B\ . \end{aligned} \tag{2.11}$$

Usually, χ_s is written, by making use of the free electron model, as $\chi_s=3N_s g_s^2\mu_B^2/8\zeta_0$, where ζ_0 is the energy of the Fermi level for the s electrons. As we have calculated the paramagnetic susceptibility of conduction electrons using the Bohm-Pines collective description of electron interactions[11], and the values of χ_s can be obtained if the effective mass and the electron density are given, we shall make use of these values for χ_s in this paper.

§ 3. Comparison with Experimental Results

At very high temperature the paramagnetic susceptibility for transition metals is expected to follow the formula (2.9). For Ni, Pd, and Pt the degeneracy temperatures of d holes will be relatively low since the numbers of d holes per atom are small. Then it will be supposed that Ni, Pd, and Pt are the best examples to interpret their susceptibilities by (2.9) at the highest temperature where the susceptibilities have so far been measured (~1800°K).

The experimental values of susceptibility for Ni, Pd, and Pt are plotted against $(T-\theta_p)^{-1}$

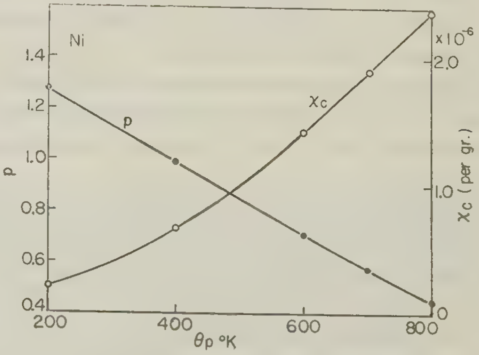

Fig. 1. Values of p and χ_c as functions of θ_p when susceptibility of Ni at high temperatures is expressed as $C/(T-\theta_p)+\chi_c$, where $p=kC_{\mathrm{mole}}/(N_0\mu_B^2)$.

where the value of θ_p is given as a parameter and at higher temperatures these curves χ vs. $(T-\theta_p)^{-1}$ become linear. By extrapolating these lines to the value $(T-\theta_p)^{-1}=0$ we can find the values of C, or $p=kC_{\text{mole}}/(N_0\mu_B^2)$ where N_0 is Avogadro's number, and χ_c as functions of θ_p. These analyses are shown in Figs. 1, and 2 by making use of Terry's data for Ni[12] and Wucher's data for Pd[13]. The values of p for Pt, which are obtained from Honda's data[14] in this way, become smaller than the value which has been estimated before from the susceptibility at lower temperatures[2]. The values of susceptibility for Pt measured by Honda may be inaccurate, because these values are not smoothly connected with the values at lower temperatures obtained by Hoare and Matthews[15].

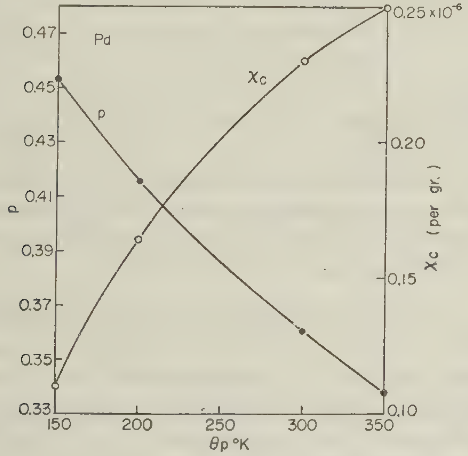

Fig. 2. Values of p and χ_c as functions of θ_p when susceptibility of Pd at high temperatures is expressed as $C/(T-\theta_p)+\chi_c$, where $p=kC_{\text{mole}}/(N_0\mu_B^2)$.

Table I. The values of exchange integral between s and d electrons for Ni, Pd, and Pt.

Element	Ni	Pd	Pt
$2J=h\Delta\nu$ cm^{-1}	2678.5	4054.7	11211.3

The values of λ in (2.4) for Ni, Pd, and Pt are determined by using their atomic spectra. We make use of the energy differences between the atomic states, $^1D(nd^9, (n+1)s)$ and $^3D(nd^9, (n+1)s)$, where $n=3$, 4, 5 for Ni, Pd, and Pt respectively, that is, $h\Delta\nu=2J=E(^1D)-E(^3D)$, where $E(^3D)$ is the weighted mean of the energies of the multiplet for ^3D.[16] The values of $2J$ are shown in Table I.

The paramagnetic susceptibility for the s electrons has been calculated before and is given by[11]

$$\chi_s\,(\text{per gr.})=3.178\times10^{-6}/(\rho r_s^3\gamma)\,, \qquad (3.1)$$

where ρ is density, γ is the coefficient of the increase of energy when conduction electrons have magnetic moment (e. g. $E=E_0+\gamma(n/N)^2$, where (n/N) is the degree of magnetization), and r_s is the inter-electronic spacing of s electrons measured in units of the Bohr radius, a_0,. We have $r_s=(3/16\pi)^{1/3}(a/a_0)p_s^{-1/3}$, where a is a lattice constant and p_s is the number of s electrons per atom.

Let the number of holes in the d band per atom be p_d, then $p_d=p_s=(3/16\pi)(a/a_0r_s)^3$ for Ni, Pd, and Pt.

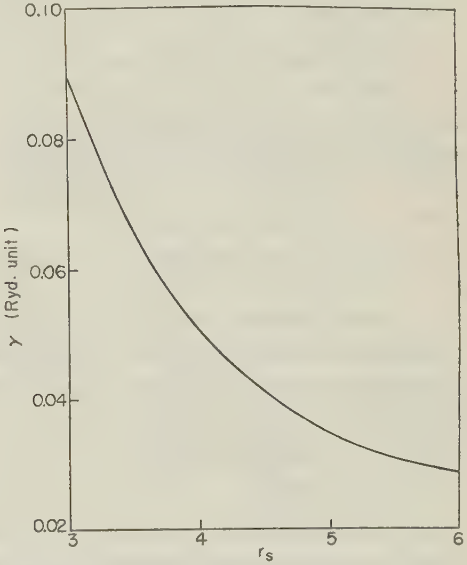

Fig. 3. Values of γ as a function of r_s when $m^*/m=1$.[11]

The values of γ, which have been obtained by the present author making use of the Bohm-Pines collective electron model[11], are shown in Fig. 3 as a function of r_s when $m^*/m=1$, where m^* is an effective mass of s electrons.

First we discuss the case of Ni. The g-factor of Ni at ferromagnetic state, g_{df}, is about 2.2[17] and that at paramagnetic state, g_{dp}, becomes about 2[18]. Then the values of λ at ferromagnetic state and at paramagnetic state which are obtained from (2.4) and J in Table I are different, and they are denoted by λ_f and λ_p respectively. Using $g_{df}=2.2$ and $g_s=2$, we have from (2.4), (3.1) and the value of J for Ni in Table I,

$$\lambda_f \chi_s = 0.0489 r_s^{-3} \gamma^{-1} . \qquad (3.2)$$

From the number of the Bohr magneton at 0°K[19] and (2.11) we have

$$p_d(g_{df}/2)(1+\lambda_f \chi_s) = 0.604 . \qquad (3.3)$$

p_d is calculated from the lattice constant and we have for Ni

$$p_d = p_s = 17.783 r_s^{-3} . \qquad (3.4)$$

From (3.2), (3.3), (3.4), and γ in Fig. 3 where $m^*/m=1$ is assumed, we can obtain the values of r_s, γ, $p_d=p_s$, $\lambda_f \chi_s$, and $\lambda_p \chi_s$ for Ni as follows:

$$\left.\begin{array}{l} r_s = 3.21 , \\ \gamma = 0.0788 , \\ p_d = p_s = 0.539 , \\ \lambda_f \chi_s = 0.188 , \\ \lambda_p \chi_s = (g_{df}/g_{dp}) \lambda_f \chi_s = 0.0207 , \\ \lambda_p^2 \chi_s C_d = 10.7\text{°K} . \end{array}\right\} \qquad (3.5)$$

From these numerical values and (2.10) and (3.1), the values of p, where p is defined by $C_{\text{mole}} = N_0 p \mu_B^2/k$ (N_0=Avogadro's number), and χ_s (per gr.) become

$$p = (1+\lambda_p \chi_s)^2 p_d = 0.562 , \qquad (3.6)$$

and

$$\chi_s = 1.37 \times 10^{-7} \text{ (per gr.)} . \qquad (3.7)$$

When the value of p is given by (3.6) the corresponding values of C, θ_p, and χ_c are obtained from Fig. 1 as follows:

$$\left.\begin{array}{l} C = 0.00358 \text{ (per gr.)} , \\ \theta_p = 708\text{°K} , \\ \chi_c = 1.92 \times 10^{-6} \text{ (per gr.)} . \end{array}\right\} \qquad (3.8)$$

Using the values of C, θ_p, and χ_c given by (3.8) and from (2.9) we calculate χ as a function of T and the result and the experimental results by Terry[12] are shown in Fig. 4.

The value of χ_c is fairly larger than that of χ_s in (3.7). The difference between these two values may be attributable to the temperature independent paramagnetic susceptibility, $\chi_{d,\text{orbit}}$. From the resonance experiments it has been found that $1.95 \leq g_{dp} \leq 2.05$[18]. Assuming $\Delta g_{dp} = g_{dp} - 2 \simeq |\xi|/\Delta\mathcal{E} = 0.05$ and using $|\xi| = 282.5 \text{ cm}^{-1}$ we have $\Delta\mathcal{E} \simeq 5650 \text{ cm}^{-1}$ and $\chi_{d,\text{orbit}} \simeq N_d \mu_B^2/\Delta\mathcal{E} \simeq 8 \times 10^{-7}$ (per gr.).

As the above estimation for $\chi_{d,\text{orbit}}$ is rough, it may be changed by the factor 2 or 3. At present we must inevitably satisfy this rough estimation for $\chi_{d,\text{orbit}}$.

On the other hand, as we have assumed for the sake of simplicity that the d holes are completely non-degenerate and the number of holes is constant with temperature, a part of the difference between χ_c and χ_s may be attributable to the effect of the electron transfer between s and d bands and the different temperature dependence of susceptibility when d holes are partly degenerate.

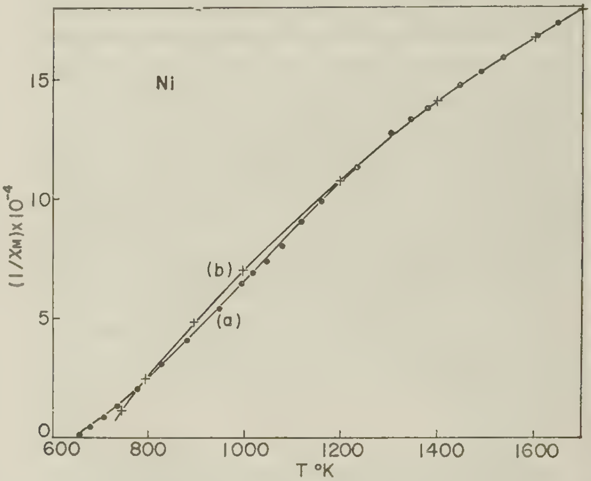

Fig. 4. Paramagnetic susceptibility of Ni. Curve (a) is Terry's experimental result[12]. Curve (b) is calculated by $C/(T-\theta_p)+\chi_c$ with $C=0.00358$ (per gr.), $\theta_p=708$°K and $\chi_c = 1.92 \times 10^{-6}$ per gr.

If the effective mass of s electrons is larger, that is, $m^*/m > 1$, we can explain the temperature dependence of susceptibility for Ni satisfactorily without introducing the temperature independent paramagnetism. For example, if we determine p and $\lambda\chi_s$ to satisfy $p = 0.604(1+\lambda\chi_s)(g_{dp}^2/2g_{df})$ and the relation between p and χ_s given in Fig. 1, we have $p=0.675$, $\chi_s = 1.54 \times 10^{-6}$ (per gr.), and $\theta_p = 624$°K. From these values we obtain $\lambda\chi_s = 0.232$, $p_d = 0.446$, $r_s = 3.42$, and $\gamma = 5.805 \times 10^3$, and from the previous calculation of the susceptibility of an electron gas[11] the effective mass for the s electron is obtained as $m^*/m = 2.51$. This value of m^*/m is large and the former interpretation where $m^*/m=1$ is assumed is more natural.

In the former interpretation, the effective field of the d holes from the s electrons is given by $\lambda M_s = \lambda^2 \chi_s M_d$ and the value of the coefficient of this effective field for Ni is obtained from (2.4) and (3.5) and Table I as

$$\lambda^2 \chi_s N_d \mu_B^2 = 6.79 \times 10^{-5} \text{ Ryd. unit.} \qquad (3.9)$$

This is fairly smaller than the value of the coefficient of the molecular field between the *d* holes, as a gas, which has been obtained (from Fig. 5 in the reference 2) as $\alpha N_d\mu_B^2=3.95\times10^{-2}$ Ryd. unit at $r_s=3.21$, although this value of α is larger by the factor 2.6 than the value which explains the temperature variation of magnetization at low temperatures. From this result it seems that the *s–d* exchange interaction is not a main origin of the ferromagnetism of Ni, although this has already been assumed in our consideration. This conclusion can also be obtained from the fact that the value of $\lambda^2\chi_sC_d$ is fairly smaller than the value of θ_p for Ni.

Now we consider the temperature dependence of susceptibility for Pd at higher temperatures. Wohlfarth[20] has analysed the magnetic properties of Pd and Pt at relatively low temperatures on the basis of the Stoner theory. The similar treatment for Pd with that for Ni will be done although Pd is not ferromagnetic. In the reference 2, we have determined the number of *d* holes for Pd as $p_d=0.32$, $r_s=4.18$ from the temperature dependence of the susceptibility at lower temperatures. We use these values, $p_d=0.32$, $r_s=4.18$, for Pd, in this paper.

From (2.4), (3.4) with $m^*/m=1$, and Table I, we have

$$\chi_s=7.75\times10^{-8}\text{ (per gr.)}\,, \tag{3.10}$$

$$\lambda\chi_s=3.21\times10^{-2}\,, \tag{3.11}$$

for Pd where we assume that $g_d=g_s=2$. Then we have

$$\left.\begin{aligned} p&=(1+\lambda\chi_s)^2p_d=0.341\,,\\ C_d\lambda^2\chi_s&=15.0^\circ\text{K}\,.\end{aligned}\right\} \tag{3.12}$$

From Fig. 2 we find the values of C, θ_p, and χ_c, which are proper to explain the temperature variation of susceptibility by the formula (2.9) with the above value of p, as follows:

$$\left.\begin{aligned} C&=0.00120\text{ (per gr.)}\,,\\ \theta_p&=343^\circ\text{K}\,,\\ \chi_c&=2.48\times10^{-7}\text{ (per gr.)}\,.\end{aligned}\right\} \tag{3.13}$$

This value of χ_c is larger than the value of χ_s in (3.10). The difference will be attributable also to the temperature independent paramagnetism. If we assume that $m^*/m=1.75$ for *s* electrons, we can explain the temperature variation of susceptibility for Pd by (2.9) without introducing the temperature independent paramagnetism as well as in the case of Ni.

Using the values of C, θ_p, and χ_c given by (3.13) we can calculate χ from (2.9), and the result and the experimental results by Wucher[13] are shown in Fig. 5.

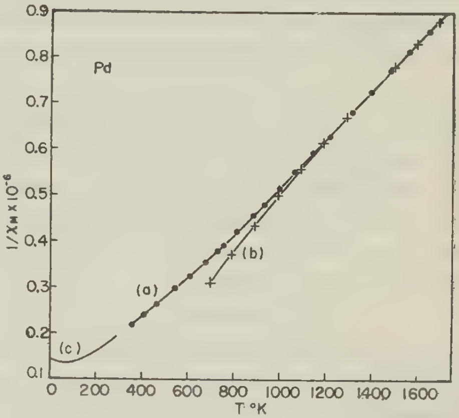

Fig. 5. Paramagnetic susceptibility of Pd. Curve (a) is Wucher's experimental result[13]. Curve (b) is calculated by $C/(T-\theta_p)+\chi_c$ with $C=0.00120$ (per gr.), $\theta_p=343^\circ$K and $\chi_c=2.48\times10^{-7}$ (per gr.). Curve (c) is Hoare and Matthews' experimental result[15]

It will be expected that there is the effect of the *s–d* exchange interaction on the temperature variation of paramagnetic susceptibility for Pd at lower temperatures too. But, as in Ni, the molecular field between *d* holes is fairly greater than the *s–d* exchange field, e. g. for Pd $\lambda^2\chi_sN_d\mu_B^2=9.51\times10^{-5}$ Ryd. unit and $\alpha N\mu_B^2=7.2\times10^{-3}$ Ryd. unit at $r_s=4.18$, and χ_c is a small part of the total susceptibility at lower temperatures, so that we can neglect the effect of the *s–d* exchange interaction at lower temperatures.

The same analysis will be applied to the temperature dependence of susceptibility for Pt. Unfortunately, there is no satisfactory experimental result for the paramagnetic susceptibility of Pt at higher temperatures.

However, we have determined the number of *d* holes for Pt as $p_d=0.30$, $r_s=4.31$ from the temperature dependence of the susceptibility at lower temperatures[2]. Then, from (2.4), (3.1) with $m^*/m=1$, and Table I, we have for Pt

$$\left.\begin{aligned} \chi_s&=4.17\times10^{-8}\text{ (per gr.)}\,,\\ \lambda\chi_s&=8.74\times10^{-2}\,,\\ p&=p_d(1+\lambda\chi_s)^2=0.355\,,\\ C&=5.41\times10^{-4}\text{ (per gr.)}\,.\end{aligned}\right\} \tag{3.4}$$

§ 4. Specific Heats of Ni, Pd, and Pt at Higher Temperatures

In this section we determine the part of the specific heats, which is considered to be the contribution from the d holes, for Ni, Pd, and Pt at higher temperatures. The dilatation terms are evaluated in the following way.

$$C_P-C_V=9TV\alpha_l^2/\beta\ , \tag{4.1}$$

where V, α_l and β are an atomic volume, linear expansion coefficient, and compressibility, respectively. As there is no measurement of the compressibilities of Ni, Pd, and Pt except at room temperature, we make use of the empirical formula[21],

$$C_P-C_V=\zeta TC_P^2\ , \tag{4.2}$$

where ζ is a proportional constant, and the value of ζ is determined by using (4.1) and the experimental values of V[22], α_l[23], and β[24] at room temperature. The results for Ni, Pd, and Pt are shown in Table II.*

Table II. Values of ζ and the Debye temperatures, Θ_D, for Ni, Pd, and Pt.

Metal	Ni	Pd	Pt
ζ cal^{-1} mol	1.001×10^{-5}	1.262×10^{-5}	1.186×10^{-5}
Θ_D°K	450	275	233

In the second place, we consider the contribution of the anharmonic terms of lattice vibrations, C_A, to the specific heat. The electronic specific heat of Cu is definitely determined by the extrapolation of the specific heat at lower temperatures, γT, also at higher temperatures because the degeneracy temperature of conduction electrons is very high. Then, by subtracting the Debye specific heat of lattice vibrations, the contribution of the dilatation term, and the electronic specific heat γT, from C_P, we can estimate the specific heat due to the anharmonic terms for Cu. It should be noted that this part of the anharmonic terms may contain the increase of the specific heat due to the s–d transfer in Cu if the energy difference between the Fermi level of s band and the top of d band is small. But we assume that this energy difference is large and the s–d transfer does not occur in Cu up to the melting point. Also for Ni we use the same values of specific heat of the anharmonic term with those of Cu.

The Debye specific heats, C_D, are calculated from the numerical tables[25] and the Debye temperatures given in Table II.

The electronic specific heats of s electrons for Ni, Pd, and Pt, $C_s=\gamma_sT$, are calculated from the values of p_s and r_s given above, by making use of the collective correction given by Fletcher and Larson[26]. The results are shown in Table III, where we assume $m^*/m=1$ for s electrons.

Table III. Electronic specific heats of s electrons, γ_sT, and classical limits of specific heats of d holes, $(3/2)Rp_d$, for Ni, Pd, and Pt.

Metal	Ni	Pd	Pt
$p_s=p_d$	0.539	0.32	0.30
r_s	3.21	4.18	4.31
$\gamma_s\times10^4$ cal/(deg.^{2} mole)	1.10	1.18	1.19
$(3/2)Rp_d$ cal/(deg. mole)	1.60	0.953	0.894

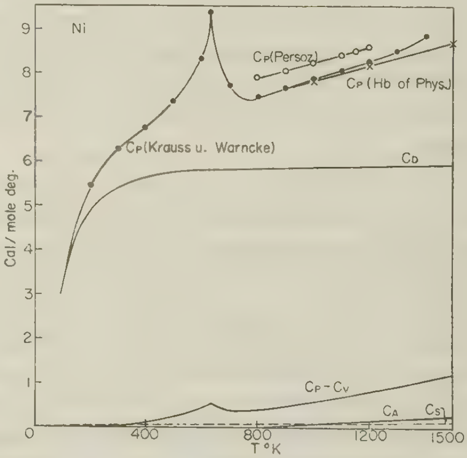

Fig. 6. Specific heats of Ni, e.g. C_P, C_P-C_V, the Debye specific heat C_D, anharmonic term C_A, and electronic specific heat of s electrons C_s, are shown. Curves (1), (2), and (3) are, respectively, Persoz's data[27], Krauss and Warncke's data[28], and data given in reference 29.

The respective parts of specific heat of Ni and the observed results of C_P[27),28),29] for Ni are shown in Fig. 6. In Fig. 7 the residual specific heats, $C_R=C_V-C_D-C_A-C_s$, which are considered to be the d holes, calculated from the various results of C_P, and the extrapolation of the specific heat at lower temperatures, $\gamma T=1.74\times10^{-3}T$ cal/mole deg., are shown.

---

* The analysis of specific heat of Ni has been worked out by E. Sawado and the detail will be published elsewhere.

From the result shown in Fig. 7 it is found that the d holes are almost non-degenerate at $T>1200$°K, the equipartition of energy holds, and the specific heat of d holes is nearly equal to $(3/2)Rp_d=1.6$ cal/mole deg. Thus the effect of the s–d transfer of electrons and accordingly the increase of the specific heat for Ni cannot be expected to be large, although it is, perhaps, certain that the mechanism of the s–d transfer exists practically. The same will be said of the cases of Pd and Pt.

The assumptions, made use of in § 3, that the number of d holes is constant and the d holes are nondegenerate at higher temperatures where we discuss the paramagnetic susceptibility are thus justified.

The same analyses of specific heats of Pd and Pt at higher temperatures are shown in Figs. 8, 9, 10 and 1129), where the anharmonic terms are neglected because the melting points

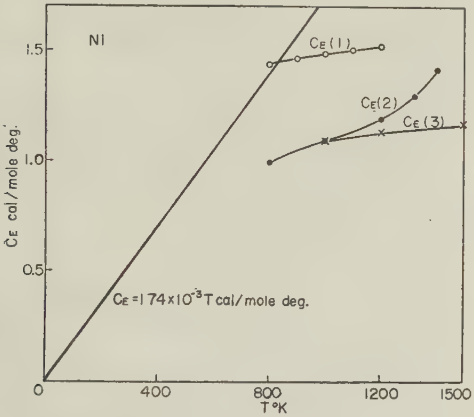

Fig. 7. Residual specific heat of Ni, $C_E=C_V-C_D-C_A-C_S$, and the extrapolation of the specific heat of Ni at lower temperatures, $\gamma T=1.74\times10^{-3}T$ cal/mole deg., are shown. Curves (1), (2), and (3) are, respectively, the residual specific heats obtained from Persoz's data27), Krauss and Warncke's data28), and data given in reference 29.

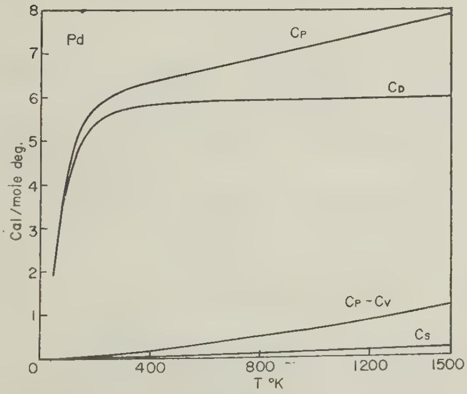

Fig. 8. Specific heats of Pd, e.g. C_P29), C_P-C_V, the Debye specific heat C_D, and electronic specific heat of s electrons C_S, are shown.

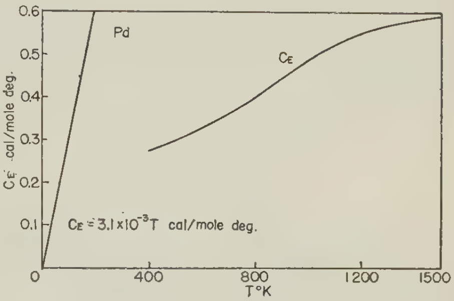

Fig. 9. Residual specific heat of Pd, $C_E=C_V-C_D-C_S$, and the extrapolation of the specific heat of Pd at lower temperatures, $\gamma T=3.1\times10^{-3}T$ cal/mole deg., are shown.

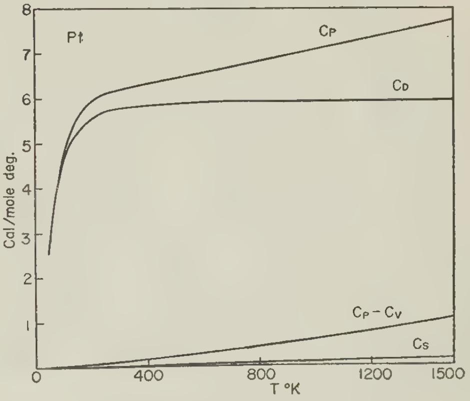

Fig. 10. Specific heats of Pt, e.g. C_P29), C_P-C_V, the Debye specific heat C_D, and electronic specific heat of s electrons C_S, are shown.

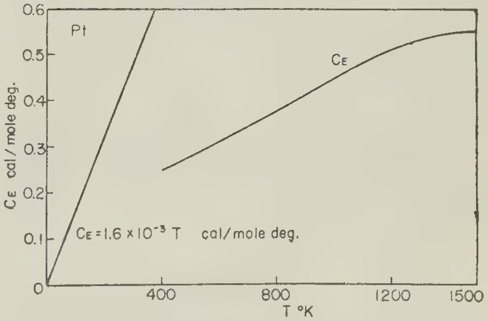

Fig. 11. Residual specific heat of Pt, $C_E=C_V-C_D-C_S$, and the extrapolation of the specific heat of Pt at lower temperatures, $\gamma T=1.6\times10^{-3}T$ cal/mole deg., are shown.

of Pd and Pt are high and they are expected to be small at temperatures under investigation.

§ 5. Conclusion

The temperature variations of the paramagnetic susceptibility for Ni, Pd, and Pt are explained by the itinerant model of d electrons with taking into account the s–d exchange interaction and the temperature-independent paramagnetism. The susceptibility at higher temperatures is approximately expressed by

$$\chi=\frac{C}{T-\theta_p}+\chi_c\ .$$

The values of χ_c obtained for Ni and Pd are fairly larger than the values which are expected to be due to the susceptibility of s electrons. The main parts of χ_c are attributable to the temperature-independent orbital paramagnetism of d electrons.

From the values of specific heats of Ni, Pd, and Pt at higher temperatures, it seems that the increases of electronic specific heat due to s–d transfer do no exist or are very small even if they exist.

From the above analyses and the results of the previous calculations²⁾, it is found that the s–d exchange interactions in Ni, Pd, and Pt are not stronger than the interactions between d holes when they are treated as an electron gas. Thus, contrary to the Zener theory³⁰⁾, we conclude that the s–d exchange interaction is not a main origin of the ferromagnetism of Ni, but gives only a slight modification to it.

It is supposed that the effect of the s–d exchange interaction on the paramagnetic susceptibility may exist also in the cases of Co and Fe. As the degeneracy temperatures of d holes for Co and Fe are fairly higher than Ni, the formula (2.9), just as it is, does not hold in Co and Fe, but the formula (2.7) with χ_d given by (7.9) in the reference 2 will be applicable and the experimental results of susceptibility for Co and Fe will be satisfactorily explained.

Magnetic Properties of Intermetallic Compounds in Manganese-Tin System: $Mn_{3.67}Sn$, $Mn_{1.77}Sn$, and $MnSn_2$

By Kō YASUKŌCHI, Kazuo KANEMATSU
Department of Physics, College of Science and Engineering, Nihon University, Tokyo
and Tetuo OHOYAMA
Department of Physics, Faculty of Science, Tokyo Metropolitan University

(Received September 29, 1960)

The magnetic properties of $Mn_{3.67}Sn$, $Mn_{1.77}Sn$, and $MnSn_2$ were investigated. In $Mn_{3.67}Sn$, an anomalous magnetic phenomenon was found, which may be due to its antiferromagnetism. The Néel temperature T_N, the effective number of Bohr magnetons per Mn n_p, and the asymptotic Curie point θ_a are 365°K, 3.58, and −275°K, respectively. $Mn_{1.77}Sn$ is ferrimagnetic. The estimated saturation magnetization per Mn at 0°K, $n_f\mu_B$, as well as n_p and the Curie temperature T_C, were determined after various heat treatments. With lowering the annealing temperature, T_C was increased from 226° to 263°K, and n_f was increased from 0.92 to 1.23, while n_p stayed nearly constant at about 3.4. These behaviors are interpreted in terms of the effect of atomic ordering. It was also found that $MnSn_2$ exhibited an antiferromagnetic behavior. T_N, θ_a, and n_p are 324°K, +190°K, and 3.48, respectively.

§ 1. Introduction

The phase diagram of the whole range of manganese-tin system was first studied by Williams[1], and the existence of three intermetallic compounds was confirmed by the thermal analysis and also by the microscopical observation. His assignments on the compositions of these compounds, Mn_4Sn, Mn_2Sn, and probably MnSn, were corrected later by Nial[2] and by Nowotny and Schubert[3], who carried out the detailed X-ray analysis and also determined the crystal structures of these compounds. The results obtained by both X-ray works were substantially in agreement. Nowotny and Schubert concluded as follows: The most manganese-rich compound is $Mn_{3.67}Sn$ ($Mn_{11}Sn_3$) with a hexagonal, $D0_{19}$ (Ni_3Sn) type of structure. The second compound has a homogeneity range of $Mn_{2.05}Sn$ to $Mn_{1.77}Sn$, and has a hexagonal, $B8_2$(Ni_2In) type of structure. And the third compound is not MnSn as regarded earlier, but $MnSn_2$ which has a body centered tetragonal, C16 ($CuAl_2$) type of structure.

The magnetic properties of the alloys of this system have been studied by several authors, but the results are not in agreement with one another. Based upon the simple observations using a magnetic compass, Williams[1] reported that the transitions from ferromagnetism to paramagnetism took place in Mn_4Sn and Mn_2Sn at 117°C and 263°C, respectively. First quantitative measurements of the magnetization over the whole range of composition in this system were carried out by Honda[4], and a sharp maximum of the thermo-magnetic remanence was found at the composition of Mn_4Sn. Potter[5] measured the magnetization of the alloys at the liquid air temperature as well as at the room temperature, and roughly estimated the Curie points of the compounds at 0°C for Mn_4Sn and 150°C for Mn_2Sn. Guillaud[6] reported that ferromagnetism was exhibited throughout the composition range from 13 to 78 at% Mn with the Curie point ca. −11°C, while all alloys containing more manganese, including Mn_4Sn, were non-magnetic after annealed at 500°C. Recently, Ochsenfeld[7] found an anomalous antiferromagnetic behavior in the range of composition less than 15.5 at% Mn. He also concluded, standing upon the older phase diagram, that Mn_4Sn and Mn_2Sn were ferromagnetic with Curie points of 178°C and −11.5°C, respectively. The ferromagnetism of the alloys in this system was noticed by some authors to be very sensitive to the heat treatment[5),6)].

The present paper reports the results of some magnetic measurements which have been carried out on all the three compounds $Mn_{3.67}Sn$, $Mn_{1.77}Sn$, and $MnSn_2$, as well as the effects of heat treatments on the magnetic behaviors of $Mn_{1.77}Sn$.

§ 2. Preparation of Specimens and Experimental Procedures

The compositions of the intermetallic compounds used for this study were $Mn_{3.67}Sn$, $Mn_{1.77}Sn$, and $MnSn_2$. These specimens were prepared as follows: Powders of electrolytic manganese (99.9%) and tin (five-nine purity) were mixed at the desired proportions, and the mixtures were sealed in evacuated glass tubes, and heated by an electric furnace at 500°C for two days to promote the reactions. The starting materials thus obtained were next subject to the following heat treatments: For $MnSn_2$, the starting material was first crushed into powder, heated to promote the peritectic reaction, and the same procedures were repeated for several times, until the X-ray diagram confirmed a fairly complete formation of the compound. For $Mn_{1.77}Sn$ and $Mn_{3.67}Sn$, the starting materials were charged in alumina crucibles, sealed in evacuated silica tubes, and melted at 1100°C. Finally, after homogenized at 840°C for 40 hours, they were quenched into water. After this treatment, the specimens of $Mn_{1.77}Sn$ were held at every 50°C from 750°C to 400°C for several days, and then quenched into water. On the other hand, the specimens of $Mn_{3.67}Sn$ were annealed at 750°C and 550°C for several days, and quenched into water.

The specimens were examined by means of an X-ray diffractometer to ascertain their crystal structures. The temperature dependences of the magnetizations of these specimens were measured from the liquid oxygen temperature up to 900°K, under the field of 7.5 kilo-oersteds, by means of a pendulum magnetometer in their ferromagnetic region, and also by means of a magnetic torsion balance in their paramagnetic region. In both apparatus the magnetization was determined by measuring the forces exerted on the specimens placed in an inhomogeneous field.

§ 3. Experimental Results and Discussions

$Mn_{3.67}Sn$

The X-ray diagram for our specimen of $Mn_{3.67}Sn$ had a similar feature to that reported by Nowotny and Schubert[3], and then could be interpreted as corresponding to a hexagonal, $D0_{19}$ (Ni_3Sn) type of structure. But the lattice parameters are $a=5.67_5$Å, $c=4.52_9$Å, and $c/a=0.798$, and somewhat different from theirs. This forms a superstructure based on the close packed hexagonal one. According to the detailed examination of intensities of diffraction by Nowotny and Schubert, tin atoms in the structure for the stoichiometric (3:1) composition are randomly substituted by the excess atoms of manganese.

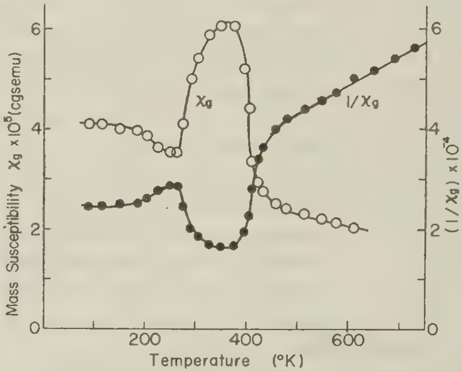

Fig. 1. Magnetic property of $Mn_{3.67}Sn$. Dependences of magnetic susceptibility and its reciprocal on temperature.

Recently we reported that $Mn_{3.25}Ge$[8], which has the same structure as $Mn_{3.67}Sn$, was antiferromagnetic in its disordered state. In Fig. 1, are plotted the values of magnetic susceptibility for $Mn_{3.67}Sn$ and its reciprocals against temperature. As seen in the figure, the susceptibility begins to increase strikingly at 270°K with increasing temperature and falls off rather abruptly at 400°K, and then decreases gradually. The reciprocal susceptibility *vs.* temperature curve has a minimum and the Curie-Weiss law holds very well at higher temperatures. These features were not affected by the heat treatments mentioned above. Thus an antiferromagnetic behavior was also found in this phase of manganese-tin system, and the point of minimum of the $1/\chi_g - T$ curve, 365°K, might be the Néel temperature. The asymptotic Curie point and the effective number of Bohr magnetons, calculated from the straight part of the $1/\chi_g - T$ curve, are -275°K and 3.58 respectively.

Williams and Honda have made some remarks on the existence of a thermo-magnetic remanence. We also observed the thermomagnetic effect below the Néel point besides the antiferromagnetic behavior described above. This phenomenon is quite simillar to the magnetic behavior of Mn_2Pd_3[9], which is antiferromagnetic and exhibits thermo-magnetic remanence too. The complex situation of the magnetic properties of the compound is presumably understood by introducing a coexistence of ferromagnetic and antiferromagnetic regions coupled by exchange interaction. But, taking into accout the non-stoichiometry of the compound, an alternative explanation for this phenomenon may be possible if we assume that an unbalance of spin arrangement is caused by the excess of manganese atoms. To clarify the mechanism of the phenomenon, more detailed investigations will be necessary.

$Mn_{1.77}Sn$

The saturation magnetizations σ_g of $Mn_{1.77}Sn$ after the heat treatments are plotted against temperature in Fig. 2. As seen from the figure, it is ferromagnetic below the room temperature. The reciprocals of the values of the magnetic susceptibilities above Curie points are shown in the same figure. It is seen that, by the effect of heat treatments, the saturation magnetization σ_0 at absolute zero of temperature, extrapolated from the $\sigma_g - T$ curves, varies from 44 to 59 cgs emu/g and the Curie point T_C, determined from $\sigma_g^2 - T$ curves, also varies from 226° to 263°K. The $1/\chi_g - T$ curves are concave against abscissa, and all asymptotic Curie points may be regarded to be positive.

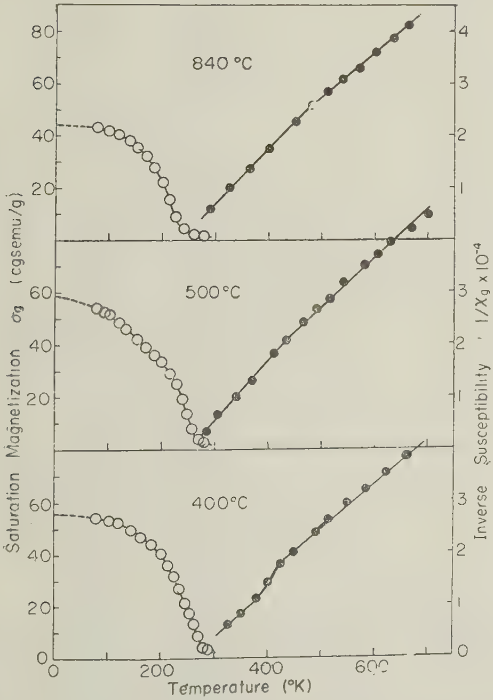

Fig. 2. Magnetic property of $Mn_{1.77}Sn$. Temperature dependences of saturation magnetization and inverse susceptibility after annealed at 840°C, 500°C and 400°C.

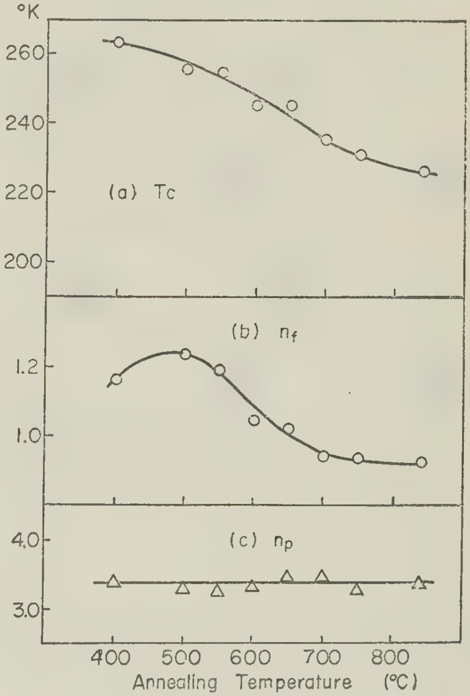

Fig. 3. Dependences of Curie temperature, saturation magnetization, and paramagnetic moments of $Mn_{1.77}Sn$ on annealing temperature. The latter two are expressed in terms of the number of Bohr magnetons per manganese atom.

The dependences of various magnetic constants on the annealing temperature are shown in Fig. 3, where T_C is the Curie temperature, n_f is the saturation magnetization at 0°K expressed in terms of the Bohr magneton, and n_p is the effective number of Bohr magnetons calculated from the slope of $1/\chi_g - T$ curves. As the annealing temperature is lowered from 840°C, (a) T_C increases monotonically from 226° to 263°K; (b) n_f remains nearly constant, 0.92, until the annealing temperature is lowered to 650°C, then increases gradually toward its maximum value 1.23

at 500°C and finally decreases slightly at 400°C; (c) n_p does not change appreciablly, about 3.4.

As to the crystal structure of $Mn_{1.77}Sn$, fortunately the result of detailed examination by Nowotny and Schubert[3] was available.

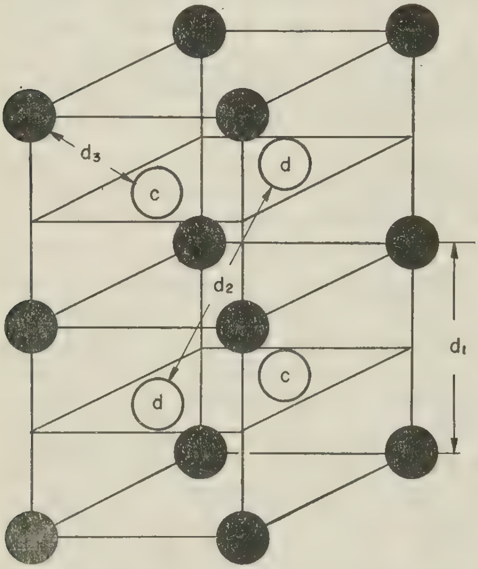

Fig. 4. Crystal structure of $Mn_{1.77}Sn$ ($B8_2$ type). Closed circles: A sublattice (2 (a) site). Open circles: B sublattice (c and d mean 2 (c) and 2 (d) sites, respectively). $d_1=2.76$Å, $d_2=3.75$Å, $d_3=2.89$Å.

According to their result, the Mn_2Sn phase has a hexagonal, $B8_2$ type of structure, which is illustrated in Fig. 4, and has the atomic positions as follows:

2 (a) 0, 0, 0; 0, 0, 1/2;
2 (c) 1/3, 2/3, 1/4; 2/3, 1/3, 3/4;
2 (d) 1/3, 2/3, 3/4; 2/3, 1/3, 1/4.

They reported that the lattice parameters were $a=4.37_0$Å, $c=5.47_5$Å, $c/a=1.25_0$, and the picnometric density was 7.40 g/cm³. These values gave 1.87 formula weights of $Mn_{1.77}Sn$ per unit cell, and the atomic arrangement was determined as follows:

2 Mn in 2 (a)
1.87 Sn+0.13 Mn randomly distributed in 2 (c)
1.18* Mn distributed in 2 (d).

Now the X-ray diagrams for our specimens annealed at temperatures above 650°C had quite similar feature to that of theirs, but the lattice parameters and the picnometric density had somewhat different values: $a=4.39_8$Å, $c=5.51_6$Å, $c/a=1.25_4$, and 6.9 g/cm³, respectively, giving 1.74 formula weights of $Mn_{1.77}Sn$ per unit cell. Therefore, the atomic arrangement in these specimens may be as follows:

2 Mn in 2 (a)
1.74 Sn+0.26 Mn in 2 (c)
0.82 Mn+1.18 atomic holes in 2 (d).

However, it was clearly shown by the X-ray diagrams for our specimens that the hexagonal structure was modified in three stages in the course of heat treatments. The three stages correspond to the following ranges of annealing temperature: (1) above 650°C, (2) between 600°C and 450°C, and (3) below 400°C. In the first stage, neither the diffraction angles

* Indices in the last column are those with respect to the larger unit cell, $a'=3a$.

---

* This number of Mn in 2 (d) was 1.30 in Nowotny and Schubert's paper, but here the corrected number is shown.

nor the intensities of the individual lines were varied appreciably, showing that the structure was essentially unchanged from that described above. In the second stage, a few superstructure lines which could be indexed with lattice constants $a'=3a$ and $c'=c$, the (42.0) line being the strongest among these, appeared and became stronger and stronger with lowering the annealing temperature. Finally, in the third stage, a great number of additional diffraction lines, which also could be indexed with $a'=3a$ and $c'=c$, appeared.

The picnometric density of our specimen was nearly constant at 6.9 g/cm³, irrespective of preceding heat treatment. This value is considerably smaller than that of Nowotny and Schubert, and our X-ray diagram gives the lattice parameters larger than theirs. These disagreements may be ascribed to the different procedures in the preparation of the specimens; ours were melted and solidified in vacuum, while theirs were made in the atmosphere under salt flux.

Now, the atomic sites 2 (a) are different from 2 (c) and 2 (d) with respect to their surroundings. Thus, as shown in Fig. 4, the whole lattice can be divided into two sublattices; sublattice A consisting of 2 (a) (closed circle) and sublattice B consisting of 2 (c) and 2 (d) (open circle).

From the X-ray examinations, it appears that, in this compound, the crystal structure is not drastically changed and the population of manganese atoms among the two sublattices is not largely affected by the heat treatment. Moreover, n_p stays nearly constant. Thus it seems that the magnetic moments of individual manganese atoms also are not changed by these heat treatments. We further assume that the magnetic moments of individual manganese atom on the two sublattices have the following spin quantum numbers:

$S_A=3/2$ for 2 Mn in A sites
$S_B=\ 1$ for 1.08 Mn in B sites

n_p^2 may be calculated from these values as the weighted mean of $S(S+1)g^2$ and, if we assume the Landé factor to be $g=2$, this gives $n_p=3.54$, which may be compared to the experimental values 3.48 to 3.25. In addition, when the two partial magnetizations are absolutely saturated in the oposite directions, the above S values give $n_f=1.25$ as the ferrimagnetic moment, which is in good agreement with the experimental value for the specimen annealed at 500°C. Thus we are led to assume a negative (antiferromagnetic) interaction between the two sublattices, A and B*. It should be noted here that, in $Fe_{1.67}Ge$[10], which has the same crystal structure and also the same type of distribution of atoms among the atomic sites as in the present compound, the experimental values of both the saturation magnetization at 0°K and the paramagnetic moment above T_C are in good agreement with those calcutated from the assignments $S=1$ for Fe in the A sites, and $S=1/2$ for Fe in the B sites**. Since the manganese atom has one less electrons than iron atom, this may be regarded as another support to the above assumption of spin moments for manganese atoms in $Mn_{1.77}Sn$.

It may be interesting that the heat treatments do not affect the paramagnetic moment (n_p) of the compound above the Curie temperature, but give rise to changes in the saturation magnetization at 0°K (n_f) and the Curie temperature (T_C). The constancy of n_p, together with the result of X-ray analysis, has led us to assume the magnetic moments for individual manganese atoms to be constant. We shall discuss the variations in n_f and T_C below, in relation to changes in the interactions between manganese atoms owing to the change in the atomic distribution among the lattice sites, which is brought about by the effect of annealing.

In addition to the above assumption that the interaction between the two sublattices (A–B interaction) is negative, we further assume that the interactions within the A lattice (A–A interaction) is negative and that within the B lattice (B–B interaction) is positive. These assumptions are equivalent to the assumptions that the exchange interactions for Mn_A–Mn_A, Mn_B–Mn_B, and Mn_A–Mn_B are negative, positive, and negative respectively, and do not conflict with the interaction *vs.* Mn–Mn distance curve (*J-r* curve) proposed experimentally by Guillaud[6] and by Willis and Rooksby[11], since the corresponding nearest neighbor Mn–Mn distances in the present compound are 2.76Å, and 3.75Å and 2.89Å, respectively. The positive asymptotic Curie point, however, suggests the existence of fairly strong positive interaction, while the *J-r* curve leads to a weak one. Thus we propose a relatively strong positive one between the manganese atoms within the B sublattice, by the effect of superexchange interactions through the tin atoms, which lie in the same sublattice, the angle of Mn–Sn–Mn being 120°. This proposal of a superexchange interaction between manganese atoms through IVb elements is also supported by the fact that the magnetic behaviors of $MnSn_2$, $FeGe_2$ and $Fe_{1.67}Ge$[10] can be also well understood by magnetic structures based on the superexchange interactions of this kind.

---

* The ferrimagnetic structure of this compound is supported also by the dependence of the saturation magnetization upon the manganese concentration within the region of the same phase, measured for the specimens annealed at the same temperature, 500°C. The details will be reported later.

** According to our measurements, $n_f=1.59$ and $n_p=3.14$ for $Fe_{1.67}Ge$, and the calculated values are 1.60 and 2.45, respectively.

Now we shall consider the behaviors of the magnetic constants n_f and T_C of the compound in relation to the variation of interactions caused by the structural variations in three stages. First we make the following assumptions: (1) In the initial state realized in the specimens annealed at 840°C, the (negative) A–B interaction is not so strong that the triangular configuration of the partial magnetizations such as discussed by Yafet and Kittel[12] is brought about by the negative A–A interaction, lowering the partial magnetization M_A slightly (still $M_A > M_B$), and (2) the A–B interaction is not affected by the short range order, but is increased by the formation of the long range order in the B lattice, i.e. 2(c) and 2(d) sites of the $B8_2$-type structure. Then the observed behaviors of the magnetic constants may be phenomenologically interpreted as in the following paragraphs.

In the first stage, with the annealing temperatures above 650°C, it can be considered that a short range ordering takes place within the B lattice, giving no essential changes in the X-ray diagram. This ordering in the B lattice may bring about an increase in the positive B-B interaction which originates from the superexchange interaction proposed above. Then T_C may be increased by this increase in the positive interaction, while by the above assumptions, the partial magnetizations M_A and M_B, and also n_f, are not changed appreciably, as long as the ordering is a short range one.

It may be probable that the second stage corresponds to the growth of a long range order in the arrangement of the atoms and holes within the B sublattice, as a few superstructure lines appear and increase their intensities with lowering the annealing temperature. Then, by the above assumptions, the A–B interaction increases and makes the alignment of the individual moments within the A lattice more perfect, leading to an increase in the ferrimagnetic resultant magnetization $M_A - M_B$ and therefore in n_f. The increases in the positive B–B interaction and also in the negative A–B interaction must bring about an increase in T_C. It can be considered that, with the development of the ordered structure at the end of this stage, 500°C, the partial magnetization of the A sublattice, M_A, reaches the value corresponding to the perfect alignment of the individual moments, and the resultant magnetic moment of the compound takes the value which may be approximated by the calculation based on the assignments $S_A = 3/2$ and $S_B = 1$, as mentioned above.

In the third stage, with the annealing temperatures below 400°C, in addition to the superstructure lines which appear in the second stage, a large number of additional lines appear. It may be allowable to ascribe the increase in the number of the diffraction lines and the complication of the X-ray diagram to some displacements of constituent atoms from the normal positions in $B8_2$-type structure, which may presumably be induced by the perfect ordering of the atomic holes in a lower symmetry. Such a deformation of the whole lattice makes the situation so complex that it is difficult to ascribe the observed behaviors of n_f and T_C to some changes in the interactions in a simple way. But it may be considered that the behaviors in this stage does not conflict with the above interpretations.

$MnSn_2$

The X-ray diagram for the specimen with the composition of $MnSn_2$ was quite similar to that reported by Nowotny and Schubert[3], except the diffractions from white tin phase.

Thus the main phase in the specimen was identified with $MnSn_2$, which was determined by them to have C16 type of structure.

Fig. 5 (a) shows the temperature dependence of the magnetic susceptibility of the specimen. As seen in the figure, the $\chi_g - T$ curve has an anomalous feature; a small peak at 324°K followed by a sharp rise toward lower temperature. The reciprocals of the susceptibilities are plotted against temperature in Fig. 5 (b). The $1/\chi_g - T$ curve indicates the validity of the Curie-Weiss law at higher temperatures, and the straight part of the curve is extrapolated to the asymptotic Curie point of +190°K, and the slope of it corresponds to a paramagnetic moment of 3.48 Bohr magnetons per manganese atom.

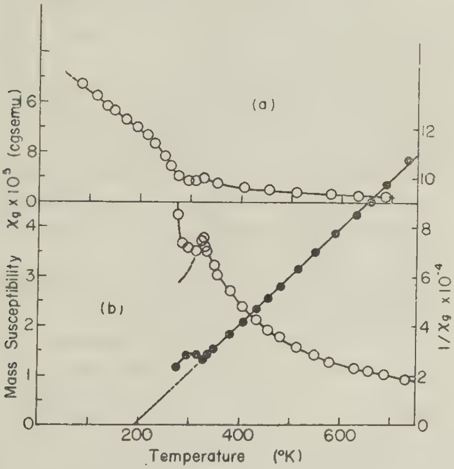

Fig. 5. (a) Temperature dependence of magnetic susceptibility of the specimen with a composition $MnSn_2$. (b) Temperature dependence of inverse susceptibility of the same specimen, with a part of (a) enlarged and estimated susceptibility of the compound $MnSn_2$ (dotted line).

The rapid rise in the magnetization at lower temperatures may be ascribed to the ferrimagnetism of Mn_2Sn phase, because the rise begins at a temperature corresponding to the Curie point of this phase. Moreover, though the X-ray diagram could not detect the presence of this phase, it is rather natural to consider that the specimen of this composition contains this phase, because of the peritectic nature of the reaction in the formation of $MnSn_2$ phase. It is seen in Fig. 5 (b) that the susceptibility of $MnSn_2$ corrected by subtracting the estimated contribution of Mn_2Sn phase (dotted line) behaves like an antiferromagnetism. Thus the temperature of the peak, 324°K, may be considered as the antiferromagnetic Néel point of the compound $MnSn_2$.

Recently, it was reported by Ochsenfeld[7] that the inverse susceptibility *vs.* temperature curves of the tin alloys containing less manganese than 15.5 at% exhibited anomalous antiferromagnetic behaviors. But these behaviors can be interpreted as a superposition of the antiferromagnetism of $MnSn_2$, mentioned above, and the paramagnetism of dilute manganese alloy with tin, observed by Busch and Mooser[13].

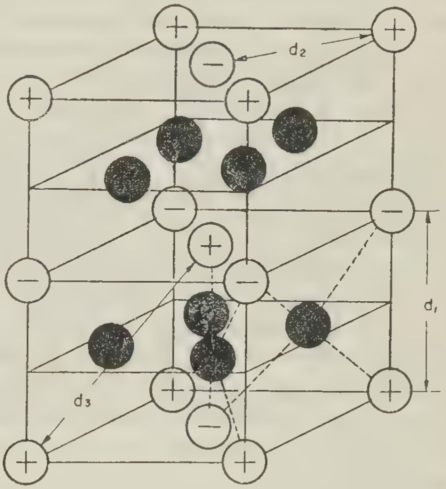

Fig. 6. Crystal structure of $MnSn_2$ (C16 type) and proposed magnetic structure. Closed circle: Sn; open circle: Mn. $d_1 = 2.72$Å, $d_2 = 4.70$Å, $d_3 = 5.43$Å.

Now we shall discuss the magnetic structure of this compound. The structure of the compound is shown in Fig. 6. The nearest neighbor Mn–Mn distances are 2.72Å along the *c* axis, 4.70Å along the face diagonal in the basal plane, and 5.43Å along the body diagonal. The angles of Mn–Sn–Mn for the pairs of manganese atoms along the face diagonal (second neighbor) and along the body diagonal (third neighbor) are 111° and 146°, respectively. According to the *J-r* curve for the manganese atom, mentioned in the discussion of $Mn_{1.77}Sn$, the direct interactions between manganese atoms may be negative for the pair of the first neighbors and positive for the pairs of the second and the third neighbors, corresponding to the interatomic distances above mentioned. The experimental fact that the asymptotic Curie point of this antiferromagnetism is positive suggests the existence of fairly strong positive interaction. Thus, in addition to the direct interactions, it is likely that the positive superexchange interaction between manganese atoms through tin atoms, proposed in the compound $Mn_{1.77}Sn$, plays an important role in this compound, too. In this structure, the superexchange interaction can exist between second and third neighbor manganese atoms. The interaction between the third neighbors would be stronger than that of the second neighbors for the sake of the proper angle of Mn–Sn–Mn. If the negative (direct) interaction between the first neighbors and the positive (indirect) interaction between the third neighbors overshadow the interaction between the second neighbors, the arrangement shown in Fig. 6 will be realized, since it makes all first neighbors antiparallel and all third neighbors parallel. The whole lattice is divided into two, crystallographically identical, sublattices. Therefore, all manganese atoms may have the same value of spin moment, to which we propose the value $S=3/2$. The effective Bohr magneton number per manganese atom in the compound is given by $g\sqrt{S(S+1)}$ and calculated to be 3.87, if we assume the Landé factor to be $g=2$, which is fairly in good agreement with the experimental value, 3.48.

The authors wish to express their hearty thanks to Prof. S. Kaya, the President of Tokyo University, for his constant encouragement and are also very grateful to Prof. R. Kimura of Tokyo Metropolitan University and Profs. Y. Tomono and S. Iida of Tokyo University who gave them opportunities to use the facilities to achieve the work.

The Magnetic Investigation of Mn^{++}, Co^{++}, Ni^{++} and Cu^{++} Ammine and Anhydrate Salts at Low Temperatures

By Takashi WATANABE

Department of Physics, Faculty of Science, Tokyo Metoropolitan University, Tokyo, Japan

(Received October 1, 1960)

The magnetic susceptibility measurements of ammine salts and anhydrate salts of Mn^{++}, Co^{++}, Ni^{++} and Cu^{++} ions at the temperature above 90°K have been carried out previously by Kido and the present author. The magnetic susceptibilities of these salts obtained by them show no deviation from the Curie-Weiss law down to 90°K. The results for magnetic susceptibility measurements of these salts at liquid helium and liquid hydrogen temperatures are given in the present report. The susceptibility measurements were carried out by the Hartshon bridge method. The salts which were studied are $Mn(NH_3)_6Cl_2$, $Mn(NH_3)_2Cl_2$, $Mn(NH_3)Cl_2$, $MnCl_2$, $Co(NH_3)_6Cl_2$, $Co(NH_3)_2Cl_2$, $Co(NH_3)Cl_2$, $CoCl_2$, $Ni(NH_3)_6\cdot Cl_2$, $Ni(NH_3)_6(ClO_4)_2$, $Ni(NH_3)_2Cl_2$, $Ni(NH_3)Cl_2$, $NiCl_2$, $Cu(NH_3)_4SO_4\cdot H_2O$, $Cu(NH_3)_2SO_4$ and $CuSO_4$. The antiferromagnetic or metamagnetic behavior in all other salts except $Mn(NH_3)_6Cl_2$, $Mn(NH_3)_2Cl_2$, $Co(NH_3)_2Cl_2$, $Ni(NH_3)_6Cl_2$, $Ni(NH_3)_6(ClO_4)_2$ and $Cu(NH_3)_2SO_4$ was found in the temperature range from 1.5°K to 20.4°K. The magnitude of the Weiss temperatures θ is largest for Ni^{++} and smallest for Mn^{++} in each coordinated salts of $M(NH_3)_6Cl_2$, $M(NH_3)_2Cl_2$, $M(NH_3)Cl_2$ and MCl_2 (M is one of Mn^{++}, Co^{++} and Ni^{++} ions). The unexpected results are found in the case of $Ni(NH_3)_6Cl_2$ and $Ni(NH_3)_6(ClO_4)_2$, as compared with the results of N.M.R. by Kim and Sugawara.

§1. Introduction

The reports of the magnetic susceptibility measurements of ammine complex salts are very few up to this time, especially, at low temperatures. Most of measurement in the present report was carried out from 20.4°K down to 1.5°K. The magnitude of the Weiss constant θ obtained from the susceptibility for Mn^{++}, Co^{++}, and Ni^{++} salts except the hexammine salts is largest for Ni^{++} and smallest for Mn^{++} in the temperature above 90°K[1]. This order of magnitude is not changed also in the hexammine salts below liquid hydrogen temperatures. The Weiss temperatures θ's defined in Eq. (1) of the salts of $M(NH_3)_2Cl_2$ and $M(NH_3)Cl_2$ type (M is Co^{++} and Ni^{++} ions) are negative and these salts show the nature of metamagnetics like in $CoCl_2$ and $NiCl_2$. The unexpected results of $Ni(NH_3)_6Cl_2$ and $Ni(NH_3)_6(ClO_4)_2$ will be seen in the later chapter.

The magnetic measurement for $CuSO_4$ was carried out by de-Haas and Gorter[3], Borovik-Romanov, Kalasik and Kleines[4], and Borovik-Romanov and Kleines[5]. But these results for a powder sample show the complicated behaviors, as seen in the later chapter.

The method of the preparation of each sample was given in the previous report[1]. The measurements are made with an A. C. Hartshon bridge[2] and the frequency for measurement is 120 c/s, where as a static method was used in the previous study[1]. The thermocouple of copper-constantan is inserted into measuring vessel for the measurement of temperatures in the intermediate temperature range (from 20.4°K to 60°K), as shown in Fig. 1. The diameter of thermocouple wire is selected as small as 0.06 mm, in order to reduce the heat leakage from the thermocouple lead and to minimize the experimental error by eddy current loss. The caliblation of e.m.f. of thermocouple has been carried out by the measurement of magnetic susceptibility for $Fe(NH_4)$-alum. By darkening the inside of Déwar vessel, the time for the ascent of temperature in a sample is reduced to about one hour and seven hours in the temperature ranges from 4.2°K to 20.4°K and from 20.4°K to 70°K, respectively. The susceptibilities of $Ni(NH_3)_2Cl_2$, $Ni(NH_3)Cl_2$, $NiCl_2$ and $CuSO_4$ in intermediate temperatures are measured by the above mentioned method. The sensibility of the thermocouple is not enough when the measurement is started from 4.2°K and the error of temperature measurement is ±1.5~3°K.

§ 2. The Experimental Results

The values of molar susceptibility χ_m, the magnetic moment p_{exp} (the Bohr magneton unit) and g-value in paramagnetic region are written as

$$\chi_m=\frac{C}{T+\theta}, \tag{1}$$

$$p_{\text{exp}}=\frac{1}{\mu_B}\sqrt{\frac{3kC}{N}}=2.839\sqrt{C} \tag{2}$$

and

$$g=p_{\text{exp}}\{S(S+1)\}^{-1/2}, \tag{3}$$

where C, θ, k, μ_B, N and S are respectively the Curie constant, the Weiss constant, the Boltzmann factor, the Bohr magneton, the Avogadro number and spin quantum number.

The values of p_{exp}, g, θ and T_{tr} (the magnetic transition temperature) determined in the low temperature range are given in the following tables and figures.

(1) $Mn(NH_3)_6Cl_2$, $Mn(NH_3)_2Cl_2$, $Mn(NH_3)Cl_2$ and $MnCl_2$ (Table I, Figs. 2 and 3)

(2) $Co(NH_3)_6Cl_2$, $Co(NH_3)_2Cl_2$, $Co(NH_3)Cl_2$ and $CoCl_2$ (Table II, Figs. 4 and 5)

(3) $Ni(NH_3)_6Cl_2$, $Ni(NH_3)_6(ClO_4)_2$, $Ni(NH_3)_2Cl_2$, $Ni(NH_3)Cl_2$ and $NiCl_2$ (Table III, Figs. 6 and 7)

(4) $Cu(NH_3)_4SO_4\cdot(H_2O)$, $Cu(NH_3)_2SO_4$ and $CuSO_4$ (Table IV, Figs. 8 and 11)

complex salts belong to anti CaF_2 type[6], and it seems that the symmetry charactor of crystalline field is almost cubic. The crystal structures of diammine and monoammine salts are not yet known, and the crystal structure of anhydrous salt $MnCl_2$ belongs to CdI_2 type[7] and these of $CoCl_2$ and $NiCl_2$ belong to $CdCl_2$ type.[8] Hammel[9] has suggested that the symmetry of $CuSO_4$ belongs to the hexagonal symmetry and that three copper ions are contained in the unit cell.

1) Mn^{++} ($3d^5$, $^6S_{1/2}$)

Since the orbital level of this ion is singlet, the energy level of Mn^{++} ion is not splitted by crystalline field and an anisotropy caused by the crystalline field does not remain. Thus, the most of the Weiss constant originate from the isotropic exchange interaction.

$Mn(NH_3)_6Cl_2$ and $Mn(NH_3)_2Cl_2$: $\theta \simeq 0.2°C$, $g = 2.00 \pm 0.02$ and the susceptibility obeys the Curie-Weiss law down to 1.5°K in the case of manganous hexammine chloride $Mn(NH_3)_6Cl_2$, as seen in Table I and Fig. 2. The temperature at which magnetic anormally of this salt appears, is perhaps below 1°K. $\theta = 1°C$ and $g = 1.98 \pm 0.02$ in the case of manganous diammine chloride $Mn(NH_3)_2Cl_2$. The values of susceptibility of this salt decrease somewhat below the values expected from the Curie-Weiss law in the range below 1.8°K, as seen in Table I and Fig. 2.

$Mn(NH_3)Cl_2$ and $MnCl_2$: Manganous monoammine chloride $Mn(NH_3)Cl_2$ shows the antiferromagnetic behavior, as seen in Fig. 3. The value for susceptibility of this salt represents a maximum at the temperature about 2.6°K and this value decreases in the range below 2.6°K. The value of susceptibility of manganous chloride anhydrate $MnCl_2$ deviates from the Curie-Weiss law below about 2.0°K, but it is constant in the temperature range from 1.4°K to 2.0°K. The anomaly that Murray and Robert[10] have pointed out, did not appear down to 1.4°K.

2) Co^{++} ($3d^7$, $^4F_{5/2}$)

$Co(NH_3)_6Cl_2$: The value of the Weiss constant θ of cobaltous hexammine chloride $Co\cdot(NH_3)_6Cl_2$ is larger than that of nickel hexammine chloride $Ni(NH_3)_6Cl_2$ above 90°K ($\theta = 17°C$). Values of g-factor and θ of $Co(NH_3)_6\cdot Cl_2$ below 20.4°K are different from these at high temperatures, as follows.

	high temperature region (above 90°K)	low temperature region (below 20.4°K)
p_{exp}	4.88 ± 0.06	3.70 ± 0.04
g	2.53 ± 0.03 ($S=3/2$)	4.27 ± 0.02 ($S=1/2$)
θ	17°C	2.7°C
	(from Table II and Fig. 4)	

These phenomena arise from the level splitting of ground state due to spin orbit coupling $\lambda(L \cdot S)$ ($\lambda = -200\,\text{cm}^{-1}$). The susceptibility becomes nearly constant below 1.5°K. But the possibility that the value of susceptibility of this salt becomes constant in the very low temperatures, may be doubtfull, because each orbital level of Co^{++} ion has the Kramers' doublet. The antiferromagnetic charactor of $Co(H_2O)_6Cl_2$ at very low temperatures has been found by T. Haseda.[11)]

$Co(NH_3)_2Cl_2$, $Co(NH_3)Cl_2$ and $CoCl_2$: The values of g-factor and θ for $Co(NH_3)_6Cl_2$ decrease at low temperatures. Such behaviors would be expected also in the cases of $Co \cdot (NH_3)_2Cl_2$, $Co(NH_3)Cl_2$ and $CoCl_2$, but could not be observed in the case of powdered samples. $Co(NH_3)_2Cl_2$ and $Co(NH_3)Cl_2$ have respectively the magnetic transition points of 16°K and 20°K, and the Weiss temperatures θ for both salts have negative signe ($\theta < 0$), as seen in Figs. 4 and 5. The magnetic characters of these salts are similar to that of $CoCl_2$ and it seems that these salts are metamagnetic. The present result of $CoCl_2$ agrees well with the result given by Bizette et al.[12)]

3) Ni^{++} ($3d^8$, $^3F_4$)

$Ni(NH_3)_6Cl_2$: The susceptibility of nickel hexammine chloride $Ni(NH_3)_6Cl_2$ becomes nearly constant in the temperature range below 1.6°K, as shown in Fig. 6. The possible explanations of this behavior are such as the following two.

i) The value of susceptibility seems to decrease below 1.42°K to which the present measurement was performed and the Neél point may be somewhere about 1.5°K.

ii) The ground level of Ni^{++} ion which is splitted by the combined action of cubic field and spin-orbit coupling, is orbital singlet. And so the value of susceptibility becomes constant in the temperature range corresponding to λ^2/Δ_i, where Δ_i is the level separation.

The present experiment could not make clear the above two possibilities, because the measurement could not be carried out down to 1.0°K and the single crystal was not used. But if it is allowed to assume the latter situation (ii) for the explanation of the present result, we may conveniently use the spin Hamiltonian method[12)–14)] in the analysis of the result for $Ni(NH_4)$-Tutton salt. The Hamiltonian is, in this case,

$$\mathscr{H} = -DS_z^2 - E(S_x^2 - S_y^2) + g\mu_B H(\alpha S_x + \beta S_y + \gamma S_z)\,. \qquad (4)$$

From the above Hamiltonian (4), the relation between the susceptibility and the temperature is derived (in the case of Ni^{++} ion, $S=1$) as follows,

$$\chi_{m(\text{powder})}(T) = \chi_{m(\text{powder})}(0) \times \frac{1 - \dfrac{(D+E)(D-3E)}{(D-E)(D+3E)} e^{-2E/kT} - \dfrac{4DE}{(D-E)(D+3E)} e^{-(D+E)/kT}}{1 + e^{-2E/kT} + e^{-(D+E)/kT}} \qquad (5)$$

and at absolute zero degree,

$$\chi_{m(\text{powder})}(0) = \frac{2Ng^2\mu_B^2}{3} \cdot \frac{D+3E}{2E(D+E)}\,. \qquad (6)$$

Some couples of the trial values of D and E are estimated from the relation (6) using extrapolated value to $T=0$. Substituting such values of D and E into the relation (5), final couple of the values are determined by comparison with the experimental result. These values thus obtained at low temperatures are respectively

$$D = 43\,\text{cm}^{-1} \quad \text{and} \quad E = 5\,\text{cm}^{-1}\,.$$

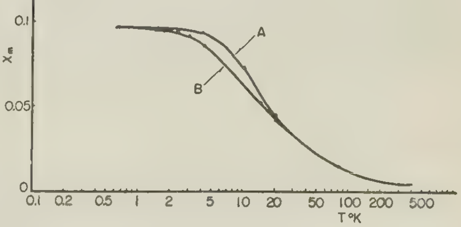

Fig. 9. Calculated and measured molar susceptibility versus temperature (°K) for $Ni(NH_3)_6Cl_2$. A-calculated curve and B-measured curve.

* χ_{exp}:—the experimental values of susceptibility.

** χ_{cal}:—the calculated values of susceptibility.

*** This is the inserting value in Fig. 9.

The estimated values of susceptibility using above numerical values of D and E, and the measured values of susceptibility in any temperature are given in Fig. 9 and Table V.

The values of $D-E$ and $2E$ are about twenty times larger than those of Ni(NH$_4$)-Tutton salt which are determined from the results of E.S.R. or magnetic susceptibility. These values in nickel hexammine chloride salt may be hardly accepted as reasonable values, but they may explain the fact that the reasonance line of $Ni(NH_3)_6Cl_2$ could not be observed in the range below 74°K, although the wave length of 0.8 cm was used.[16]. While E.S.R. of this salt can be observed from room temperature down to 74°K. The color of this salt is blush purple in the region from room temperature down to liquid oxygen and pinky purple below liquid nitrogen temperatures. If above behaviors for $Ni(NH_3)_6Cl_2$ have been considered, the crystal structure of this salt may happen to deform in the range from 70°K to 80°K. It may be said that g-value of $Ni(NH_3)_6Cl_2$ in the range below liquid hydrogen temperatures is 2.20±0.02 which is somewhat larger than 2.17±0.03 in the range above 90°K.

$Ni(NH_3)_6(ClO_4)_2$: The magnetic character of $Ni(NH_3)_6(ClO_4)_2$ is different from that of $Ni(NH_3)_6Cl_2$ below 4.2°K, as seen Fig. 6. The values of susceptibility of $Ni(NH_3)_6(ClO_4)_2$ increase even at 1.5°K, and the result for this salt obeys the Curie-Weiss law down to about 2°K. The color of this salt changes from bluish purple to pinky purple below 80°K similarly to $Ni(NH_3)_6Cl_2$.

If the exchange interaction energy is neglected, from the relation (5) and (6) the values of D and E are estimated respectively, as follows:

$$D=6.0\ \mathrm{cm}^{-1} \quad \text{and} \quad E=1.0\ \mathrm{cm}^{-1}.$$

If the exchange interaction $A\cdot S_iS_j$ is considered, the spin-Hamiltonian becomes[17]

$$\mathscr{H}=-DS_z^2-E(S_x^2-S_y^2)+\mu_B g(H_xS_x+H_yS_y+H_zS_z)+AS\cdot\langle S\rangle\,. \tag{7}$$

$AS\cdot\langle S\rangle$ in the above Hamiltonian represents the thermal equiliblium approximation of $A\cdot S_iS_j$. When the magnitude of exchange interaction is smaller than that of crystalline field splitting, the relation of χ_m and T in any temperature derived from the Hamiltonian (7) is given by (in the case of Ni^{++} ion, $S=1$),

$$\begin{aligned}\chi_{m(\text{powder})}(T)&=\frac{1}{3}(\chi_x+\chi_y+\chi_z)\\&=\frac{2}{3}Ng^2\mu_B^2[\{1-e^{-(D+E)/kT}\}/[(D+E)\cdot\{1+e^{-2E/kT}+e^{-(D+E)/kT}\}+2A\{1-e^{-(D+E)/kT}\}]\\&\quad+\{e^{-2E/kT}-e^{-(D+E)/kT}\}/[(D-E)\cdot\{1+e^{-2E/kT}+e^{-(D+E)/kT}\}+2A\{e^{-2E/kT}-e^{-(D+E)/kT}\}]\\&\quad+(1-e^{-2E/kT})/[2E\cdot\{1+e^{-2E/kT}+e^{-(D+E)/kT}\}+2A(1-e^{-2E/kT})]]\end{aligned} \tag{8}$$

and in the absolute zero degree the relation of χ_m is

$$\chi_{m(\text{powder})}(0) = \frac{2Ng^2\mu_B{}^2}{3}\left(\frac{1}{D+E+2A} - \frac{1}{2E+2A}\right). \qquad (9)$$

The relation of the Curie-Weiss law in the high temperature range is

$$\chi_{m(\text{powdcr})}(T) = \frac{2Ng^2\mu_B{}^2/3}{3kT+2A}. \qquad (10)$$

Above relations for the susceptibility have been kindly derived for the present author by Dr. T. Moriya. Each values of A, D and E whicn are determined by the similar process to the case of $Ni(NH_3)_6Cl_2$ are

$$A = 0.7 \pm 0.1\ \text{cm}^{-1},$$
$$D = 4.0\ \text{cm}^{-1}$$

and

$$E = 0.38\ \text{cm}^{-1}.$$

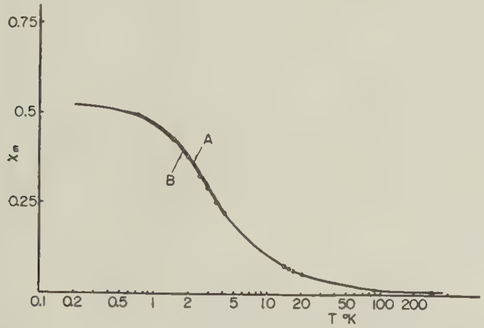

Fig. 10. Calculated and measured molor susceptibility versus temperature (°K) for $Ni(NH_3)_6(ClO_4)_2$.
A-calculated curve and B-measured curve.

The calculated values of susceptibility using above values of A, D and E, and the experimental values of susceptibility in any temperatures are shown in Fig. 10 and Table VI. According to the observation by Kim and Sugawara[18),19)] the proton resonance lines of $Ni(NH_3)_6Cl_2$ (in powder and single crystals) and $Ni(NH_3)_6(ClO_4)_2$ (in powder) disappear respectively at 1.6°K and 7°K. But the values of θ estimated from magnetic susceptibility and the temperatures for disappearance of N.M.R. lines in $Ni(NH_3)_6Cl_2$ and $Ni(NH_3)_6 \cdot (ClO_4)_2$ do not agree with each other as shown in Table VII. The proton line of $Ni(NH_3)_6Cl_2$ disappears at 1.6°K where the value of susceptibility becomes nearly constant, but the proton line of $Ni(NH_3)_6(ClO_4)_2$ disappears at about 7°K while the susceptibility obeys the Curie-Weiss law down to 2°K. On

* χ_{exp}:—the experimental value of susceptibility.
** χ_{cal}:—the calculated value of susceptibility.
*** This is the inserting value in Fig. 10.

Table VII.

	θ	The temperature of disappearance of N.M.R. line
$Ni(NH_3)_6Cl_2$	8°K	1.6°K (by Kim and Sugawara)
$Ni(NH_3)_6(ClO_4)_2$	0.7	7 (〃)

the other hand, the proton line of $Ni(H_2O)_6 \cdot Cl_2$ disappears at about 7°K. This salt is antiferromagnetic below 6.2°K[20] and the specific heat of this salt exhibits a lambda-shaped anamalous peak at 5.34°K.[21] It seems that the disappearance of proton line in this case can be explained by the antiferromagnetic transformation[22]*. But when the results of Table VII are considered we can not infer that the disappearance of the proton lines of $Ni(NH_3)_6Cl_2$ and $Ni(NH_3)_6(ClO_4)_2$ are due to the antiferromagnetic transition. On the other hands, if the disapperance are due to the spin-quenching below the temperature comparable to an interval of the splitting of ground levels, the temperature of disappearance of N.M.R. line should coincide with that of spin-quenching. But it is not the case.

$Ni(NH_3)_2Cl_2$, $Ni(NH_3)Cl_2$ and $NiCl_2$: The observed relations of $\chi - T$ of $Ni(NH_3)_2Cl_2$ and $Ni(NH_3)Cl_2$ are similar to each other, except the detail in the low temperature range as shown in Fig. 7. The sign of the Weiss constant θ are negative ($\theta<0$) and the order of magnitude of θ is

$$|\theta_{Ni(NH_3)_2Cl_2}| < |\theta_{Ni(NH_3)Cl_2}| < |\theta_{NiCl_2}| \; .$$

(as seen in Table III)

So, it may be probable that the magnetic characters of these salts are metamagnetic like in $NiCl_2$. The order of magnitude of θ indicates that Ni^{++} ions are diluted magnetically by NH_3 ligand. The present result of $NiCl_2$ agrees well with the results of Bitter, Starr and Kaufmann[23], and Bizette, Tisaï and Terrier[12].

4) Cu^{++} ($3d^9$, $^2D_{5/2}$)

$Cu(NH_3)_4SO_4 \cdot (H_2O)$: The result of this salt in the temperature range between 1.02°K and 20.4°K was already published by the present author and T. Haseda[24]. We have proposed the possibility that the magnetic interaction is probably linear chain like in this salt, in order to explain the magnetic susceptibility of single crystals in that report.

$Cu(NH_3)_2SO_4$: The magnetic susceptibility of $Cu(NH_3)_2SO_4$ in the temperature below 20.4°K deviates from the Curie-Weiss law in the temperature above 90°K. And the Weiss constant θ of this salt is almost zero degree in the temperature range from 1.5°K to 4.2°K, as seen in Fig. 8 and Table IV. The following data of the magnetic moment p_{exp} and the Weiss temperature θ are the quotation from Table IV.

	high temperature region (above 90°K)	low temperature region (below 4.2°K)
p_{exp}	$1.92 \pm 0.03\,\mu_B$	$1.47 \pm 0.02\,\mu_B$
θ	22 ±3°C	0 ±0.2°C

The magnetic moment p_{exp} of this salt is 1.47 μ_B in the temperature range from 1.5°K to 4.2°K as shown in the above results. If 1.47 μ_B at the low temperature range is compared with 1.92 μ_B at the high temperature range, these results mean that 73% of the magnetic moment at high temperatures is free and that 27% of this is quenched by some reason in liquid helium temperatures. 27% of magnetic moment corresponds to 15% of electron spin for $S=1/2$. The partial quenching of magnetic moment can be found

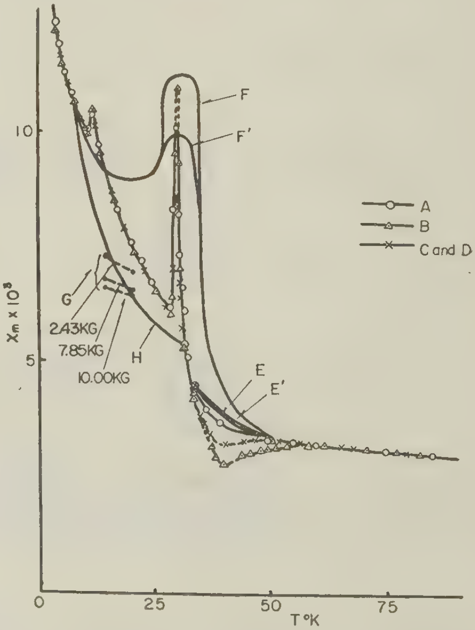

Fig. 11. Molar susceptibility versus temperature (0°K) for $CuSO_4$ anhydrate. E' and F' are the susceptibility curve under the external applied field of 1000 and they correspond to E and F respectively.

---

* Recently, Prof. T. Sugawara of Tokyo University have found the symmetric pattern on proton line with 180° period in $Ni(H_2O)_6Cl_2$ due to the antiferromagnetic ordering at liquid helium temperatures.—private communication.

Table VIII.

$CuSO_4$	The temperature of dehydration	time	condition
A	300°C	1 hr	in air
B	270	2 hrs	〃
C	300	1 hr	in vacuum
D	300	——	+conc. H_2SO_4
E	270	——	〃
F	300	——	$+(NH_4)_2SO_4$

also in the case of $Cr_3(CH_3COO)_6(OH)_2Cl_2 \cdot 8H_2O$[25], but it seems that such a result can not probably be expected in the case of spin state of $S=1/2$ only.

$CuSO_4$: The magnetic measurement of $CuSO_4$ anhydrate was carried out previously by de-Hass and Gorter[3] (1931), recently by Romanov-Borovik, Kalasik, Kleines[4] and Romanov-Borovik, Kleines[5]. The about twenty kinds of samples are prepared for the present experiment according to the several conditions of dehydrating process from the separate sources. The results of magnetic susceptibility of $CuSO_4$ anhydrate are different from sample to sample at about 35°K. The curves of A, B, C, D, E and F in Fig. 11 are respectively for the samples that were prepared by the conditions in Table VIII.

The curve G in Fig. 11 is the results by de-Haas and Gorter. The curve H corresponds to the case in which the external magnetic field of about 1000 Oe is applied to the specimens A, B, C, D and E in the range between 10°K and 35°K, and E′ is for the case in which the external field of about 1000 Oe is applied to the specimen E at the range between 38°K and 45°K. The curve F′ is also the result of application of magnetic field of about 1000 Oe in the case of F.

All the samples in the present results show the magnetic transition at about 35°K as shown in Fig. 11. The transition point of specific heat of lambda-type at 35°K was found by Stout[26] and following to his report this peak of the specific heat corresponds to 1/3 spin quenching (at $S=1/2$ state). The value of susceptibility in the transition point at 35°K is different for the each run, as mentioned above. The magnetic field dependency of susceptibility can be found respectively in the ranges from 10°K to 36°K and from 38°K to 45°K. The values of susceptibility decrease with increasing magnetic field in the former range and increase somewhat with increasing magnetic field in the latter range. It seems that the magnetic property in the former temperature range is parasitic ferromagnetism. The magnetic field dependency of susceptibility could not be found below 10°K, but the results in this temperature range do not obey the Curie-Weiss law and these resulting curves (for the relation of $\chi \sim T$) have the asymptotic line to $T=0$. On the other hand, the sample of $CuSO_4$ which is produced from the mixed fusion state of $CuSO_4+(NH_4)_2SO_4$ was measured in the present experiment and the results are given by the curves F and F′ in Fig. 11. These results is different from the former results of the present experiment at about 35°K, as seen in Fig. 11. The antiferromagnetic character in this case does not appear in the range between 38°K and 45°K, but this result is in agreement with the former results in the temperature below 10°K. The narrow peaked values at 35°K in the former results may be enhanced by the crystal defect. It seems that such ambigous results are attributed to the crystal imperfection existing in the powder sample. Above all, the parasitic ferromagnetic character of this salt in the temperature range from 10°K to 35°K may be also attributed to the existence of crystal imperfections probably.

§ 4. Conclusion

The following conclusions are derived from the results and the discussion of former chapter.

i) The values of the Weiss constant θ decrease with the increasing number of coordinated ligand in Mn^{++}, Co^{++}, Ni^{++} and Cu^{++}

salts.

ii) The values of the Weiss constant θ in each ammine and anhydrated salts are minimum in the case of Mn^{++} ion salt.

iii) It seems that $Co(NH_3)_6Cl_2$ in the temperature below 1.5°K shows antiferromagnetic character, because as pointed out in the preceding chapter the ground orbital level of Co^{++} ion is triplet state and each orbital level has the Kramers' doublet. The expectation that the susceptibility of $Co(NH_3)_6Cl_2$ has constant value in low temperatures may be hardly probable.

iv) The Weiss temperatures θ of $Co(NH_3)_2 \cdot Cl_2$, $Co(NH_3)Cl_2$, $Ni(NH_3)_2Cl_2$ and $Ni(NH_3)Cl_2$ are negative and it seems that these salts show the nature of metamagnetism like in $CoCl_2$ and $NiCl_2$.

v) The crystalline fields of $Ni(NH_3)_6Cl_2$ and $Ni(NH_3)_6(ClO_4)_2$ are predominantly cubic. But the magnetic properties of these salts below 10°K are inconsistent with each other salts as mentioned in preceding chapter. The reliability of values of D and E in $Ni(NH_3)_6 \cdot Cl_2$ (in section 3) is not enough. On the other, if the consideration in section 3 is allowed, the values of level splitting of $(D-E)$, $2E$ and the value of the exchange interaction A of $Ni(NH_3)_6(ClO_4)_2$ are very smaller than the values of $Ni(NH_3)_6Cl_2$, and these values of the former salt are the same order with the values of Ni-Tutton salt. Kim and Sugawara[18),19)] reported the result that proton resonance lines of $Ni(NH_3)_6(ClO_4)_2$ and $Ni(NH_3)_6 \cdot Cl_2$ disappeared respectively at 7°K and 1.6°K. So we can not produce any conclusion from the said dissimilarity between the result of N.M.R. by Kim and Sugawara and the present result of the magnetic susceptibility below 10°K. The proton resonance lines of $Ni(NH_3)_6Cl_2$ and $Ni(NH_3)_6(ClO_4)_2$ disappear in low temperatures, and these behaviors can not be interpreted by the magnetic transformation and can be hardly interpreted by the energy level splitting.

vi) The magnetic transformation of $CuSO_4$ anhydrate is probably at about 35°K. But the reproducible result of magnetic susceptibility of this salt can be hardly obtained from the measurement of sample used in the present experiment. Such a nonreproducibility of magnetic measurement at about 35°K might be caused by the crystal imperfections which would be created in the dehydrated process. And it seems probable that the parasitic ferromagnetic character of this salt in the temperature range 10°K to 35°K is also attributed to the existence of crystal imperfections.

Acknowledgement

The present author wish to express his sincere thanks to Prof. K. Kido who has encouraged him for the present study, and Prof. E. Kanda and Dr. T. Haseda of Tohoku Univ. who have given him many facilities throughout this investigation. He says his thanks also to Mr. Takashi Sato of the Research Institute for Iron, Steel and Other Metals of Tohoku Univ. for his helpful assistance. This work was indebted to the Scientific Research Expenditure of the Section of Low Temperature of the Ministry of Education.

Ultrasonic Attenuation in Tin Single Crystals at Low Temperatures*

By Kazuo KAMIGAKI
The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai

(Received November 14, 1960)

The ultrasonic attenuation coefficient and velocity in the superconducting and the normal states of tin single crystals were measured at temperatures between 1.5° and 4.2°K. It was found that (1) the anisotropy of ultrasonic attenuation in different crystallographic directions exists in the case of comparatively long wavelengths (the product of the mean free path of conduction electrons and wave number of sound waves is less than unity). (2) Also the ratio of longitudinal to shear wave attenuation was found to be larger than that predicted from the free electron model.

§1. Introduction

The recent theory of superconductivity prosed by Bardeen and others (BCS)[1] makes clear the nature of phonon-electron interaction in the superconducting state. This theory is founded on the spherical or isotropic energy distribution of conduction electrons in momentum or wave vector space. In real metals, however, the Fermi surface is not spherical. Recently, Morse[2] and Bezuglji[3] found in tin single crystals the anisotropic deviation of the ultrasonic attenuation from the BCS theory in the frequency range of $ql>1$, where q is the wave vector of ultrasonic waves and l the mean free path of the conduction electrons. In connection with these experiments, the present author planned to measure the ultrasonic attenuation and velocity of the longitudinal and the shear waves along different crystallographic directions of tin single crystals for the frequency range $ql<1$.

§2. Test Piece and the Method of Measurements

The tin single crystals (99.98 per cent) were prepared by the Bridgman method. Each specimen was machined into a rod about 1.2 cm in diameter and 1.2 cm in length. The crystallographic directions of the specimens were determined within ±1° by the light figure method[4]. The specimen was placed in a liquid helium cryostat of the usual type.

The ultrasonic attenuation coefficient was measured by the pulsed wave technique. The electronic apparatus and the measuring procedure were the same as those used in the previous measurements[5]. The frequencies of the ultrasonic waves used in the present experiment were 9, 15 and 25 Mc/s respectively. Quartz crystals were used as transducers: an X-cut disk 0.7 cm in diameter was prepared

---

* The expense of this work was partly defrayed by the Grant-in-Aid for Fundamental Scientific Research of the Ministry of Education.

for the longitudinal waves and a rectangular Y-cut plate 1×1.02 cm in size for the shear waves. The crystals were cemented to the specimens with Bond CA 100. The accuracy of the attenuation measurement was ±3 per cent. Sound velocity was determined by measuring the time difference of successive pulses by means of an electronic delay circuit, and the accuracy of measurement in this case was about 2 per cent. A maximum magnetic field of 600 Oe was applied to destroy the superconducting state of the specimen.

§ 3. Results of Measurements and Discussions

First, the variation of longitudinal attenuation at 15 Mc/s with the magnetic field was measured and the results are shown in Fig. 1.

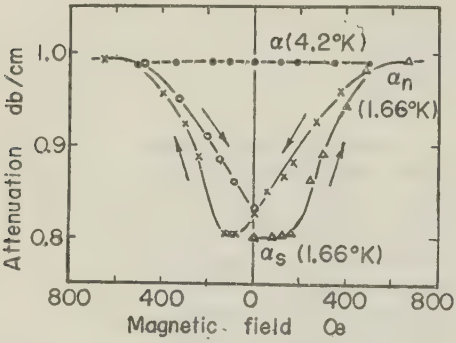

Fig. 1. Dependence of longitudinal ultrasonic attenuation on the magnetic field. The broken line shows the attenuation at 4.2°K and the solid line at 1.66°K.

The broken line shows the attenuation at 4.2°K, which is a temperature above the superconducting transition point T_c; only a slight effect due to the magnetic field could be observed. While the measurement at 1.66°K, which is below T_c, shows that the attenuation increases with the field strength gradually from about 200 Oe and becomes saturated at about 500 Oe as is shown by a solid curve in Fig. 1. By reversing the field direction the attenuation follows the hysteresis curve, this would be due to the heterogeneous transformation between the normal and the superconducting states. The same feature was observed in the shear wave attenuation.

Longitudinal and shear wave attenuation coefficients at 15 Mc/s were measured at temperatures between 1.5°K and 4.2°K. The results are plotted in Fig. 2, the direction of transmission being shown on the pole figures. As was shown by the previous measurements[6,7,8] the attenuation coefficient in the superconducting state decreased rapidly just below T_c and then slowly with further lowering of temperature. On the contrary, attenuation in the normal state was found to remain almost unchanged with temperatures. The same attenuation behavior was also observed at 9 and 25 Mc/s.

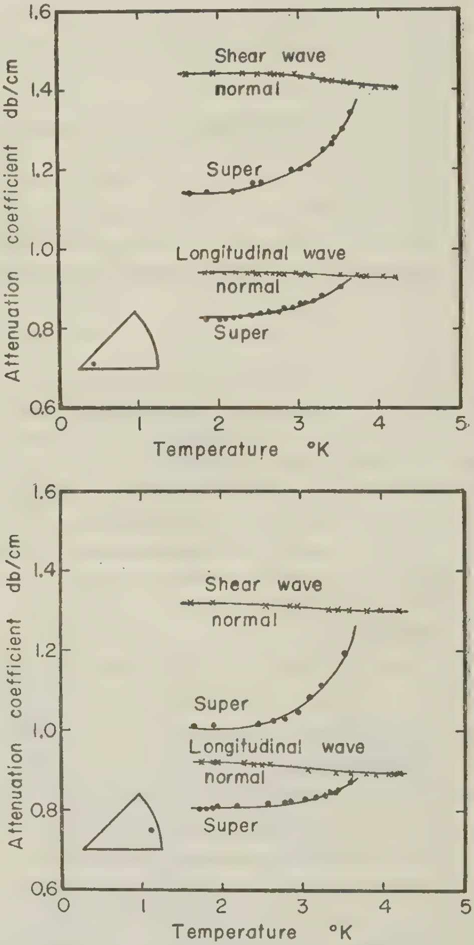

Fig. 2. Longitudinal and shear wave attenuation coefficients at 15 Mc/s.

Longitudinal and shear wave velocities v_L and v_T were measured for the same specimen and the results obtained are shown in Fig. 3. In the present case, both v_L and v_T were almost unchanged with temperature and with the transformation between normal and superconducting states within the accuracy of the measurement[8,9].

It is to be noted here that there is, of course, a background attenuation which is non-electronic in origin. The electronic attenuation was determined by extracting the extrapolated superconducting attenuation to 0°K. Both superconducting and normal state attenuations, which are electronic, are taken from this extrapolated value and written as $\alpha_s(T)$ and $\alpha_n(T)$ at T°K. Now in Fig. 4 the values of $\alpha_n(0)$ along the same crystallographic direction at different frequencies are plotted against the square of the frequency. As this figure shows, the value of attenuation is proportional to the square of the freqency. The dependence of attenuation on frequency f was discussed by several authors in a classical[10,11] and in a quantum mechanical way[12], which showed that α_n is proportional to f or f^2 according as $ql>1$ or <1; hence it is concluded for the present case that $ql<1$. In such a case the attenuation of the longitudinal waves is written in the following form

$$\alpha_n = \frac{8}{15}\frac{\pi^2 f^2}{\rho v_L^3}\frac{\hbar^2(3\pi^2 N)^{2/3}}{e^2}\sigma\,, \qquad (3)$$

where ρ is the density, σ the electrical conductivity, N the number of electrons in the unit volume, and e the electron charge. From the slope of the curve in Fig. 3, the value of product $N^{2/3}\sigma$ is found to be 0.63×10^{34}.*

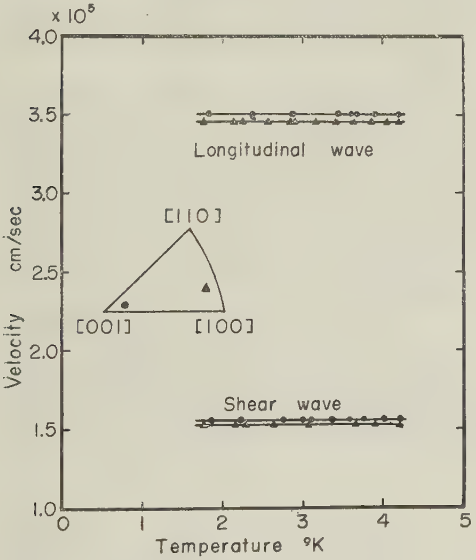

Fig. 3. Velocity of the longitudinal and the shear waves.

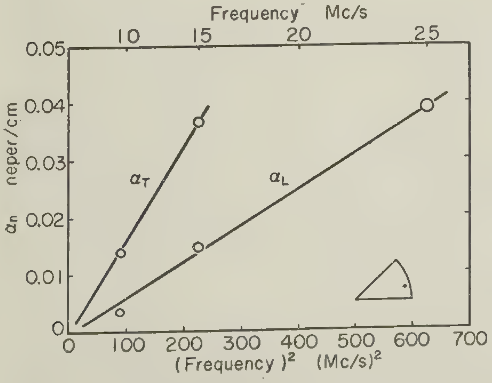

Fig. 4. Relations between α_n and the square of the frequency for longitudinal and shear waves.

According to the BCS theory of superconductivity which was based on the spherical Fermi surface assumption, the variation of ultrasonic attenuation with temperature is given for the case of $ql>1$. However, this assumption is not exactly applicable to the real metals. Some deviation from the theoretical curve was found out in the measured values for different directions of a crystal in the case of $ql>1$[2,3]. Now, in Fig. 5 the ratio α_s/α_n is plotted against reduced temperature for different crystallographic directions, which shows that also in the case $q<1$ the observed values for different orientations deviated from each other. α_s/α_n is slacker in the directions near [100] than the other. This tendency

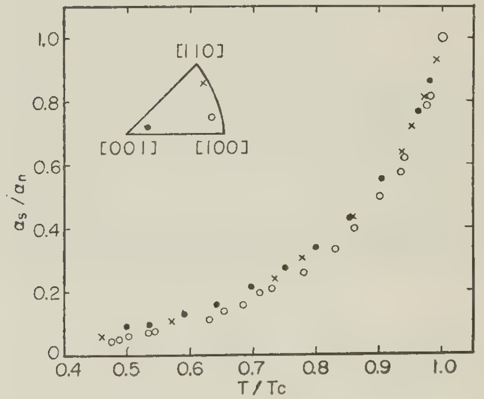

Fig. 5. Ratios between superconducting and normal state attenuation of longitudinal waves at 15 Mc/s for various orientations of tin single crystals.

---

* The residual electrical resistance of the present specimen is estimated at $2\times10^{-8}\,\Omega$-cm, making use of equation (1) and measured values of resistance $1\times10^{-10}\,\Omega$-cm and attenuation 0.82 neper/cm (10.3 Mc/s) in 99.999% tin single crystal[8].

agrees closely with the results obtained in the case of $ql > 1$. The origin of such anisotropy will be the deviation of the electronic energy contour from the spherical symmetry in the tetragonal tin crystal.

Moreover, according to the classical calculations[10,11], the ratio of the electronic attenuation of longitudinal waves α_L to that of shear waves α_T at the same frequency is given

$$\frac{\alpha_L}{\alpha_T}=\frac{4}{3}\frac{v_T^3}{v_L^3}, \qquad (2)$$

assuming the isotropic velocity distribution for conduction electrons. Making use of the observed values in Figs. 3 and 4, the applicability of the above equation is examined. As shown in the following Table, $4v_T^3/3v_L^3$ is obtained as 0.18; while from the slope of both curves in Fig. 4, α_L/α_T is found to be 0.35 in the direction shown in the pole figure, so that the ratio of both sides of equation (2) is calculated as 0.51. This value is less than the value 0.92 due to Mason and Bömmel[8] in the direction near [100]. The deviation of both values from unity would result from the assumption of isotropy used in the theory.

Table I.

	$\frac{4}{3}\frac{v_T^3}{v_L^3}$	$\frac{\alpha_L}{f^2}$	$\frac{\alpha_T}{f^2}$	$\frac{\alpha_L}{\alpha_T}$	Ratio

The Thermoelectric Power of Magnesium-Cadmium Alloys

By Seiichiro Noguchi

Department of Physics, Tokyo Metropolitan University Tokyo

(Received December 2, 1960)

The thermoelectric power of magnesium-cadmium alloys was measured relative to pure copper at temperatures between room temperature and 300°C. The measurements were made in the entire ranges of the composition and the data were analyzed by a band-model approximation to obtain some information about the band structure of the alloys in the magnesium-cadmium system.

The thermoelectric power at 300°C as a function of composition shows a smooth trend as well as that of an earlier investigation of the Hall measurements[1], although the result of the thermoelectric power at room temperature shows that there are three maxima and two minima, while the result of the Hall coefficient gives two maxima and one minimum. In the alloys of the composition corresponding to the ordered phase, anomalies in the thermoelectric power are observed at the transition point. The results of the thermoelectric power indicate that there is no evidence of any extinction or initiation of a band by the alloying. The situation of the Fermi level in A-overlap is discussed.

§ 1. Introduction

The relation between an axial ratio and an electronic band structure of some hexagonal alloys has been studied by a number of investigators[2-6]. The measurement of axial ratio, however, gives only indirect evidence of a variation of the band structure with alloying.

The experiments on transport properties, such as the Hall effect and the thermoelectric power which are sensitive to the condition of the conduction electrons, are desirable to obtain the direct information on the band structure. It is of great interest to study magnesium-cadmium system because there is a solid solution range in the entire compositions at higher temperatures, and the variation of the axial ratio is appreciably large, namely, the ratios are 1.887 for cadmium and 1.623 for magnesium[2]. The Hall measurements have indicated that the variation of the assumed bands is partly agreement with what is supposed by the results of the axial ratio measurements. The both measurements can not, however, show the detailed features, such as the initiation and the extinction of a band.

The present work will give a further information to this question. The variation of the thermoelectric power on the order-disorder transition is also investigated, and is discussed at the comparison with the results of the Hall effect which have been reported recently by Yonemitsu and Sato[7].

§ 2. Experimental Procedure

Eleven alloys were prepared for this investigation in the same way as for the Hall measurement[1]. The purity of the constituent metals is 99.9% for both magnesium and cadmium.

In the present measurement, a differential methods was used in place of a usual one, and the thermoelectric power of the specimens was obtained relative to pure copper and then the absolute thermoelectric power of the sample was determined by adding the known absolute thermoelectric power of pure copper observed by Cusack and Kendall[19]. The thermoelectric power of the specimens in the temperature range of the order-disorder transformation can not be observed by means of a usual method of measuring the thermoelectric force. The reason is as follows: In this method, one end of the sample is held at some constant temperature, for instance, at 0°C, and the other end is heated slowly up to scheduled temperature, then the thermoelectric voltages with increasing temperature are obtained and are differentiated with respect to temperature in order to obtain the thermoelectric power at every temperature. Therefore, when we try to measure the thermoelectric power during the order-disorder transition with this method, the lower end of the specimen is in an ordered state while the higher end is in a disordered state. Thus, observed thermoelectric voltage between these two ends may have no physical meaning.

We have employed the differential method for above reason, but this method has the same sort of disadvantage as the former one, although the extent of the disadvantage is far smaller. In an ordered alloy the order parameter is given as a function of temperature. When the two ends of such an alloy are kept at some different temperatures each other, these two ends have different states of order in their equilibrium. Unfortunately, without keeping two points of a specimen at the different temperatures, we essentially can not measure the thermoelectric power. This is the reason why the thermoelectric measurement can not be used in the investigation of the kinetics of the orderdisorder transition in spite of its sensitivity to the transition. This flaw, however, may be able to be diminished appreciably with the reduction of the temperature difference between the two ends. In the differential method used here, the difference of temperature was four to six degrees near the transition points.

When we measure the thermoelectric power of a specimen at the temperature at which the order-disorder transition occurs, we shall meet the other difficulty, that is the anomalous heat absorption during the transition. The variation of temperature difference between two ends of the specimen is so rapid that we could hardly observe the thermoelectric power at these temperatures. In the present measurements, heating of the specimens was made at the rate as slow as possible in order to avoid the above effect. The rate was about 0.5°C/min. or less. In spite of various experimental cares, the thermoelectric power in equilibrium state during the order-disorder transition can not essentially be measured by the above reasons. For the present discussion, however, the accurate data for perfect ordered and disordered states are necessary rather than the data for intermediate states. In the present work, all the specimens were measured in argon atmosphere.

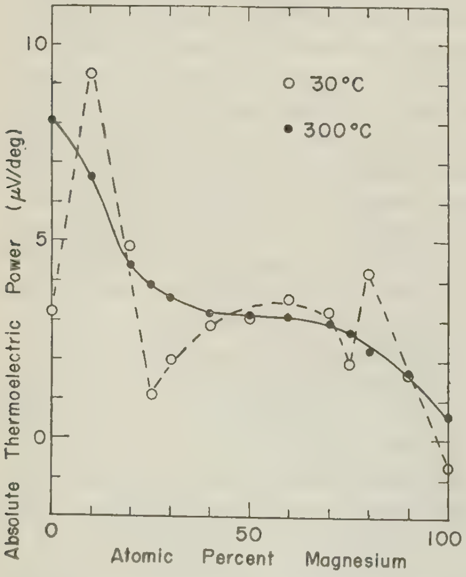

Fig. 1. The concentration dependence of the absolute thermoelectric power in Mg-Cd alloys.

§ 3. Results

Concentration dependence

The absolute thermoelectric power of cadmium at 300°C is obtained to be 8.03 microvolt per degree, and decreases monotonically with the increasing contents of magnesium, then, for the pure magnesium, reaches the value of 0.77 microvolt per degree. The magnesium-cadmium system has a single phase over the entire compositions at higher temperatures than 253°C. At these temperatures, all the alloys have a hexagonal close-packed structure but the axial-ratios are appreciably different for different compositions. On the other hand, at the lower temperatures, e. g. at room temperature, it has been reported that three ordered phases are present. Because of the existence of these phases, there is a notable difference between the composition dependence of the thermoelectric power at 300°C and that at room temperature. The concentration dependence of the both cases are given in Fig. 1. The thermoelectric power as a function of composition has two minima for the compositions corresponding to $MgCd_3$ and Mg_3Cd and it has a maximum for the approximate composition corresponding to MgCd. This behavior is in contrast to that for the Hall coefficient which shows two maxima for $MgCd_3$ and Mg_3Cd and a minimum for MgCd. In both cases, however, the compositions of ordered phases correspond to the extreme value. Extra two maxima are observed in the result of the thermoelectric power.

Temperature dependence

The temperature dependences of thirteen alloys are shown in Fig. 2–6. At higher temperature region, i. e. in the disordered state, all the specimens except cadmium have the tendency that the thermoelectric power de-

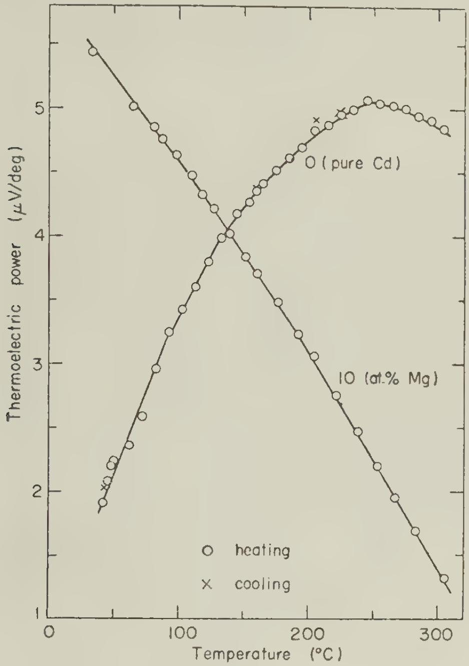

Fig. 2.

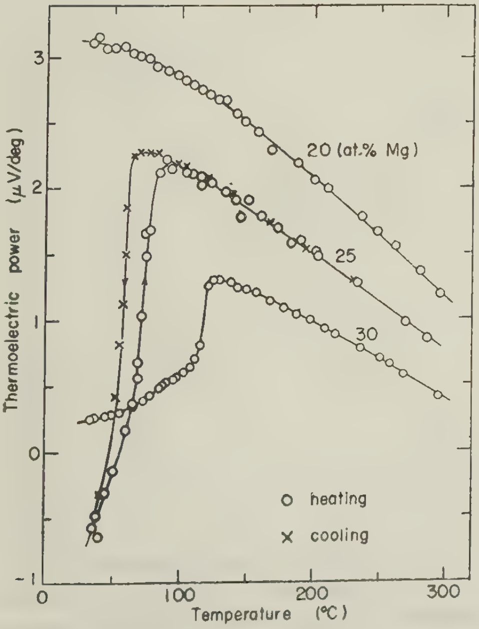

Fig. 3.

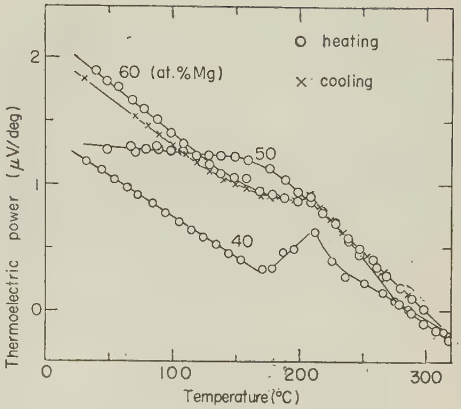

Fig. 4.

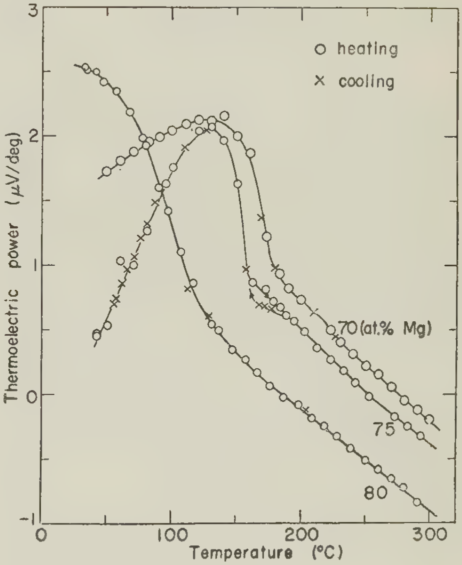

Fig. 5.

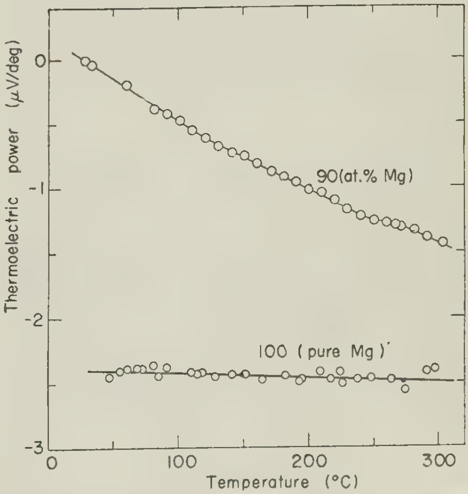

Fig. 2–6. The thermoelectric power relative to copper as a function of temperature.

creases with increasing temperature. For cadmium the thermoelectric power shows an anomalous behavior which has a maximum at about 250°C.

For the ordered phases, the temperature dependence is more complicated than that for the disordered phase. The thermoelectric power increases with increasing temperatures for both ordered phases, $MgCd_3$ and Mg_3Cd, while for MaCd its thermoelectric power appears to decrease with elevating temperature.

§ 4. Discussion and Conclusions

The magnesium forms the substitutional solid solution with the cadmium in any compositions at high temperatures. Although magnesium and cadmium are both divalent metals, each axial ratios are 1.6235 and 1.885 at 310°C, respectively. It has been found by Hume-Rothery and Raynor that the axial-ratio of the alloys of both metals shows a monotonic and continuous change with composition. The lattice-spacing relation has been interpreted in terms of the electronic structure and the sizes of their constituent atoms. As for the variation of the electronic structure is concerned, however, the measurements of the electrical properties are more suitable than the lattice parameter is. In the earlier work[1], we observed the concentration dependence of the Hall coefficient in order to study the electronic structure of magnesium-cadmium alloys. The Hall effect measurements show that most of the results agree with those given by the lattice-spacing measurements. There are some disagreements, however, between them if we study in detail. The present work is done in order to obtain further informations about the overlaps and the holes.

The first Brillouin zone of a hexagonal close-packed structure can contain just two electrons per atom, and the alloys in this system have two conduction electrons per atom. Therefore, we may consider that the number of electrons in the overlaps and of holes are relatively small and they will behave as free electrons. So we can write the thermoelectric power of this system as follows[8]

$$S=\sum_i \sigma_i S_i / \sum_i \sigma_i \,, \tag{1}$$

where σ_i is conductivity, S_i is the thermoelectric power when only the band i is presented in the system and i refers the species of band. In order to interpret the results of Hall measurements obtained by us we have assumed that there are two overlaps and two holes. These overlaps and holes may contain less carriers than a quarter per atom, therefore the relaxation times of them have such a dependence as $\tau=\tau_0 E^{-1/2}$, τ_0 is independent of the energy. If such a dependence and the standard form of bands are assumed, it can be expressed as

$$\begin{aligned}\sigma_i S_i &= \alpha_i (n_i e^2 \tau_i / m_i^*)(\pi^2 k^2 T / 3e\zeta_i) \\ &= \alpha_i e \pi^2 k^2 T C_i \tau_{i0} / 3m_i^* \,, \end{aligned} \tag{2}$$

where n is the number of carriers and n_i is given as $C_i^{3/2}\,\zeta_i$, ζ is the Fermi energy, and α is the dimensionless constant being -1 for a normal band and $+1$ for an inverted one. C_i is an energy-independent parameter. The other symbols have their ordinary meanings. The equation (2) indicates that $\sigma_i S_i$ is independent of the Fermi energy of the band i. In other word, the term $\sigma_i S_i$ becomes to be independent of the number of carriers, the number being changed by alloying[8].

As a fact, the resultant thermoelectric power would be proportional to the total resistivity[10]. This provisional composition-dependence, however, is quite different from the

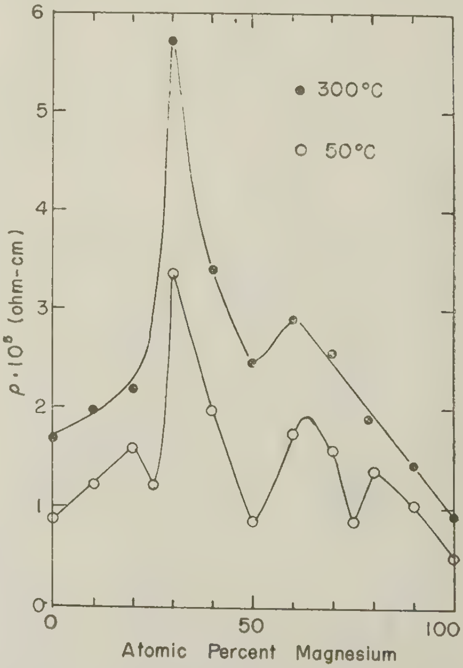

Fig. 7. The concentration dependence of electrical resistance in Mg-Cd alloys. (After Grube and Schiedt.)

observed one as compared with Fig. 7. This difference may indicate that either of our assumptions is wrong. Since the assumption that all the carriers behave as nearly free electrons is allowed for a band possesing small number of carriers, the another assumption that there exist only four bands, α, β, γ and δ, should be corrected. Then, let us try to find any other band in the alloys by which we can explain the present results. The first Brillouin zone of the close-packed hexagonal structure is shown in Fig. 8. For electron moving in all directions, there is an energy discontinuity across the A-faces in the figure, except the edges of the faces, such as PQ and QR. The Brillouin zone shown in the figure is the smallest volume in k-space surrounded everywhere by an energy discontinuity for electrons moving in all directions. It is called the complete zone. With the subtraction of the small truncated prisms from the complete zone, we can get the so-called incomplete zone. One of the truncated prisms is shown in the figure by dotted lines. There may exist an overlap from the incomplete zone across the A-faces into the truncated prisms.

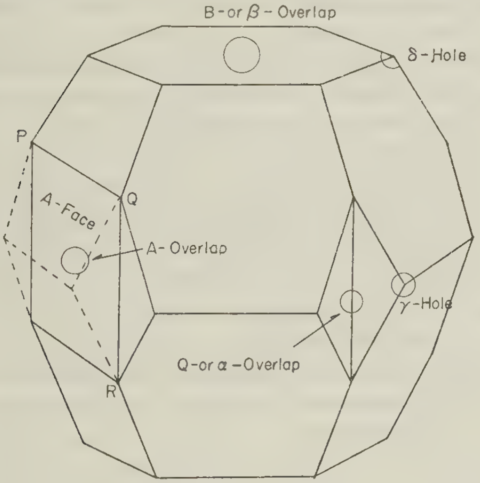

Fig. 8. The first Brillouin zone of h.c.p. structure.

The overlap will be termed the A-overlap. By taking into account this overlap, we will qualitatively explain the present experimental results.

The relation between the state density and energy in A-overlap is shown in Fig. 9. If the Fermi level in this overlap passes from L to M with increase of magnesium contents, we will expect the actual concentration dependence[18]. If we concern with only the variation of axial ratio, the movement of Fermi level should occur in the opposite direction as suggested by Hume-Rothery and Raynor. However, we can interpret this situation by the fact that the energy gap at A-face will be changed with alloying.

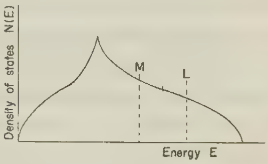

Fig. 9. The assumed energy density of A-overlap.

Let us consider the initiation and extinction of bands in this system. Mott and Jones expected that there exist A- and B-overlaps in cadmium and A- and Q-overlaps in magnesium by their calculation[11]. If this conclusion is true, the Q-overlap will extinct and the B overlap will initiate at some compositions when the concentration of cadimum increase from pure magnesium. If it is assumed that the initiating or extincting bands are normal form, the initiation or extinction gives rise to a discontinuous change in the thermoelectric power of the system[8,9]. From our results such a discontinuity can not be detected. Therefore, there are no evidence of the initiation or extinction of bands in the whole ranges of concentration.

The influence of ordering formation on the thermoelectric power also will be discussed. The Hall measurement shows the following results: In all the super-lattice alloys in this system their Hall coefficients are increased by the formation of order[7]. As given in the preceding section, however, the variation of thermoelectric power in the order-disorder transition is not so simple. When ordered states are destroyed near transition temperature, a decrease of the thermoelectric power is observed in the cases of Mg_3Cd and MgCd, but an increase for $MgCd_3$.

The variation of the Hall coefficient has been interpreted in terms of newly formed Brillouin zones being established by the formation of ordered state. Such a disagrement between the Hall coefficient and the thermoelectric power in the tendency of the variation by the transition may be interpreted by considering the following factor: The *A*-overlap will make an important role for the thermoelectric power than for the Hall coefficient, because all the bands in these alloys except *A*-overlap may be supposed that they posses the standard form and considerably small numbers of carriers. The both ordered structures, Mg_3Cd and $MgCd_3$, are hexagonal close packed but their lattice parameters and axial ratios are of course different from those of the disordered structures. In MgCd, the structure makes a slight deformation into a orthorohombic structure by the formation of order[12]. These variations of the structure may give inevitably rise to the variations of Brillouin zone boundaries and of the energy gaps across the zone boundaries[13-15].

The first Brillouin zone of the disordered structure is closely related to the Fermi surface since the magnesium-cadmium alloys are divalent. On the contrary, the Fermi surface of Cu_3Au may be fairly apart from the Brillouin zone boundaries of the disordered structure, but it may be closely related to the boundaries of the ordered structure[16,17]. For such a system, we may conclude that the variation of the transport properties in order-disorder transition is responsible for the interaction between the Fermi surface and the Brillouin zone of the ordered state.

In the case at hand, the Brillouin zone of the disordered structure is in strong interaction with the Fermi surface. When the ordered state is formed, the Brillouin zone which has been formed in the disordered structure is deformed and the energy gap across its zone boundary may be influenced appreciably. These changes will make an important role to the conduction phenomena of these alloys, though the interaction between the newly established Brillouin zone on the formation of ordered state and the Fermi surface will produce an effect. Then it is difficult to say how the Brillouin zone formed by ordering contributes to the physical properties of the alloys in this system.

Resonance Transfer of Ionization Energy in Semiconductors*

By Shigeharu KOSHINO

Radiation Center of Osaka Prefecture, Shinke-Cho, Sakai, Osaka

and Toshihiko ANDO

Department of Physics, Kyoto University, Kyoto

(Received January 11, 1961)

The thermal conductivity of semiconductor due to the resonance transfer of ionization energy of impurity state caused by the interelectronic interaction is calculated in each of three temperature ranges, the extrinsic, the exhaustion and the intrinsic ranges. The obtained conductivity increases exponentially with the temperature in the extrinsic range, but decreases in the exhaustion range. In the intrinsic range it increases again exponentially with the temperature when the temperature is lower than a critical point, but decreases as the temperature increases beyond the critical point. The experimental detection of our conductivity is possible under an appropriate condition in the intrinsic range, while impossible for almost all other cases.

§1. Introduction

It is well known that the thermal energy is transported by electrons as well as by phonons in semiconductors. The former transport is in general essentially analogous to the metalic one, which means that the thermal and the electrical conductivities satisfy the Wiedemann-Franz law. Recently, however, an anomalous thermal conduction which does not satisfy the Wiedemann-Franz law has been observed in several kinds of semiconductor.[1),2)] Because of the inapplicability of the Wiedemann-Franz law the mechanism giving rise to the anomalous conduction will not contribute to the electrical conduction. The exciton conduction and the ambipolar diffusion have been proposed by Joffe[2)] and Prise[3)], respectively. In the present paper we propose the third mechanism, the resonance transfer of ionization energy of impurity state.

Let us first consider two localized donor (or acceptor) states, one of which is occupied by an electron and the other is open. The interelectronic interaction between the trapped electron and a conduction electron can cause the resonance transition in which the trapped electron is excited into the conduction band and the conduction electron is trapped simultaneously by the open donor. This transition transfers the ionization energy of donor state from the latter donor to the former. If there is the temperature difference between the two donor states, the net current of ionization energy is produced. This process will be formulated in the next section.

When the temperature gradient is present in the sample, the resonance transfer of ionization energy between every two donors produces the net current of the thermal energy throughout the sample. We shall discuss how to formulate the thermal conductivity in §3. The calculation of matrix elements will be performed with the neglect of their dependence on the wave number of electron and the thermal conductivity will be obtained in §4. The explicit formula of thermal conductivity will be obtained in the extrinsic range in §5, in the exhaustion range in §6 and in the intrinsic range in §7. In these sections numerical values for n-Ge and n-InSb will be obtained and it will be shown that our conductivity is hard to be observed in the extrinsic and the exhaustion ranges. In the intrinsic range, however, it can be observed experimentally under an appropriate condition. It is necessary for the observation that the impurity concentration is sufficiently large. When the concentration is so large that the impurity band model is useful, on the other hand, the resonance transfer will be inefficient since it is based on the localization of impurity state.

---

* A short note on this work has been published in J. Phys. Soc. Japan **15** (1960) 1538.

§ 2. Elementally Process

Our discussions will be restricted in n-type semiconductors. Let us first formulate the probability of the resonance transfer of ionization energy between two donors. The resonance transfer is caused by the interelectronic interaction. According to the one-electron approximation method, electronic states are obtained by taking up only an average of the interelectronic Coulomb interaction. The rest part which remains by the substraction of the average field from the true interaction is the perturbation which induce the resonance transition.

Now we assume that the interelectronic interaction is the screened Coulomb type and that the donor state is hydrogen-like. Furthermore, for the simplification, we assume that electronic wave functions in the conduction band are plane waves and the electronic mass is isotropic. The matrix element V of the resonance transition in which an electron in $\boldsymbol{k}$-state is trapped by the donor 1 and the electron which has been trapped by the donor 2 is excited to $\boldsymbol{k}'$-state is given by

$$V=\frac{e^2\alpha^3}{\pi\mathcal{E}}\int\frac{d\tau_1\,d\tau_2}{|\boldsymbol{r}_1-\boldsymbol{r}_2|}\exp\{i\boldsymbol{k}\cdot\boldsymbol{r}_1-i\boldsymbol{k}'\cdot\boldsymbol{r}_2-\beta|\boldsymbol{r}_1-\boldsymbol{r}_2|-\alpha|\boldsymbol{r}_1-\boldsymbol{R}_1|-\alpha|\boldsymbol{r}_2-\boldsymbol{R}_2|\}\,, \tag{1}$$

where $\mathcal{E}$ is the dielectric constant, e the electronic charge, α the modified reciprocal Bohr radius defined by

$$\alpha=m^*e^2/\hbar^2\mathcal{E} \tag{2}$$

and β the screening constant defined by

$$\beta=(4\pi e^2n/kT\mathcal{E})^{1/2}\,. \tag{3}$$

Here m^* is the effective mass of electron, $\hbar$ the Plank constant devided by 2π, k the Boltzmann constant, T the temperature and n the electron concentration in the conduction band.

We assume next that the temperature of the donor state 1 is T_1 and that of the donor 2 is given by

$$Q_1=\frac{1}{(2\pi)^5\hbar}\int(E_0+E)|V|^2f(T_1)\{1-f'(T_2)\}\,g(T_2)\{1-g(T_1)\}\delta(E'-E)\,dk\,dk'\,, \tag{4}$$

where f and g are the distribution function of electrons in the conduction band and in the donor state, respectively, and E_0 is the energy difference between the donor state and the bottom of the conduction band. The inverse thermal current Q_2 is given by (4) in which T_1 and T_2 are replaced by each other. The net thermal current from the donor 1 to the donor 2 is given by Q_1-Q_2. Expanding f and g in power series with respect to $\Delta T=T_1-T_2$ and retaining to the first order terms, we obtain the net thermal current

$$\begin{aligned}Q&=\Delta T\cdot Q'\\&=\Delta T\cdot\frac{1}{(2\pi)^5\hbar}\int(E_0+E)|V|^2\delta(E'-E)\left\{g(1-g)\frac{\partial f}{\partial T}-f(1-f)\frac{\partial g}{\partial T}\right\}dk\,dk'\,.\end{aligned} \tag{5}$$

§ 3. Thermal Conductivity

An electron trapped by a donor interacts with phonons as well as with other electrons. The thermal energy is transported to and from the donor by the electron-phonon interaction from and to the phonon system as well as by the resonance transfer from and to other donors. Let us devide the discussion into three cases: a) the electron-phonon interaction is weaker than the interelectronic interaction, b) the electron-phonon interaction is stronger than the interelectronic interaction while the thermal current due to the phonon conduction is smaller than due to resonance transfer and c) the electron-phonon interaction is stronger than the interelectronic interaction while the thermal current due to the phonon conduction is larger than due to the resonance transfer.

In the first case the temperature of the donor electron is in large part governed by the thermal current due to the resonance transfer and the thermal conductivity may be calculated independently within the electron system neglecting the electron-phonon interaction. In the second case it is expected that the donor electron is in thermal equilibrium with the local phonon system as far as phonons are in the internal local equilibrium. The temperature is governed by the thermal current due to the resonance transfer, which is similar to the first case. The difference of this case from the first one is in the heat capacity of the donor electron. In the last case the temperature of the donor electron is in large part governed by the phonon current. If the temperature at every donor position is known from the phonon current, the thermal current due to the resonance transfer can be calculated in principle. In every case we encounter the difficulty which results from the random distribution of donor. In the first and the second cases we encounter furthermore another difficulty that the temperature of donor is not independent of the thermal current. In order to avoid these difficulties, we assume that the position probability of every donor is uniform and that the temperature gradient is uniform and every donor electron is in the local equilibrium.

Let us now imagine a plane which is perpendicular to the temperature gradient in the sample. The thermal conductivity may be given by the total net thermal current through the plane devided by the area of the plane and by the temperature gradient. By the perpendicular plane the sample is devided into two parts, the higher and the lower temperature parts. We choose then a donor in the higher temperature part. The distance of the donor from the plane is denoted by a. We specify the position of every donor in the lower temperature part by using the spherical coordinate system, the origin of which is the donor chosen in the higher temperature part and the basic axis is vertical to the plane. The temperature difference between the origin donor and a lower temperature donor, the position of which is (R, θ, φ), is given by

$$\Delta T = R\cos\theta (dT/da)\,. \tag{6}$$

Inserting the relation (6) into Eq. (5), multiplying by the donor density N and integrating over the position of the lower temperature donor within the whole volume of the lower temperature part, we obtain the total net thermal current from the donor chosen in the higher temperature part to the lower temperature part beyond the perpendicular plane

$$2\pi N(dT/na)\int_a^\infty\int^{\cos^{-1}(a/R)} Q'\cos\theta\sin\theta\, d\theta\, R^3\, dR\,. \tag{7}$$

Integrating (7) over the position of the higher temperature donor within the whole volume of a cylinder, the axis of which is parallel to the temperature gradient and the cross section is so large that the surface effect is negligible, multiplying by the density of donor, deviding by the area of the cross section of the cylinder and by the temperature gradient, we obtain the thermal conductivity due to the resonance transfer

$$\kappa = 2\pi N^2\int_0^\infty\int_a^\infty\int_0^{\cos^{-1}(a/R)} Q'\cos\theta\sin\theta\, d\theta\, R^3\, dR\, da\,. \tag{8}$$

§ 4. Matrix Element

In the proceeding section we have obtained the formal expression (8) for the thermal conductivity. In order to calculate the integral (8) we must obtain the explicit formula of the matrix element (1). The integral (1) cannot be calculated analytically. Let us neglect $\boldsymbol{k}$ and $\boldsymbol{k}'$ in the integrand of (1) in order proceed the analytical calculation. The neglect of $\boldsymbol{k}$ and $\boldsymbol{k}'$ corresponds to the replacement of every matrix element by that of the process in which one electron is transferred to and the other electron is transferred from the bottom of the conduction band. In this approximation we obtain the matrix element

$$V=-(4\pi e^2/\mathcal{E})F(R)\,, \tag{9}$$

where

$$F(R)=\{\alpha/(\alpha^2-\beta^2)R\}\{C_1(e^{-\alpha R}-e^{-\beta R})+e^{-\alpha R}(C_2R+C_3R^2+(\alpha/3)R^3\}\,. \tag{10}$$

Here R is the distance between the two donors, and

$$C_1=(2\alpha)^4/(\alpha^2-\beta^2)^3\,, \qquad C_2=(11\alpha^4-4\alpha^2\beta^2+\beta^4)/\alpha(\alpha^2-\beta^2)^2$$

and

$$C_3=(3\alpha^2-\beta^2)/(\alpha^2-\beta^2)\,.$$

Inserting the matrix element (9) into Eq. (5), we obtain

$$Q'=(16m^{*3}e^4k/\pi\hbar^7\mathcal{E}^2)\,g(1-g)IF(R)^2\,, \tag{11}$$

where

$$I=\int_0^\infty(E_0+kTx)^2f(1-f)x\,dx\,. \tag{12}$$

The thermal conductivity (8) is then reduced to

$$\kappa=(16m^{*3}e^4k/\pi\hbar^7\mathcal{E}^2)N^2g(1-g)IJ\,, \tag{13}$$

where

$$J=\pi\int_0^\infty\int_a^\infty F(R)^2(1-a^2/R^2)R^3\,dR\,da\,.$$

Inserting Eq. (10) into the integrand of the above equation, we obtain

$$\begin{aligned}J=\{\pi\alpha^2/(\alpha^2-\beta^2)^2\}[&(C_1{}^2/8)\{\alpha^{-3}+\beta^{-3}-16(\alpha+\beta)^{-3}\}\\&+(C_1C_2/2)\{\alpha^{-4}-16(\alpha+\beta)^{-4}\}+(1/2\alpha^5)\{C_2{}^2+2C_1C_3\}\\&-32C_1C_3/(\alpha+\beta)^5+(5/2\alpha^6)\{(\alpha/3)C_1+C_2C_3\}\\&-\{160\alpha/3(\alpha+\beta)^6\}C_1+(15/4\alpha^7)\{C_3{}^2+(2\alpha/3)C_2\}\\&+35C_3/4\alpha^7+35/6\alpha^7]\,,\end{aligned} \tag{14}$$

where $\int_a^\infty\exp(-2\beta R)\,dR/R$ has been replaced by $(1/2\beta a)\exp(-2\beta a)$. Eq. (14) is asymptotically reduced to

$$J=\begin{cases}2^5\pi/\alpha^6\beta^3 & (\alpha\gg\beta)\,,\\ 143\pi/6\alpha^5\beta^4 & (\alpha\ll\beta)\,.\end{cases}$$

Asymptotic expressions for the thermal conductivity are then given by

$$\kappa=\begin{cases}(2^9m^{*3}e^4k/\hbar^7\mathcal{E}^2\alpha^6\beta^3)N^2g(1-g)I & (\alpha\gg\beta)\,, & (15)\\ (1144m^{*3}e^4k/3\hbar^7\mathcal{E}^2\alpha^5\beta^4)N^2g(1-g)I & (\alpha\ll\beta)\,. & (16)\end{cases}$$

From Eqs. (2) and (3) the condition $\alpha\gg\beta$ is reduced to

$$n/T\ll1.7\times10^{18}(m^*/m)^2/\mathcal{E}\,. \tag{17}$$

§ 5. Extrinsic Range

It is convenient to divide the discussion into three cases corresponding to the three temperature ranges, the extrinsic, the exhaustion and the intrinsic ranges. At sufficiently low temperature conduction electrons are supplied by donors and the electron distribution in the conduction band may be given by

$$f=(N/2A)^{1/2}\exp\{-(2E+E_0)/2kT\}\,,$$

where

$$A=2(m^*kT/2\pi\hbar^2)^{3/2}\ .$$

The probability of the exsistence of electron in the donor state and the concentration of conduction electron may be given by

$$g=1-(A/2N)^{1/2}\exp\{-E_0/2kT\}$$

and

$$n=(AN/2)^{1/2}\exp\{-E_0/2kT\}\ ,$$

respectively. It is obvious that the Bohr radius is much smaller than the screening radius at low temperature. In fact the condition (17) is reduced to

$$T^{-1/4}e^{-E_0/2kT}\ll 3.3\times 10^{10}(m^*/m)^{5/4}/\mathcal{E}N^{1/2}$$

at low temperature. It is noted that our discussion is restricted to the case of the low donor concentration since the donor electron has been assumed to be well localized. Then the thermal conductivity may be expressed by the asymptotic equation (15). We obtain

$$\kappa=9.5\times 10^{-2}(m/m^*)^{33/8}\mathcal{E}^{11/2}N^{5/4}T^{3/8}(E_0^2+4E_0kT+6k^2T^2)\exp\{-E_0/kT\}$$
$$\text{erg/cm-sec-degree}\ . \qquad (18)$$

It is noted that the temperature dependence of the thermal conductivity is influenced strongly by the temperature dependence of the screening constant. The thermal conductivity (18) is much smaller than the conductivity due to the phonon current.

§ 6. Exhaustion Range

The exhaustion of the donor electron occurs in general at sufficiently high temperature which is even lower than the intrinsic temperature. If the electron concentration in the conduction band is not so large, the distribution of conduction electron may be given by the Boltzmann distribution

$$f=(N/A)\exp\{-E/kT\}\ .$$

The occupation probability of donor state is then given by

$$g=(2N/A)\exp\{E_0/kT\}\ ,$$

and also it may be assumed that the electron concentration in the conduction band is equal to the donor concentration.

If $\alpha\gg\beta$, we obtain the thermal conductivity

$$\kappa=7.7\times 10^{-25}(E_0^2+4E_0kT+6k^2T^2)\mathcal{E}^{11/2}(m/m^*)^6N^{5/2}T^{-3/2}\exp\{E_0/kT\}$$
$$\text{erg/cm-sec-degree}\ . \qquad (19)$$

It is noted that the thermal conductivity (19) decreases as the temperature increases. The condition $\alpha\gg\beta$ is reduced to

$$T\gg 6\times 10^{-19}\mathcal{E}(m/m^*)^2N\ ,$$

which is usually satisfied. The thermal conductivity (19) is reduced to

$$\kappa=2.8\times 10^{-49}(1+3.5\times 10^{-2}T+4.5\times 10^{-4}T^2)N^{5/2}T^{-3/2}e^{116/T}\qquad \text{cal/cm-sec-degree} \qquad (20)$$

for n-Ge, where we have assumed $m/m^*=5$, $\mathcal{E}=16$ and $E_0=0.01$ ev., and

$$\kappa=4.5\times 10^{-44}(1+0.35T+0.046T^2)N^{5/2}T^{-3/2}e^{11.6/T}\qquad \text{cal/cm-sec-degree} \qquad (21)$$

for n-InSb, where we have assumed $m/m^*=50$, $\varepsilon=16.8$ and $E_0=0.001$ ev. The thermal conductivity (20) is always smaller than the conductivity due to the phonon current in Ge. The thermal conductivity (21) is also generally smaller for InSb, but it may be detectable experimentally when the concentration of donor is of the order of 10^{16}.

§ 6. Intrinsic Range

Conduction electrons excited from the valence band are important at sufficiently high temperature. When the electron concentration in the conduction band is governed by the interband excitation, the distribution function may be given by

$$f=(m'/m^*)^{3/4}\exp\{-(2E+E_1)/2kT\}\ ,$$

where m' is the effective mass of hole in the valence band and E_1 is the energy width of the forbidden band. The occupation probability of donor state is also given by

$$g=2(m'/m^*)^{3/4}\exp\{-(E_1-2E_0)/2kT\}\ .$$

The concentration of donor electron may be given by

$$n=(m'/m^*)^{3/4}A\exp\{-E_1/2kT\}$$

We obtain the thermal conductivity

$$\kappa=7.4\times10^{-45}(m'/m^*)^{3/8}(m/m^*)^{21/4}\varepsilon^{11/2}T^{5/4}N^2\exp\{-(E_1-4E_0)/4kT\}\quad \text{erg/cm-sec-degree}\ , \tag{22}$$

provided $\alpha\gg\beta$, and also

$$\kappa=1.3\times10^{-42}(m/m^*)^5\varepsilon^5N^2T\exp\{E_0/kT\}\qquad \text{erg/cm-sec-degree}\ , \tag{23}$$

provided $\alpha\ll\beta$. It is concluded that the thermal conductivity due to the resonance transfer increases exponentially with the temperature when the temperature is much lower than the critical point T_c. The temperature T_c is defined by the relation $\alpha=\beta$, which is

$$T_c^{1/2}\exp(-E_1/2kT_c)=3.5\times10^2(m^*/m')^{3/4}(m^*/m)^{1/2}/\varepsilon\ .$$

For n-Ge we obtain

$$\kappa=5.1\times10^{-42}\,T^{5/4}N^2e^{-2200/T}\qquad \text{cal/cm-sec-degree}\ , \tag{24}$$

when $T<T_1$, and

$$\kappa=1.0\times10^{-49}\,TN^2e^{116/T}\qquad \text{cal/cm-sec-degree}\ , \tag{25}$$

when $T>T_1$, where T_1 is nearly equal to 2000°K. For n-InSb we obtain

$$\kappa=1.1\times10^{-36}\,T^{5/4}N^2e^{-780/T}\qquad \text{cal/cm-sec-degree}\ , \tag{26}$$

when $T<T_2$, and

$$\kappa=1.5\times10^{-35}\,TN^2e^{12/T}\qquad \text{cal/cm-sec-degree}\ , \tag{27}$$

when $T>T_2$, where T_2 is nearly equal to 500°K. From (24) it is expected that the thermal conductivity due to the resonance transfer can be observed in n-Ge samples in which the donor concentration is of the order of 10^{17} or 10^{18}, when the temperature is near 10^3 °K. The thermal conductivity (26) for n-InSb is almost consistent with Busch's experimental data provided the magnitude of N is of the order of 10^{15}.

As shown above, the thermal conduction due to the resonance transfer of ionization energy is a delicate phenomenon because of the dependence on the impurity concentration. It cannot be observed unless the impurity concentration is large. When the concentration is too large, on the other hand, it also cannot be observed because of the violation of the localization of impurity state.

§ 8. Discussions

We have obtained the thermal conductivity due to the resonance transfer of ionization energy in the extrinsic, the exhaustion and the intrinsic ranges. The obtained conductivity increases exponentially with the temperature in the extrinsic range, but it decreases in the exhaustion range. In the intrinsic range it increases again exponentially with the temperature when the temperature is lower than the critical point. As the temperature increases beyond the critical point, the obtained conductivity decreases.

The magnitude of our conductivity is much smaller than the phonon conductivity in the extrinsic range. In the intrinsic range, on the other hand, our conductivity can be observed experimentally under an appropriate condition which is, for example, the donor concentration of the order of 10^{15} for InSb and 10^{17} or 10^{18} for Ge. In the exhaustion range the observation will be possible for InSb which contains donor of the order of 10^{16}, but impossible for Ge.

The temperature dependence of the obtained conductivity is strongly dependent on the temperature dependence of the screening constant as is obvious from Eqs. (15) and (16). The β-dependence of Eqs. (15) or (16) results from our approximation, the neglect of the dependence of the matrix element (1) on the wave number of electron. If we calculated the matrix element (1) rigorously, we should obtain a somewhat different type of the β-dependence and then a somewhat different dependence of the thermal conductivity. Our calculation is only useful in the lowest approximation.

In the calculation of the thermal conductivity in § 3, we have assumed that donors are distributed quite at random and that the temperature gradient is uniform and every donor electron is in the local equilibrium. These assumptions are inevitable for us since we have no information on the donor distribution.

Ferroelectricity in (K, NH_4), (K, Rb) and (K, Tl) Ferrocyanide Mixed Crystals

By Shigeru WAKU, Kunio Masuno and Toshisuke TANAKA

Electrical Communication Laboratory, Nippon Telegraph and Telephon Public Corporation, Kichijoji, Musashino-shi, Tokyo

(Received January 21, 1961)

Substitutions of potassium ion in potassium ferrocyanide by the other mono-valent positive ions were examined. Substituents to give isomorphous ferroelectric substances through replacing some part of the K ion were found to be NH_4, Rb and Tl ions respectively. The peak of the dielectric constant versus temperature curves shifts to the low temperature side by increasing the amount of these substituents. Substituted compounds containing relatively small amount of these substituents show ferroelectric behavior similar to that of potassium ferrocyanide trihydrate.

§ 1. Introduction

In the previous papers[1),2),3)], we reported the ferroelectric behavior in potassium ferrocyanide trihydrate, $K_4Fe(CN)_6 \cdot 3H_2O$, and its isomorphous substances obtained through replacing the Fe ion by Ru, Os and Mn ions, and H_2O by D_2O. These substances crystallize with monoclinic symmetry, of which crystal class is $C_{2}h$ and space group is C_2/c at room temperature. The ferroelectric axis lies in $[1\bar{0}1]$ direction.

Subsequently, we have attempted to substitute some part of the K ion of potassium ferrocyanide trihydrate by the other monovalent ions to obtain new isomorphous ferroelectric substances.

§ 2. Preparation of the Samples

Mixed crystals were grown by the slow cooling of mother solutions, which had been Prepared beforehand by dissolving monovalent ion ferrocyanide and potassium ferrocyanide in various proportions. The preparation of monovalent ion ferrocyanide was done by mixing hydroxide of the corresponding ion and hydrogen ferrocyanide in the molecular ratio of 4:1. Mono-valent substituents to be examined were NH_4, Li, Na, Rb, Cs, Tl, CH_3NH_3, $C_2H_5NH_3$, NH_2NH_3, and NH_3OH. Among these substituents, NH_4, Rb, and Tl ions gave the isomorphous ferroelectric mixed crystals.

The mixed crystals were cut perpendicular to the cleavage plane (010) and silver-painted to measure the electric properties. The dielectric constant was measured by the tuning method in 1 MC. The hysteresis loop in 50 cps was measured by the ordinary Sawyer-Tower's circuit.

§ 3. Experimental Results

(1) *Relation between the composition of mother solution and that of the mixed crystal obtained*

The ammonium content in the mixed crystals is determined by the colorimetric analysis using Nesslar's reagent. The thallium content is determined by the gravimetric analysis in the form of TlCl. In the case of the Rb ion, however, we have failed to obtain the Rb content, because the flame photometric analysis was confused by the spectrum of K ion.

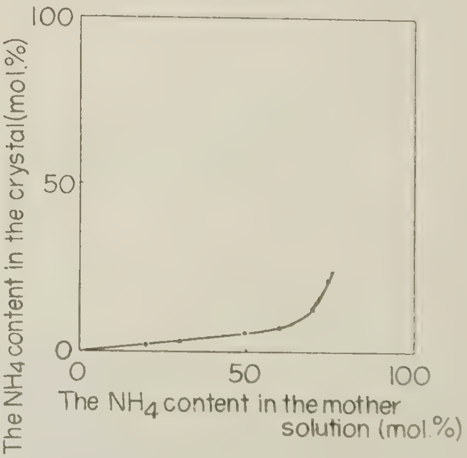

Fig. 1. Relation between the compositions of the mother solution and the obtained crystal in the case of the $(K, NH_4)_4Fe(CN)_6 \cdot 3H_2O$ type mixed crystals.

Figs. 1 and 2 show the relations between the compositions of mother solution and the obtained crystal. The composition of the grown crystal shows a considerably large deviation from that of the mother solution.

(2) *Dielectric behavior*

Figs. 3, 4 and 5 show the small signal dielectric constant versus temperature curves of these mixed crystals, having various molar percentages of the substitution ions. In the case of (Rb, K) mixed crystal, the amount of Rb ion in the mother solution is indicated, as the analysis of the crystals was not performed. The peak height and sharpness of these curves at the dielectric anomaly decrease with the increasing content of replacing ions. Figs. 6, 7 and 8 show the relation between the Curie temperature and the amount of substituting

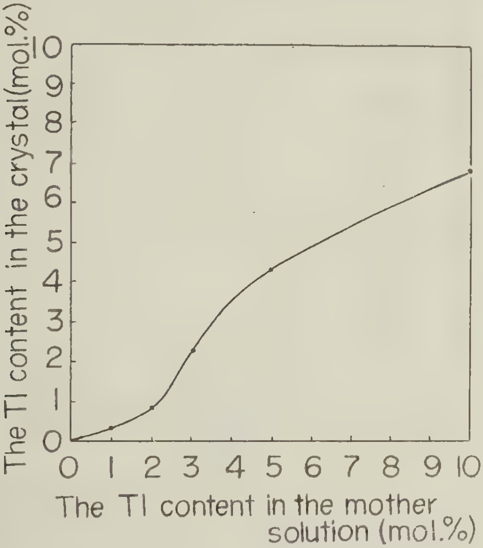

Fig. 2. Relation between the compositions of the mother solution and the obtained crystal in the case of the $(K, Tl)_4Fe(CN)_6 \cdot 3H_2O$ type mixed crystals.

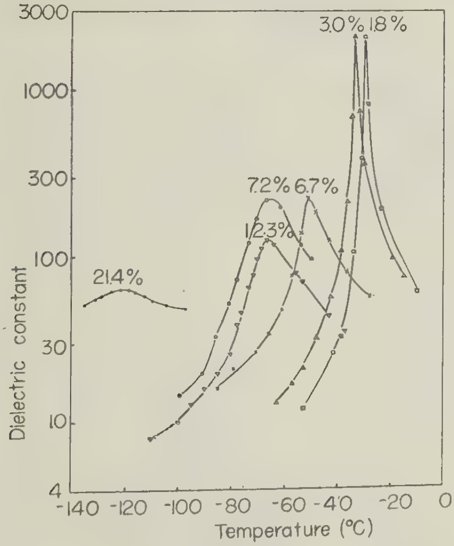

Fig. 3. Dielectric constant versus temperature curves of the $(K, NH_4)_4Fe(CN)_6 \cdot 3H_2O$ type mixed crystals in the [10$\bar{1}$] direction.

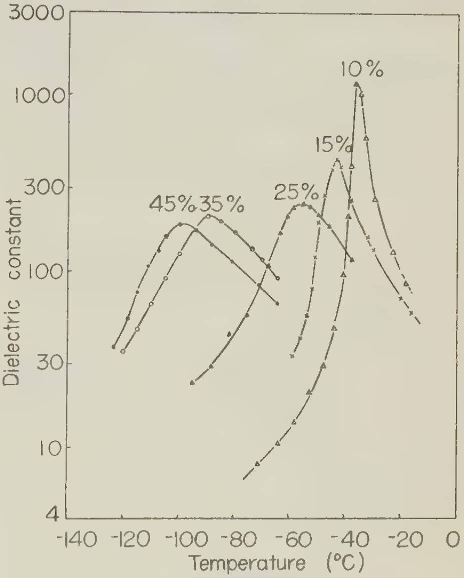

Fig. 4. Dielectric constant versus temperature curves of the $(K, Rb)_4Fe(CN)_6 \cdot 3H_2O$ type mixed crystals in the [10$\bar{1}$] direction.

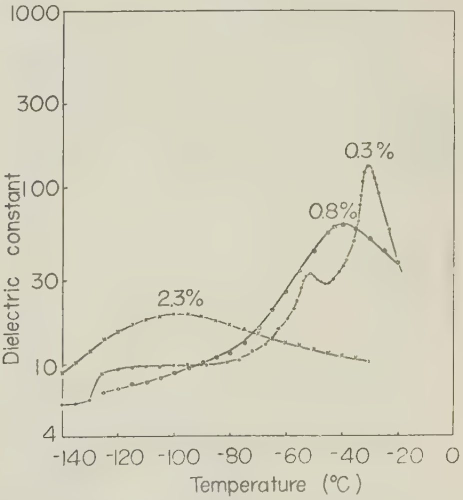

Fig. 5. Dielectric constant versus temperature curves of the $(K, Tl)_4Fe(CN)_6 \cdot 3H_2O$ type mixed crystals in the [10$\bar{1}$] direction.

ions in these three cases, respectively. A linear relation holds approximately in each case.

(3) *Ferroelectric behavior*

Ferroelectric properties of these mixed crystals disappear for relatively small content of the substituting ions. Figs. 9 and 10 show the temperature dependencies of the spontaneous polarization Ps and coercive field Ec of (Rb, K) and (NH_4, K) ferrocyanide, respectively. The ferroelectric hysteresis loop disappears or can be observed only slightly for the replacing ion contents higher than 5% for NH_4 ion, 15% for Rb ion. In the case of the Tl ion, however, hysteresis loop disappears even for very small content of replacing ion. The ferroelectric axis is [$10\bar{1}$] direction similarly to the ordinary potassium salt.

§ 4. Discussion

The ionic radii of K^+, NH_4^+, Rb^+ and Tl^+

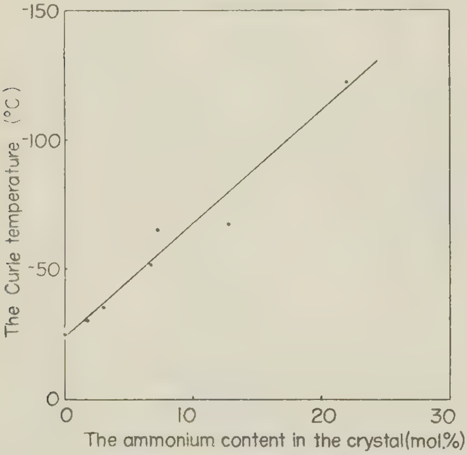

Fig. 6. Relation between the Curie temperature and the content of the replacing NH_4 ion in the case of the $(K, NH_4)_4 \cdot Fe(CN)_6 \cdot 3H_2O$ type mixed crystals.

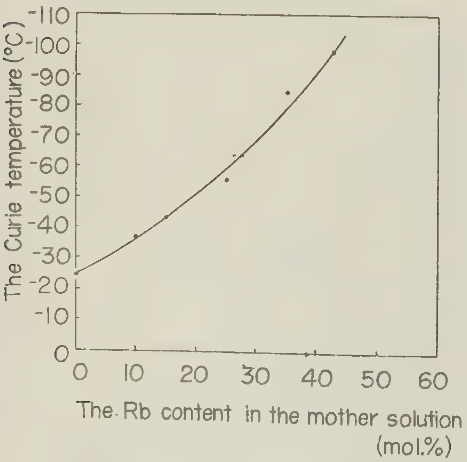

Fig. 7. Relation between the Curie temperature and the content of the replacing Rb ion in the case of the $(K, Rb)_4Fe(CN)_6 \cdot 3H_2O$ type mixed crystals.

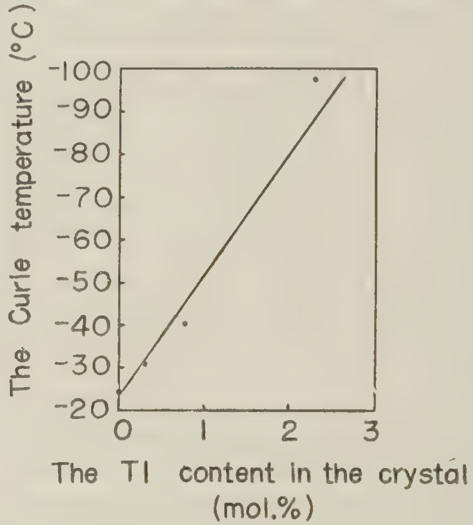

Fig. 8. Relation between the Curie temperature and the content of the replacing Tl ion in the case of the $(K, Tl)_4Fe(CN)_6 \cdot 3H_2O$ type mixed crystals.

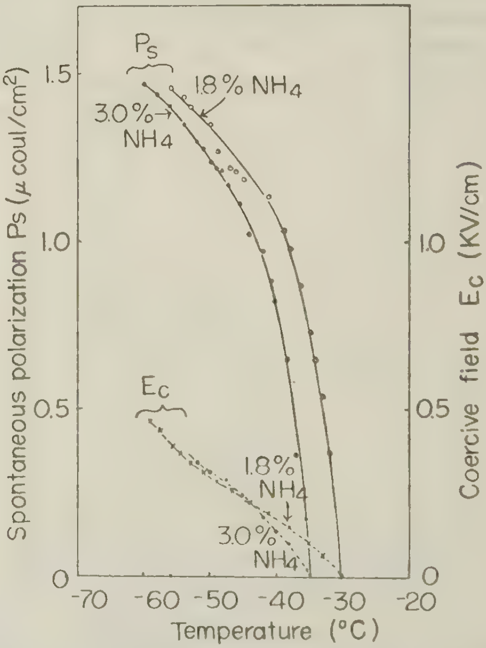

Fig. 9. Spontaneous polarization and coercive field versus temperature curves of the $(K, NH_4)_4Fe(CN)_6 \cdot 3H_2O$ type mixed crystals.

ions are 1.33, 1.59, 1.49 and 1.44Å, respectively. This means that, by substituting some part of the potassium ion in potassium ferrocyanide by the ion having larger ionic radius, the transition point shifts toward the low temperature side. Contrary to this, the ferroelectric transition temperature increases by substituting Fe^{++} ion of potassium ferrocyanide by the divalent ion having larger covalent radius of octahedral coordination[2].

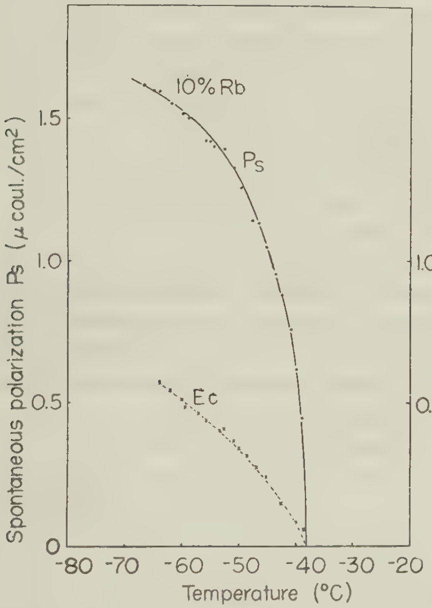

Fig. 10. Spontaneous polarization and coercive field versus temperature curves of the $(K, Rb)_4Fe(CN)_63H_2O$ type mixed crystals.

The peak height and sharpness of dielectric constant versus temperature curve decrease with the increasing content of the substituting ions. As stated before, the ion content in the mother solution and in the grown crystal shows relatively large deviation with each other. For this reason, the grown crystal shows a lamellar structure having gradually segregated concentration of the replacing ion. From the relations such as shown in Figs. 1 and 2, the segregation degree of the substituting ion in the crystal is supposed to increase with increasing concentration of the ion in the mother solution.

Considering the fact that the Curie point of the mixed crystal varies linearly with the concentration of the replacing ion in the crystal, this local change of the concentration can be taken as the reason why the peak height and sharpness of dielectric constant decrease with the increasing content of replacing ion. The ferroelectric hysteresis disappears or can be observed only slightly in these mixed crystals with the relatively small amount of replacing ion. This phenomenon may be explained as follows. The coercive field strength of potassium ferrocyanide group ferroelectrics increases rapidly with decreasing temperature. Consequently, for the mixed crystals with the Curie point varying locally, the domain switching may occur only in the limited region in the crystal having relatively small coercive field strength.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 16, No. 6, JUNE, 1961

The Superstructures of Iron Selenide Fe_7Se_8

By Atsushi OKAZAKI

Department of Physics, Faculty of Science,
Kyusyu University, Fukuoka, Japan

(Received February 4, 1961)

Iron vacancies in Fe_7Se_8 are confined to the alternate iron layers parallel to the c plane of the fundamental lattice with the NiAs structure. The origin of the ferrimagnetism of Fe_7Se_8 (T_c=187°C) may be attributed to this ordered arrangement similarly to the case of Fe_7S_8. There are two types of the superstructure: low- and high-temperature ones. The unit cell dimensions and the lattice symmetries of these structures are as follows:

low-temperature type: $A=\sqrt{3}B$, $B=2a$, $C=4c$, triclinic,
high-temperature type: $A=2a$, $C=3c$, hexagonal,

where the capital and small letters designate the super- and fundamental lattices, respectively. The transition from the triclinic structure to the hexagonal one, which means a rearrangement of the iron vacancies, begins at 240°C, proceeds gradually and finishes at 298°C.

§1. Introduction

The crystal structures and ferrimagnetic properties of iron selenide $FeSe_x$ were investigated by Hägg and Kindström[1] and Hirone, Maeda and Tsuya[2], respectively, with powder specimens. The more detailed investigation on single crystal of $FeSe_x$ system was undertaken by Hirakawa of our laboratory and it was expected that such an investigation would give us some information about the complex structural changes and ferrimagnetic properties of pyrrhotite Fe_7S_8, which had been studied by many researchers. But it was almost impossible to synthesize the single crystal of pyrrhotite.

At the beginning of the present work Fe_7Se_8 and Fe_3Se_4 were found to have superstructures[3] which stimulated our interests. In Fe_7Se_8 the iron vacancies are confined to the alternate c planes of the fundamental lattice with the NiAs structure similarly to those in Fe_7S_8 [4], but the stacking sequences of these planes along the c axis are different for the selenide and the sulphide. That is, if the capital and small letters designate the unit cell dimensions of the super- and fundamental lattices, respectively, $C=3c$ for Fe_7Se_8 and $C=4c$ for Fe_7S_8. Moreover Fe_7Se_8 (strictly speaking, Fe_7Se_8 with $C=3c$) has hexagonal symmetry, although Fe_7S_8 is monoclinic.

The work on the magnetic properties of Fe_7Se_8 by Hirakawa[5] using a torque magnetometer pointed out that the torque curves in the c plane showed a six-fold symmetry as well as small amount of component with a two-fold symmetry. The origin of this component was attributed to a lattice deformation of an undetectable order.

On the other hand, the crystal structure at high temperature was examined by the present author to resolve the following problems:
(1) Whether the superstructure disappears or not at high temperature.
(2) Whether the temperature of the disappearance coincides with Curie temperature T_c(187°C) or not, if the disappearance of the superstructure would be observed. Many specimens obtained from different ingots were examined and the results were reported shortly[6] as follows: the crystals cooled down slowly to room temperature have a superstructure with $C=4c$ (triclinic symmetry) and is very similar to that of Fe_7S_8 [4] except for the lattice symmetry. With increasing temperature from 240 to 298°C the superstructure transfers gradually to that with $C=3c$.

In the present paper the experimental and analytical details of the X-ray work on these superstructures of Fe_7Se_8 will be described together with some additional experiments to confirm the above results.

§2. Experimental

The preparation of single crystals of Fe_7Se_8 was described in the previous papers[3],[5]. Most of specimens used in the present investigation, however, were prepared by an improved method. That is, iron rods (Johnson-Matthey) were used instead of electrolytic iron powder and the reaction with selenium was performed in an evacuated silica tube by induction heating. An additional heat treatment to obtain single crystals was similar to that of the original method.

At room temperature oscillation and rotation photographs with Co*Kα* radiation were obtained by using a cylindrical camera, the diameter being 10 cm. Above room temperature these photographs were obtained by using a high-temperature camera designed and built for the present investigation. Requirements for this camera were as follows: (1) Temperature is to be measurable precisely. (2) Not only an equatorial line but also higher layer lines are to be recorded, if necessary. (3) Successive exposures are to be carried out without disturbing specimen to follow a crystal transformation. (4) To be convenient in operation.

This camera is shown in Figs. 1, 2 and 3, the details being as follows:

Furnace: It is necessary to record the higher layer lines without disturbing the homogeneity of temperature distribution around the specimen. Therefore a cylindrical Ni-foil furnace (0.018 mm thick) described by Dent and Taylor[7] is used. Current of about 20 A (20 W) is sufficient for 400°C. This furnace is durable for more than 40 hours, which is sufficient for one series of experiment. Vertical, lateral and rotational adjustment and exchange of the heater are made easily.

Temperature measurement: A junction of Chromel-Alumel thermocouple (0.3 mm dia.) is placed 1 mm above specimen, not to intercept the X-ray path. The wire of the couple is placed in such a way as shown in Fig. 1 to reduce the effect of thermal conduction through itself. Calibration by melting specimens of In, Sn, Bi, Pb and InSb having similar shape and size to those of Fe_7Se_8 specimen was carried out before and after each run. The difference between true melting point and temperature recorded by the

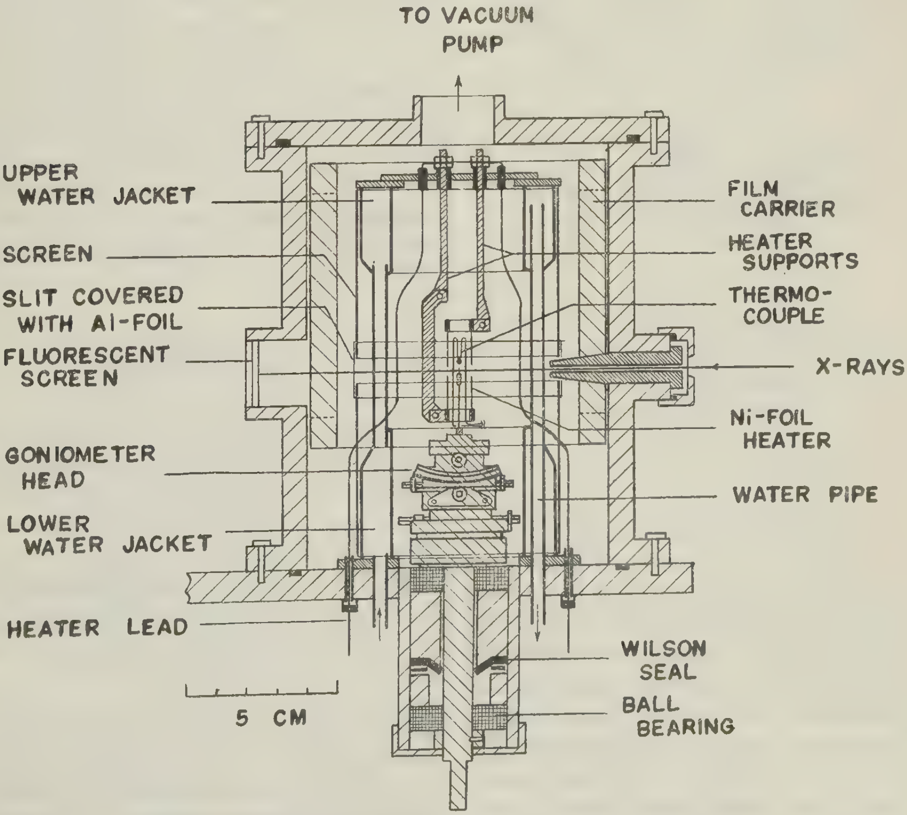

Fig. 1. Main part of the high-temperature camera.

thermocouple was less than 4°C in every specimen and a good linearity between these two temperatures was found in every case. Therefore the accuracy of temperature measurement of specimen after this calibration would be within ±2°C, and the stability of temperature during exposure (less than half an hour) was within ±0.5°C. Another thermocouple (not shown in Fig. 1) could be attached simultaneously, and its junction was placed close to shielding paper of cassette. This thermocouple indicated 10°C higher than room temperature when that of specimen was 400°C.
Atmosphere: Both furnace and camera unit are inside vacuum chamber.

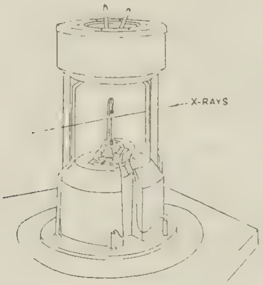

Fig. 2. A sketch of the inside of the camera. Screen and heating element are removed.

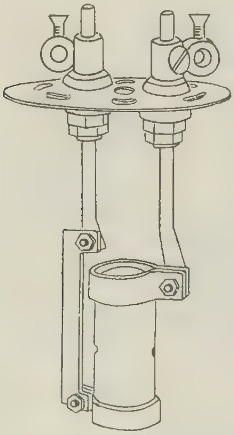

Fig. 3. A sketch of the heating element.

Film mounting: The film carrier with Straumanis-Ieviņš type film mounting, 9 cm in diameter, can be moved axially to give a series of 10 exposures of the equatorial reflexions.
Windows: Inner radiation shield is Al-foil which covers a slit of a cylindrical brass screen wound on upper and lower water jackets. Higher layer reflexions can be recorded by using another screen with a wide slit. A window for X-ray of outer vacuum chamber is Mylar sheet. Shadow of specimen during exposure is observable on a fluorescent screen. Brass pipes connecting the two water jackets, two heater leads juxtaposed to these pipes and one of supporting arms of the heater are placed in the low- and high-angle position, and reflexions with θ between 7.5 and 82.5 degrees are observable.
Specimen: The specimens on which the X-ray work was performed were formed into nearly cylindrical shape, about 1.3 mm in length and about 0.4 mm in diameter, by cutting with a small sawteeth and grinding with sand paper. These were mounted on a quartz fibre support, 15 mm in length and 0.2 mm in diameter by a small amount of potter's clay. Since a movement of arcs of goniometer head was limited to ±6 degrees by the contact of the support with the furnace and with the thermocouple wire, the axis of the specimen was made parallel to the crystallographic axis within ±2 degrees.

So far as a determination of positions of vacancies is concerned, a precise data of intensities are not necessary, if the fundamental structure is well-known. These data must be obtained to determine the displacement of the individual atoms, neighbouring to the vacancies, from the original positions caused by the existence of these vacancies. But this problem will not be mentioned in the present paper. Therefore Weissenberg photographs were taken only subsidiarily at room temperature.

§ 3. Structure Determination

(a) '*4c structure*'

Rotation, oscillation and Weissenberg photographs about each crystallographic axis indicated that Fe_7Se_8 crystallized by slow cooling has a superstructure superposed on the fundamental structure of the NiAs type. If the capital and small letters designate the unit cell dimensions of the super- and fundamental lattices, respectively, this superstructure has the following dimensions:

$$A=\sqrt{3}\,B\,,\quad B=2a\quad \text{and}\quad C=4c\,.$$

This structure will be named as the '4c structure'. Since the pycnometric density is in very good agreement with the calculated value assuming that one eighth of iron sites in the fundamental lattice are vacant, this superstructure may be attributed to an ordered arrangement of iron vacancies. Moreover the (0001) and (0003) reflexions prohibited for the ideal NiAs structure are observed. These suggest that the vacancies are confined to the alternate c planes, where the arrangement as shown in Fig. 4 is reasonable, because the periodicity of this superstructure in the c plane is twice as great as that of the fundamental lattice and one fourth of iron sites must be vacant.

For all the observed reflexions h, k and l are all even or all odd, where the indices are on the basis of the superstructure. Furthermore the ($hk0$) reflexions are observed if $(h+k)/2$ is even, indicating that, if this structure is projected on the C plane, these iron vacancies are at every iron site with equal probability. Therefore the structure as shown in Fig. 5 is the most probable one. 8 vacancies in the unit cell are at the following positions:

$$(0, 0, 0;\ 0, 1/2, 1/2;\ 1/2, 0, 1/2;\ 1/2, 1/2, 0)\ +0, 0, 0;\ 1/4, 1/4, 1/4\ .$$

From another point of view this arrangement resembles the diamond structure and the (hkl) reflexions should be systematically absent unless the following condition besides that for the face-centred lattice is also fulfilled: $h+k+l=2n+1$ or $4n$ (n: integer). This rule is satisfied for all the observed reflexions.

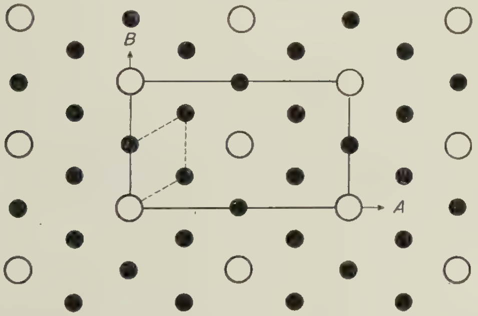

Fig. 4. Ordered arrangement of Fe atoms and vacancies in the alternate metal layer parallel to the c plane. Solid and open circles represent Fe atoms and vacancies, respectively. Unit cells of super- and fundamental lattices are indicated by full and broken lines, respectively.

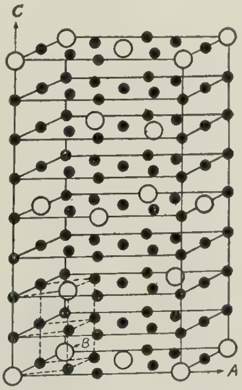

Fig. 5. Unit cell of the '4c structure' of Fe_7Se_8. Open and solid circles represent vacancies and Fe atoms, respectively. Se atoms are omitted for clarity. Broken lines indicate the fundamental unit cell. These notations will be used also in Figs. 6 and 7.

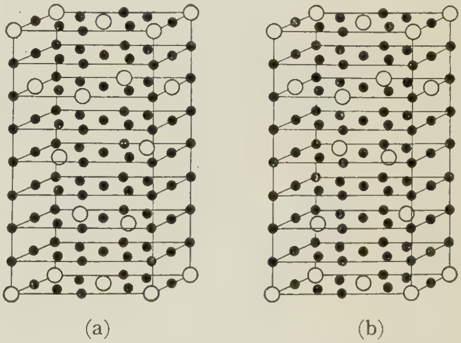

(a) (b)

Fig. 6. Superstructures obtained from that shown in Fig. 5 by turning both the A and B axes around the C axis; (a): through +60 and (b): −60 degrees. (b) is turned upside down for the sake of contrast with (a).

Now, if both the A and B axes are turned around the C axis through +60 and −60 degrees, the superstructures as shown in Figs. 6(a) and 6(b) are obtained, respectively, where (b) is turned upside down for the sake of contrast with (a). The diffraction records of these structures should contain different systematic extinctions which are different also from those of the first structure.

This was proved by turning a specimen around the C axis through 30 degrees successively, by taking oscillation photographs about the A or B axis at every step and by comparing the observed systematic extinctions with those obtained by calculation on the above models, where the maximum numbers of h, k and l are 13, 7 and 25, respectively.

The lattice constants at room temperature are as follows:

$$A=\sqrt{3}\,B=12.53\,,\quad B=2a=7.23_6\ \text{and}\ C=4c=23.5_4\,\text{Å}\,,$$
$$\alpha=89.8^\circ\,,\quad \beta=89.4^\circ\ \text{and}\ \gamma=90.0^\circ\,.$$

Except for the lattice symmetry, the superstructure of Fe_7Se_8 at room temperature is identical to that of natural pyrrhotite Fe_7S_8 described by Bertaut[4]. It was rather difficult to find a specimen of complete single crystal and there are twin structures in general. That is, reflexions corresponding to the three structures as shown in Figs. 5 and 6 are observed frequently on an oscillation photograph.

(b) *'3c structure'*

On the specimen quenched from 320°C another hexagonal superstructure, having the following unit cell dimension, was observed:

$$A=2a\ \text{and}\ C=3c\,.$$

This structure will be named as the '3*c* structure'. For convenience of comparison with the '4*c* structure', the following orthohexagonal cell was chosen throughout the analysis:

$$A=\sqrt{3}\,B\,,\quad B=2a\ \text{and}\ C=3c\,.$$

Similarly to the case of the '4*c* structure', it is found that the iron vacancies are in the alternate *c* planes with the arrangement as shown in Fig. 4.

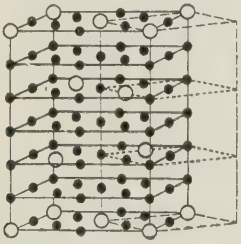

Fig. 7. An orthohexagonal unit cell of the '3*c* structure' of Fe_7Se_8. A hexagonal cell is shown by broken lines.

For all the observed reflexions $h+k$ is even, where the indices are based on the superstructure. One of the possible models is shown in Fig. 7 and this is the most probable*. 6 vacancies in the unit cell are at the following positions:

$$(0,0,0;\ 1/2,1/2,0)$$
$$+0,0,0;\ 1/4,1/4,1/3;\ 1/4,3/4,2/3^{**}\,.$$

This structure is stable even at liquid air temperature. The crystal with this structure is also ferrimagnetic and the Curie temperature is nearly the same as that of the crystal with the '4*c* structure', i.e., 189°C for the former and 187°C for the latter[8].

(c) *Transition from '4c structure' to '3c structure'*

The structural changes at high temperature were examined systematically with eleven specimens cut out from several ingots and the structure of them was examined at room temperature. To obtain information most effectively the axes of these specimens were made parallel to the *B* axis and oscillation photographs with an angular range of 20 degrees about this axis were taken at intervals of 2~10°C.

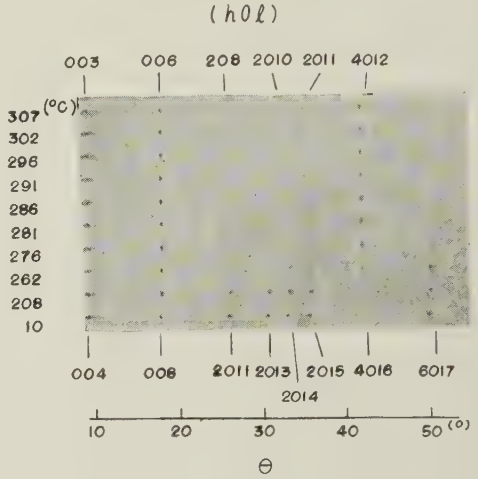

Photo. 1. Oscillation photograph indicating transition from '4*c* structure' to '3*c* structure.' Indices referred to each structure are given at the bottom or top.

At first the transition from the '4*c* structure' to the '3*c* structure' was investigated. An example is shown in Photo. 1. Indices based on the '4*c*' and '3*c*' structures are given at the bottom and the top, respectively. On the pattern of the '4*c* structure', the twin structure described in § 3 (a) is presumable. The intensity of the (008) reflexion which is one of the weakest reflexions from the fundamental lattice is reduced to 1/10 by a filter of metal foil to compare with that of the superstructure pattern, where the indices are given on the basis of the '4*c* structure'. As shown obviously in this photograph this tran-

---

* Details of this analysis have been reported previously[3].

** These positions are described incorrectly in the previous paper[3].

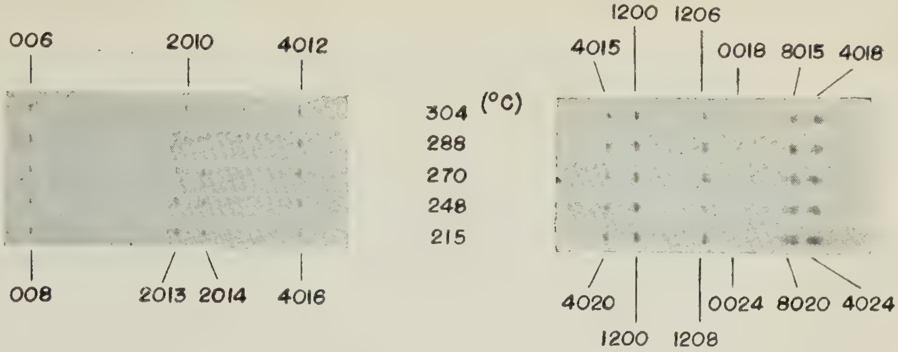

Photo. 2. A part of oscillation (left) and rotation (right) photographs in the temperature range of the '4*c* to 3*c*' transition.

sition proceeds gradually through the temperature range of about 60°C. At the intermediate state the patterns corresponding to both of these structures are observed. As shown in Photo. 2, on rotation photographs taken in this temperature range the splittings of high angle reflexions due to the triclinic deformation of the hexagonal lattice are decreasing gradually and disappear at the temperature where the pattern of the '4*c* structure' disappear on oscillation photograph. The Photo. 2 was obtained by the following procedure: a pair of an oscillation and a rotation photographs with the same specimen were taken successively at each temperature.

This transition which is independent of the magnetic transition from the ferrimagnetic state to the paramagnetic one, begins at 240°C* and finishes at 298°C**. These values are reproducible within ±2°C for specimens prepared from the same raw materials.

The reverse transition from the '3*c* structure' to the '4*c* structure' was difficult to observe in a complete form by the above method. This might be due to oxidation of specimens during exposure at high temperature and was consistent with the fact that crystals prepared from electrolytic iron powder often had the '3*c* structure' at room temperature, even if they were cooled down slowly, because it might be rather difficult to reduce iron powder completely. The reversibility and reproducibility of this transition, however, were proved by another method described in § 4.

Intensity of certain reflexion from the fundamental lattice, for example the (4012) in Photo. 1, changed remarkably with temperature. This suggested that atoms near the iron vacancies changed their positions with temperature. But this problem will not be discussed further.

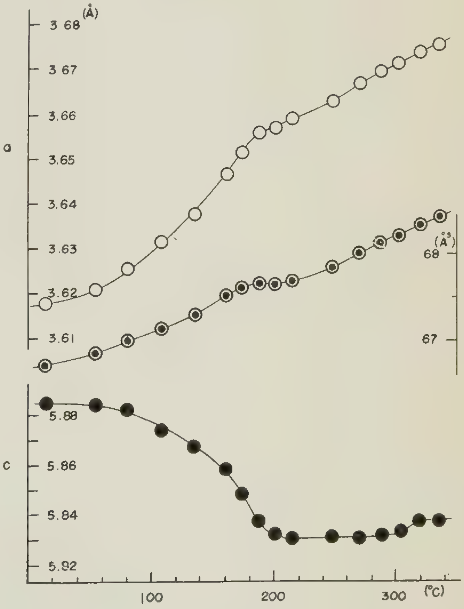

Fig. 8. Lattice constants and volume of the fundamental unit cell of Fe_7Se_8 as a function of temperature.

The lattice constants of the fundamental lattice up to 350°C are shown in Fig. 8. This is in good agreement with the results obtained with a dilatometer[5]. The anomalous behaviour below 190°C is corresponding to the magnetic transition and is observed clearly on the rotation photographs as shown in Photo.

---

*, ** These values for the specimens prepared from electrolytic iron powder were about 302 and 317°C, respectively.

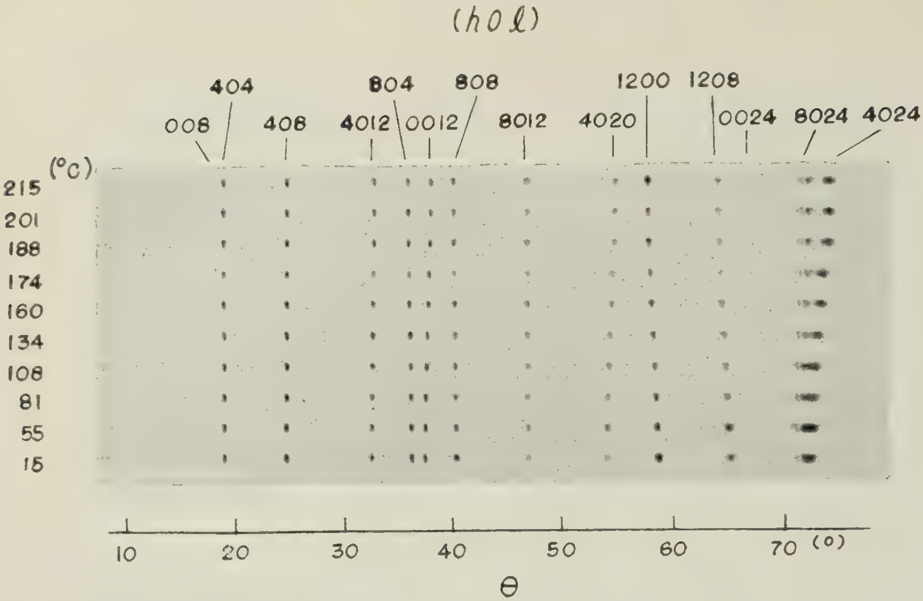

Photo. 3. Rotation photographs displaying an anisotropic thermal expansion below T_c. Indices are given on the basis of the ‘4c structure’.

3[*]. A similar behaviour has been reported by Willis[9] and Snow[10] on CrSb which is antiferromagnetic compound with the NiAs structure. Below the transition the axis of easy magnetization in Fe$_7$Se$_8$[5] and CrSb[10] is parallel and perpendicular to the c plane, respectively. This may be the cause of an opposite behaviour with respect to the a and c axes for these compounds.

(d) *At higher temperature*

The following two types of structural change were observed on the ‘3c structure’ when specimens were heated to higher temperature:

i) ‘$3c \rightarrow 1c$ type’. The transition from the ‘3c structure’ to ‘1c structure’ was observed in the temperature range from 360 to 375°C, which proceeded gradually like that from ‘4c’ to ‘3c’. The term ‘1c structure’ means a partial ordered state in which the iron vacancies remain within the alternate c planes but are distributed at random in these planes. This is concluded from the disappearance of the superstructure reflexions except for the (0003) and (0009) etc. referred to the ‘3c structure’. Such a situation has been reported by Jellinek on Cr$_7$S$_8$[11]. This transition was reversible and reproducible. At about 400°C the distribution of the vacancies became completely disorder.

ii) ‘$3c \rightarrow 2c \rightarrow 1c$ type’. For some specimens an intermediate phase was found between the ‘3c’ and ‘1c’ structures. The diffraction pattern of this intermediate phase could be indexed on the basis of a hexagonal unit cell with $A=2a$ and $C=2c$. Oscillation photographs were taken at 400°C, but the observed extinction rule could not be explained from any arrangement of iron vacancies. The intensities of this ‘2c structure’ were of the order of 1/5 compared with those of the ‘4c’ and ‘3c’ structures. Therefore this structure may be somewhat disorder. The gradual transition from ‘3c’ to ‘2c’ begins at 320°C and finishes at 385°C and the ‘2c structure’ disappears at about 450°C.

To make clear the essential behaviour, the experiments described below were carried out. Specimens with the ‘4c structure’ at room temperature were sealed into evacuated silica tubes, heated up to 450°C and quenched, but the diffraction pattern showed the ‘3c structure’ only. Consequently the reason for these different behaviours at high temperature has been unknown. The ‘2c’ and ‘1c’ structures seemed to accompany oxidation or any other chemical change.

---

[*] The relative intensities of the superlattice reflexions to those of the fundamental ones may be estimated if the (008) reflexion is compared with that in Photo. 1.

§ 4. Additional Experiments

It was found by the experiments described in § 3 (c) that the crystals with the '4*c*' and '3*c*' structures were obtained when they were cooled down slowly and quenched from 320°C, respectively. The experiments with a torque magnetometer by Hirakawa[8)], using crystals to which the heat treatments described above were applied, suggested that the torque curves in the *c* plane for specimens with the '3*c* structure' had no detectable anisotropy, but those for specimens with the '4*c* structure' showed a component of two-fold symmetry superposed on a six-fold one. This fact was confirmed directly by examining the crystal structure of the specimen on which the torque curve was measured. This was carried out as follows: Several disks with the axis parallel to the *c* axis were cut out from crystals quenched from 320°C. The planes of the disks were made flat with sand paper and polished with powder of Cr_2O_3. The torque curves in these planes showed no anisotropy. Oscillation photographs indicated that these had the '3*c* structure.' Then these disks were sealed into an evacuated silica tube and annealed at 290°C and cooled down slowly. Oscillation photographs indicated the '4*c* structure.' The torque curves contained a component of two-fold symmetry superposed on a six-fold one. On the planes of these disks three sets of parallel folds crossing each other at an angle of 60 degrees were observed. These folds might be due to twins and were parallel to the *A* axes. These processes were reversible, and moreover, when these disks were quenched from 275°C, the oscillation photographs showed the patterns of both the '4*c*' and '3*c*' structures coexisting with nearly equal proportion. When these heat treatments were repeated more and more, however, it became difficult to obtain crystals in state of the pure '4*c* structure'. These results are consistent with those described in § 3 (c).

§ 5. Discussion

On some chalcogenides of the 3*d* transition group elements, of which structures are related to the NiAs type and of which compositions are non-stoichiometric, superstructures have been reported by several researchers. Above all on pyrrhotite Fe_7S_8, synthesized crystals were examined systematically with powder specimens[12),13)] and some natural crystals were also examined[13),14)]. The origin of these superstructures, however, had not been revealed for a long while. In 1952 Néel suggested that the ferrimagnetism of pyrrhotite should be due to the ordered arrangement of iron vacancies and the superstructure might be explained also by this ordering.

The first to find such an ordered arrangement was Bertaut who investigated single crystals of natural pyrrhotite[4)]. A similar ordered structure has been found on natural smythite Fe_3S_4 by Erd et al.[15)] in which the iron vacancies are confined to every fourth metal layer and $C=6c$. Another example of such an ordering has been reported on CrS_x system by Jellinek[11)]. He found superstructures on Cr_7S_8, Cr_5S_6, Cr_3S_4 and Cr_2S_3. In each compound chromium vacancies are confined to every second metal layer. Cr_3S_4 has the same structure as that of Fe_3Se_4[3)] with $C=2c$. Cr_2S_3 has two types of superstructure: with $C=2c$ (trigonal) and with $C=3c$ (rhombohedral). These are similar to the case of Fe_7Se_8, but are attributed to the slight difference of compositions: $Cr_{0.69}S$ for the former and $Cr_{0.67}S$ for the latter, respectively. Most of these compounds are ferrimagnetic or antiferromagnetic and at their Curie or Néel temperature these ordered structures still remain as expected. It seems that similar ordered structures may be observed in many other compounds if they are examined in detail.

The author wishes to express his hearty thanks to Prof. T. Okada for his continuous guidance and encouragement and to Dr. K. Hirakawa for suggestion of the present problem, for discussions and for supplying the crystals. He is also indebted to Mr. Y. Suemune for drawing the figures. The present investigation was partly supported by the Scientific Research Expenditure of the Ministry of Education.

Note added in proof. A partial ordered arrangement has been reported also on titanium vacanies in the non-stoichiometric phase $Ti_{2+x}S_4 (0.2<x<1)$. [A. D. Wadsley: Acta Cryst. **10** (1957) 715.]

Ultrasonic Attenuation in Magnetite at Low Temperatures

By Kazuo KAMIGAKI

The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai

(Received February 20, 1961)

The ultrasonic attenuation coefficients in magnetite crystals were measured over the temperature range of 4.2°K–300°K and two kinds of attenuation peaks were observed below the transformation temperature of of ionic ordering. The attenuation is attributable to the relaxed electron diffusion between Fe^{2+} and Fe^{3+} ions on the octahedral sites in the ordered lattice of magnetite. The electron diffusion processes are classified into the single electron process and the coupled transition. The activation energy of the former process is determined to be 0.055 ev and the latter 0.36 ev.

§ 1. Introduction

Recently, low temperature internal friction was investigated on single crystals of magnetite and several kinds of ferrite in the frequency range 10^4–10^5 c/s by Fine and Kenney[1)] and Gibbons[2)]. They found the relaxation peaks in magnetite at about 40°K and 95°K. The origin of these peaks were considered as the relaxed motion of electrons between Fe^{2+} and Fe^{3+} ions induced by a lattice deformation due to the alternating stress. This consideration is based on a model that the ions of different size redistribute under the action of the external stress to reduce the elastic strain energy by the electron diffusion process. But the previous measurements mentioned above were limited to the lower frequency range and the exact evaluation of the activation energies for the relaxed electron diffusion processes have not yet been achieved. The present author planned to measure the ultrasonic attenuation at 10^6–10^7 c/s and to determine the activation energies for both peaks. Some discussions on the mechanism of both relaxation processes are also given.

§ 2. Experimental Method

The specimens were natural single crystals* obtained at Hidaka, Hokkaido, Japan and their volumes were about 1 to 2 cubic centimeters. The ultrasonic waves were transmitted through (111) or (100) plane. The former was a natural surface lapped carefully to be flat and parallel to the opposite surface. The (100) plane was cut, lapped and oriented by the X-ray diffraction method within 1°. Their low temperature transformation point at about 120°K was confirmed by the magnetic method.

---

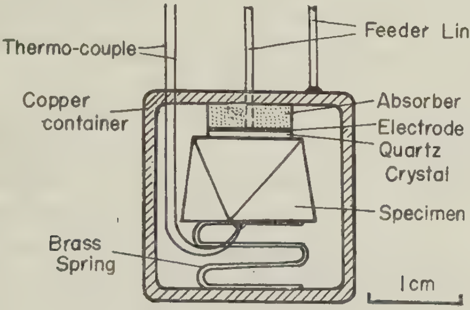

Fig. 1. Specimen holder.

The specimen was mounted in a liquid helium cryostat of the usual type together with the quartz crystal transducer. Details of the specimen holder are shown in Fig. 1. The copper container was made light in weight and the specimen occupied a greater part of the heat capacity. The temperature of the specimen was measured by an Au(2%Co)-Ag(0.2%Cu) thermo-couple. After the evaporation of liquid helium, the specimen was kept under natural heating and the rise in temperature was about fifty degrees per hour.

The apparatus and the method of the attenuation measurements were the same as those used by the author for the previous measurements[3]. The error in the present measurements was within ±3 per cent.

In the course of the measurements a maximum magnetic field of 5000 Oe was applied to the specimen to reduce the secondary effect due to the magnetic domain wall motion. Since the magnetic anisotropy of magnetite vanishes at about 130°K[4], the resistance for the domain wall motion becomes small. The attenuation took a very large value in zero field and was reduced radically in the high field as shown by **X** in Fig. 2b.

Owing to the technical difficulty in supplying liquid helium, the specimen was cooled down through the transformation point without application of the magnetic field. So the specimen must have been composed of twins of the ordered structure.

§ 3. Results of Measurements

Attenuation of the longitudinal waves transmitted along the ⟨111⟩ direction is shown in Figs. 2a and 2b at 5 Mc/s and 15 Mc/s respectively. On both curves, sharp peaks of attenuation are observed at about 60°K (first peak) and 110°K (second peak). At temperatures near the peaks, attenuation varied remarkably with temperature, so the determination of the peak point was made by observing the temperature where the attenuation was inflected from increasing to decreasing. In the

(b)

Fig. 2. (a) Ultrasonic attenuation of the longitudinal waves in magnetite along ⟨111⟩ at 5 Mc/s and (b) at 15 Mc/s.

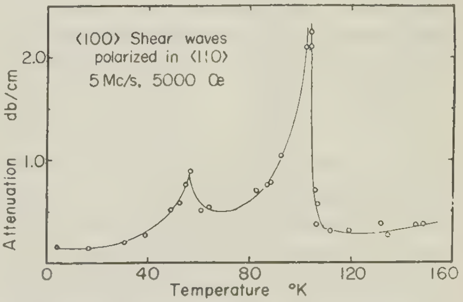

Fig. 3. Ultrasonic attenuation of the ⟨110⟩ polarized shear waves in magnetite along [010] at 5 Mc/s.

case of the first peak, both peak value of attenuation and the corresponding temperature were determined, but in the second peak attenuation increased hugely and only the temperature of inflection was determined.

Attenuation of the shear waves polarized in the ⟨110⟩ direction transmitted from the (100) plane is shown in Fig. 3. In this case similar results to those in Fig. 2 are obtained and two peaks are observed.

§ 4. Discussions

Since the half width of attenuation peaks is narrow, the attenuation is attributable to single relaxation phenomena. In Fig. 4, the ultrasonic frequency of the attenuation measurement is plotted against the inverse of the absolute temperature T at which the first or the second peak was observed. The relaxation peaks obtained by Fine and Kenney[1] and Gibbons[2] are also plotted on the same figure. As this figure shows, the relaxation frequency falls linearly with the increase of the $1/T$ value covering the points obtained at lower frequencies. Making use of the simple Arrhenius type equation activation energies and frequency factors for each sequence of the relaxation peaks are calculated and listed in Table I.

Table I.

	Activation energy ev	Frequency factor sec^{-1}
first peck	0.055	4.3×10^{11}
second peck	0.36	6.5×10^{23}

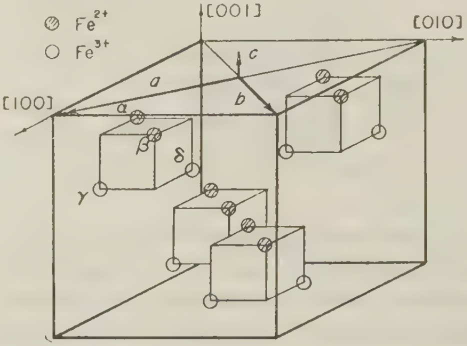

Fig. 5. The ordered arrangement of Fe^{2+} and Fe^{3+} ions in the octahedral sites of magnetite. The principal axis of disordered magnetite are shown conventionally.

The origin of the attenuation peaks is considered to be the stress-induced relaxation in the distribution of Fe^{2+} and Fe^{3+} ions occurring as a result of the transmission of the ultrasonic waves. At first, various types of deformation of the ordered magnetite crystal and the resultant distribution of Fe^{2+} and Fe^{3+} ions to reduce the strain energy should be considered. The ion arrangement in octahedral sites of the ordered magnetite crystal is shown in Fig. 5, where hatched or unhatched circles correspond to Fe^{2+} and Fe^{3+} respectively. b is in the direction of preferred distribution of Fe^{2+} and about 0.55% shorter than a, which is in the direction preferred for Fe^{3+}.[5] For simplicity, the cubic crystal axis of the spinel lattice is used and the four types of the octahedral sites are designated by α, β, γ and δ as shown in Fig. 5.

First, consider the ⟨100⟩ transmission of the longitudinal ultrasonic waves. For the compression along [100] it is preferred for Fe^{2+} to sit on α and β, and for Fe^{3+} on γ and δ, each arrangement of ions is described as $\mathrm{Fe}^{2+}(\alpha\beta)$ or $\mathrm{Fe}^{3+}(\gamma\delta)$ respectively. For the extension $\mathrm{Fe}^{2+}(\gamma\beta)\,\mathrm{Fe}^{3+}(\alpha\delta)$ or $\mathrm{Fe}^{2+}(\alpha\delta)\,\mathrm{Fe}^{3+}(\gamma\beta)$ are preferred. To complete these rearrangements, Fe^{2+} on α or β must exchange the sites with Fe^{3+} on γ or δ, respectively. These rearrangements of ions are effectively caused by the transition of an electron between Fe^{2+} and Fe^{3+} and this is expressed by the single electron process of the following type:

$$\mathrm{Fe}^{2+} \rightleftharpoons \mathrm{Fe}^{3+} + e^- \tag{1}$$

For simplicity, only the Fe^{2+} arragements are discussed hereafter. For the compression along [010] $(\alpha\beta)$ is preferred and for the extension $(\alpha\gamma)$ or $(\delta\beta)$. For the compression along [001] $(\alpha\gamma)$ or $(\delta\beta)$ and for the extension $(\alpha\beta)$. These ion rearrangements are expressed by the same process of single electron migration as in (1).

Next is the case of the ⟨110⟩ longitudinal wave transmission. For the compression along [110], preferential arrangement of Fe^{2+} is $(\alpha\beta)$ and for the extension $(\gamma\delta)$. To complete this rearrangement two Fe^{2+} on α and β migrate simultaneously into γ and δ. Such migration is completed not by the process (1) but by a simultaneous migration of two electrons, or the coupled electron migration process. By this rearrangement the axis a and b are interchanged. For the [011] compression $(\gamma\beta)$ is preferred and for the extension $(\alpha\delta)$, and for the [101] compression $(\delta\beta)$ and for the extension $(\alpha\gamma)$. In both processes of rearrangement there is an intermediate state $(\alpha\beta)$, and the process is divided into two parts, in each of which only one electron moves. Hence these processes are principally the single electron process of (1).

Also in the case of the ⟨111⟩ longitudinal wave transmission, for the [111] compression $(\alpha\beta)$ is preferred and for the extension $(\alpha\gamma)$, $(\alpha\delta)$ and $(\gamma\delta)$ are preferred. In these rearrangements the former two are the single electron process but the last is the coupled electron process.

In the case of the shear wave or the torsional wave transmission, the processes of deformation are similar to those of the longitudinal waves. Hence all the types of ion rearrangement are contained in the above considerations and listed in Table II; the unit processes are classified into the single electron process and the coupled one. Owing to the limitation in the experimental procedure, the specimens are composed of multiple twins at the ordered state. Hence the relaxation process observed in a certain direction is the superposition of the unit processes in the equivalent directions.

Table II. The preferred arrangements of Fe^{2+} in the octahedral sites of magnetite for the transmission of ultrasonic waves along various directions.

Direction of transmission		One electron process		Coupled electron process	
		Compression	Extension	Compression	Extension
⟨100⟩	[100]	$\alpha\beta$	$\begin{cases}\gamma\beta\\ \alpha\delta\end{cases}$

Now, the first peak of attenuation is explained as a stress-induced relaxation of one electron diffusion expressed by the equation (1). The first reason for such conclusion is that in the case of electric conduction in magnetite, current is carried by electrons hopping between neighbouring pairs of a ferrous and a ferric ion as represented by the equation (1). In pure magnetite, the activation energy for the electric conduction was determined by Calhoun[6] to be 0.06 ev (40°–52°K), 0.09 ev (56°–77°K) and 0.11 ev (78°–90°K). The value 0.06 ev fairly coincides with the activation energy of ultrasonic relaxation 0.055 ev obtained for the first peak, lying near 50°K. Next, the first peak was observed in all the cases of longitudinal wave transmission along ⟨100⟩, ⟨111⟩ and shear waves along ⟨100⟩. The single electron process, expressed by the equation (1) can occur in all the above cases as will be seen from Table II. The low temperature peak was also observed by the previous investigators[1,2] in some ferrites without low temperature transformation of ionic ordering, and peak height varied with the content of Fe^{2+}. This fact also supports the above explanation for the origin of the first peak.

The activation energy for the second peak observed directly below the transformation point is 0.36 ev and considerably higher. This peak is regarded as a stress-induced relaxation corresponding to the simultaneous exchange of paired Fe^{2+} ions with paired Fe^{3+} or the coupled electron process in Table II. According to the previous measurements,[1),2)] the second peak was not observed in magnetite for the ⟨100⟩ longitudinal waves nor in various ferrites without low temperature ionic ordering in octahedral sites. From Table II, it can be seen that in these cases the coupled exchange of ions does not occur. In the conductivity measurements, the activation energy was obtained as 0.11 ev at temperatures near the second peak. This value is considerably lower than the activation energy of ultrasonic relaxation, so the latter can not be considered as the single electron process expressed by (1). As a consequence, it is concluded that the second peak of attenuation is a stress-induced relaxation, the elementary process of which is the coupled exchange of ions through the coupled diffusion of electrons in the ordered octahedral sites of magnetite.

The author wishes to expresss his hearty thanks to Professor T. Hirone of this Institute for his kind guidance throughout the present work and to Professor S. Miyahara of the Hokkaido University for his kind furnishing with specimens and helpful discussions. He is also indebted to the members of Hirone Laboratory and those of Miyahara Laboratory for their kind advices on the present study.

Addendum Shear wave attenuation was measured at 35 Mc/s in the same way as in the case of Fig. 3. The first peak was observed at 68°K and the second at 112°K, both are to be plotted in Fig. 4.

Crystal Structures and Electrical Properties of Alkali Antimonides

By Jun-ichi CHIKAWA, Shuji IMAMURA
Technical Research Laboratories, Japan Broadcasting Corporation, Setagaya-ku, Tokyo, Japan
Kenzo TANAKA and Makoto SHIOJIRI
Department of Physics, Faculty of Science, Kyoto University

(Received March 2, 1961)

Both X-ray study and electrical measurement were simultaneously carried out keeping the specimen in vacuum. In K–Sb and Na–Sb, the crystallization into the hexagonal structure from amorphous state and the transition from *p*-type semiconductor to *n*-type one occur simultaneously with successive activation by alkali metal. But Cs–Sb keeps constantly *p*-type in spite of the crystallization into the cubic structure from amorphous state. In Rb–Sb, the transition of the structure occurs, i.e., amorphous→cubic→hexagonal, and *n*-type conduction appears in the hexagonal structure. In order to explain these facts, the relation between the excess alkali atoms and the crystal structure was considered.

The cubic phase of Rb_3Sb was found to be the same as the structure of Cs_3Sb. The unit cell ($a=8.84\pm0.02$Å) is described by the space group $Fd3m$-O_h^7 with eight rubidium atoms at $(0,0,0;\ 0,\frac{1}{2},\frac{1}{2};\ \frac{1}{2},0,\frac{1}{2};\ \frac{1}{2},\frac{1}{2},0)+0,0,0$ and $\frac{1}{4},\frac{1}{4},\frac{1}{4}$ and four antimony and four rubidium atoms occupying at random the other positions $(0,0,0;\ 0,\frac{1}{2},\frac{1}{2};\ \frac{1}{2},0,\frac{1}{2};\ \frac{1}{2},\frac{1}{2},0)+\frac{1}{2},\frac{1}{2},\frac{1}{2}$ and $\frac{3}{4},\frac{3}{4},\frac{3}{4}$.

§ 1. Introduction

Alkali antimonides are intermetallic compounds composed of alkali metal and antimony as represented by M_3Sb, the film of which is photosensitive to visible light. Among them, cesium antimonide has been investigated by many investigators in relation to its electrical and photoelectrical properties because of its excellent photo-emissivity.

Brauer and Zintl[1] showed that the crystal structures of K_3Sb and Na_3Sb are hexagonal (Na_3As type) and that Li_3Sb has a hexagonal structure (the high-temperature modification) and a cubic structure (the low-temperature modification, probably Cu_3Al type). For Cs_3Sb, two different cubic types has been reported; Gnutzmann[2] found that the unit cell of Cs_3Sb is a perfectly ordered cubic lattice of Cs and Sb (Cu_3Al type); on the other hand, Jack and Wachtel[3] found that it is randomly distributed by Cs and Sb atoms over equivalent positions to a certain extent. Recently we became aware that the structure of Rb_3Sb were reported independently by Gnutzmann[2] and by Zhuravlev, Smirnov and Mingazin[4], who found that Rb_3Sb has a hexagonal structure (Na_3As type). However, these X-ray studies have been made on powder specimen only and therefore the structure of practical photosensitive film has been unknown at all.

Imamura[5], one of the authors, studied the behaviors of the electrical properties of the alkali antimonide films in the process of preparation of the specimens, and suggested that Rb_3Sb might exist in both the hexagonal and the cubic forms. In order to study such relation between the physical properties and the structure as in the case of Rb_3Sb, X-ray work must be done by use of the same specimen film for which the physical properties are measured. However, it is difficult to accomplish this purpose, because an extremely thin air-tight window is needed to reduce the absorption of X-ray. In all the X-ray work made in the past, powder specimens were used, and there was no definite evidence that the photosensitive film has the structure as in the case of powder specimens. Hence, employing the test tubes with which both X-ray study and observation of the electrical properties of alkali antimonide films could be carried out, the relation between the electrical properties and the crystal structure of alkali antimodes were investigated. We also found a new cubic phase of Rb_3Sb in this experiment.

§ 2. Experiment

Rubidium-antimony film was prepared in an evacuated glass tube as shown in Fig. 1. In order to obtain X-ray photographs, the entrance and the exist window were mounted on both sides of the tube and covered with mica plates (10 μ in thickness) to admit X-rays.

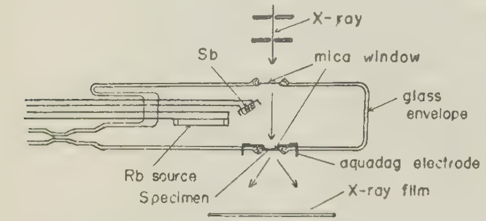

Fig. 1. Preparation of alkali antimonide film and arrangement in X-ray diffraction.

A tungsten filament with antimony and a rubidium source were mounted in the tube. The tube was evacuated and baked at 350°C for three hours. After antimony was evaporated on the exist mica window, metallic rubidium vapour was made by reducing rubidium chromate with silicon powder in an ordinary way to react with the antimony film at 150°~250°C. During the reaction, the sign of the thermoelectromotive force and the electrical resistance of the film were measured with two aquadag electrodes mounted near the exit window. After the measurements, the tube was tipped off from the evacuation system in a vacuum of 3×10^{-6} mmHg and then X-ray diffraction was carried out with placing an X-ray film at a distance of 26 mm from the exit window of the tube, as shown in Fig. 1.

In the above method, however, diffraction lines at high angles disappeared owing to the increase in absorption of the exit mica window. So we also prepared the powder specimen by using tiny flakes of antimony films which were made by tearing off evaporated films from glass substrate, as shown in Fig. 2. After reacting with rubidium under the same condition, the powder specimen was manipulated into the X-ray capillary and sealed off under vacuum to mount on a Debye-Scherrer camera. In this case, we could not measure the electrical properties of powder specimens, but a composition of specimen, Rb/Sb, was measured as follows: weighed tiny flakes of antimony films (about 2 mg) were put into the glass envelope in Fig. 2. After the X-ray photographs were taken with the capillary containing the powder specimen prepared as mentioned above, which was weighed, and the capillary was broken and washed with Aqua regia, so that the capillary without the specimen was weighed. The amount of the specimen was calculated as the difference of two weighing values of the capillary with the specimen and without the specimen, and the amount of rubidium as the difference between the amount of the specimen and the amount of the used tiny flakes of antimony films. Thus, a composition of specimens was calculated.

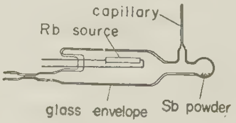

Fig. 2. Preparation of powder specimens of alkali antimonides.

All the X-ray photographs of specimens in this experiment were taken at room temperature with copper radiation.

§ 3. Results

Structure of Rb_3Sb

The electrical resistance of the specimen increases rapidly with successive activation by rubidium, and then it reaches a maximum value at which the specimen has stoichiometric composition Rb_3Sb. With supplying rubidium furthermore, the resistance remarkably decreases[5].

When the resistance of the specimen approached the maximum value in the process of reaction, the X-ray photograph of the specimen showed a halo diffraction pattern at low Bragg angle, as shown in Fig. 3 (A). Consequently, the specimen was considered to be amorphous. After the specimen was annealed at 150~200°C for 5 hours, many diffraction lines appeared which, however, have not yet been interpreted.

Just after the peak resistance was attained by supplying rubidium, the specimen had the cubic structure which was a new phase of

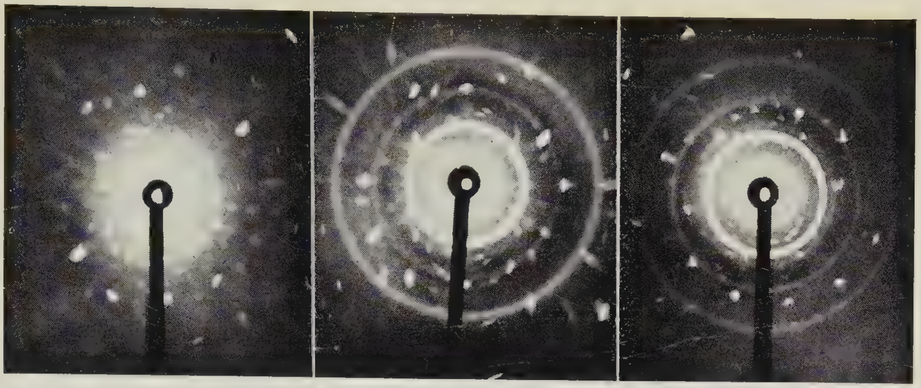

Fig. 3. Diffraction patterns of rubidium-antimony film. (A): At the initial stage in activation process. (B): Cubic phase of Rb_3Sb. (C): Hexagonal phase of Rb_3Sb.

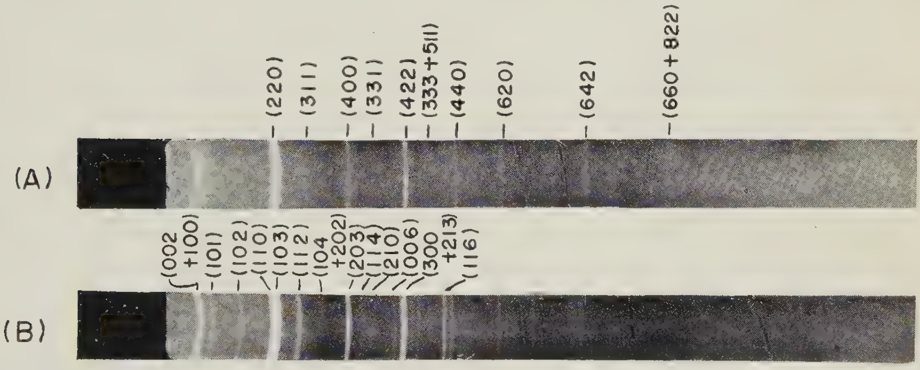

Fig. 4. Diffraction patterns of powder specimens of Rb_3Sb. (A): Cubic phase. (B): Hexagonal phase.

Rb_3Sb. By supplying rubidium a little more the cubic phase was transformed into the hexagonal phase. The X-ray photographs of the cubic and the hexagonal phases which were taken after the reaction at 180°C are shown in Figs. 3(B) and (C), respectively. X-ray photographs were also taken with the powder specimens, as shown in Figs. 4(A) and (B). The diffraction patters in Figs. 4(A) and (B) were respectively identified with those in Figs. 3(B) and (C). In Figs. 3(B) and 4(A), however, very weak diffraction lines of the hexagonal structure appear among the strong diffraction lines of the cubic structure. This shows that these specimens have not a homogeneous composition.

The diffraction pattern in Fig. 4(A) indicates a cubic cell with the constant:

$$a = 8.84 \pm 0.02\ \text{Å}\ ,$$

and can be interpreted by the same structure of Cs_3Sb as that found by Jack and Wachtel[3] (see Fig. 5(A)). That is, the structure is represented by space group $Fd3m\text{-}O_h^7$ and eight rubidium atoms occupy the positions at $(0,0,0;\ 0,\frac{1}{2},\frac{1}{2};\ \frac{1}{2},0,\frac{1}{2};\ \frac{1}{2},\frac{1}{2},0)+0,0,0$ and $\frac{1}{4},\frac{1}{4},\frac{1}{4}$, and four antimony and four rubidium atoms occupy at random other positions at $(0,0,0;\ 0,\frac{1}{2},\frac{1}{2};\ \frac{1}{2},0,\frac{1}{2};\ \frac{1}{2},\frac{1}{2},0)+\frac{1}{2},\frac{1}{2},\frac{1}{2}$ and $\frac{3}{4},\frac{3}{4},\frac{3}{4}$. The crystal structure factors are

$$F = 4(f_{Sb} + 3f_{Rb})$$

$$\text{for } h, k, l \text{ all even and } h+k+l = 4n\ ,$$

$$F = 0$$

$$\text{for } h, k, l \text{ all even and } h+k+l = 4n+2\ ,$$

and

$$F = \sqrt{8}\,(f_{Sb} - f_{Rb})$$

$$\text{for } h, k, l \text{ all odd}\ .$$

The calculated spacings and intensities of the reflections for this structure are in good agreement with the observed values (see Table I).

Gnutzmann[2] reported that Cs_3Sb has the structure of Cu_3Al type. Scheer and Zalm[2]

expected the ordered Cu_3Al-type structure to be the stable modification of Cs_3Sb and the disordered structure of proposed by Jack and Wachtel to be an unstable modification and suggested that this might account for the observations that a prolonged heating of photocathodes resulted in an irreversible decrease in photosensitivity. It is important to determine whether the photosensitive film has an ordered or a disordered structure. In Cu_3Al type, four antimony atoms are situated at $(0, 0, 0;\ 0, \frac{1}{2}, \frac{1}{2};\ \frac{1}{2}, 0, \frac{1}{2};\ \frac{1}{2}, \frac{1}{2}, 0)$ and twelve rubidium atoms at $(0, 0, 0;\ 0, \frac{1}{2}, \frac{1}{2};\ \frac{1}{2}, 0, \frac{1}{2};\ \frac{1}{2}, \frac{1}{2}, 0)$ $+\frac{1}{2}, \frac{1}{2}, \frac{1}{2};\ \frac{1}{4}, \frac{1}{4}, \frac{1}{4};$ and $\frac{3}{4}, \frac{3}{4}, \frac{3}{4}$, and the crystal structure factors are

$$F=4(f_{\mathrm{Sb}}+3f_{\mathrm{Rb}})$$

for h, k, l all even and $h+k+l=4n$,

$$F=4(f_{\mathrm{Sb}}-f_{\mathrm{Rb}})$$

for h, k, l all even and $h+k+l=4n+2$,

and

$$F=4(f_{\mathrm{Sb}}-f_{\mathrm{Rb}})$$

for h, k, l all add .

It was impossible to observe the reflection lines for which $h+k+l=4n+2$ with h, k, l all even, notwithstanding that the intensities of the reflections with h, k, l all odd were observed (see Table I). Consequently, it does not seem to be proper to consider the structure of the cubic phase of Rb_3Sb as Cu_3Al-type.

Recently, Zhuravlev, Smirnov and Mingazin[4] reported that Rb_3Sb has the structure of Na_3As type (Fig. 5 (C)). This agrees with our result for the hexagonal phase of Rb_3Sb. (The photograph of Fig. 4 (B) give the lattice constants: $a=6.32\pm0.02$ Å, $c=11.19\pm0.02$ Å).

Electrical properties

Imamura[5] found several facts from observation of the sign of the thermo-electromotive force during the preparation: In Cs–Sb, the sign is always negative, indicating that positive charge carriers are predominant, but in K–Sb and Na–Sb the transition from *p*-type to *n*-type takes place just after, or in some case even before, the peak resistance has been attained. In Rb–Sb, this transition occurs rather later than the former two. He also suggested that the transition from *n*-type to *p*-type is associated with the structure change from the amorphous to the hexagonal or from the cubic to the hexagonal, and that rubidium antimonide has either the cubic or the hexagonal phase.

In order to examine whether the structures are responsible for the electrical properties, the X-ray photographs of Cs–Sb, K–Sb and Na–Sb were taken by the method as described in § 2. The sign of thermo-electromotive force was also observed. In Cs–Sb, the transition from the amorphous to the cubic phase took place by supplying cesium and the transition to hexagonal phase did not appear by supplying cesium furthermore, and the sign was always negative. In K–Sb and Na–Sb, the transition from amorphous to hexagonal phase (Na_3As type) took place after attaiment to the peak resistance and the transition from *p*-type to *n*-type. In this case, the cubic phase was not observed. In Rb–Sb, the transition from *p*-type to *n*-type took place in the cubic phase containing the hexagonal phase. These results are almost in agrement with the Imamura's suggestions. It may be concluded that an alkali antimonide of the amorphous or cubic phase is a *p*-type semiconductor and of the hexagonal phase is an *n*-type one.

The space among the atoms in the hexagonal lattice is larger than that in the cubic lattice, as seen from Table II. The excess alkali atoms can be easily accommodated at the interstitial positions in the hexagonal lattice and act as donors. On the other hand, the cubic lattice cannot accommodate so many excess alkali atoms at the interstitial position that the cubic phase indicate an *n*-type conduction. This can be seen from the fact that the cubic lattice of Rb_3Sb is transformed into the hexagonal one by diffusing rubidium in a large quantity. The excess alkali atoms in the cubic lattice may occupy the Sb sites to indicate *p*-type conduction, because such substitution is possible to a certain extent in the disordered lattice as shown in Fig. 5 (A). The transition from the cubic phase to the hexagonal one is prohibited for Cs_3Sb. This may be assigned to the large ionic radius of Cs atom. In fact, although we also prepared a specimen of Cs–Sb by evaporating antimony at 180°C in a glass tube which was filled with Cs vapour, the hexagonal phase was not observed. In this case, excess Cs atoms may initially occupy Sb sites substitutionally. The more excessive cesium may deposit on the wall of the glass envelope or on the surface of the specimen.

Table II. Comparison of the hexagonal and the cubic phase in Rb_3Sb.

Crystal type	Lattice constants (Å)		Density g/cm³	Small distance (Å)		
	a	*c*		Sb–Sb	Sb–Rb	Rb–Rb
Hexagonal	6.32	11.19	3.25	6.32	3.65	3.73
Cubic	8.84		3.64	3.83	3.83	3.83

The diameter of the halo in Fig. 3 (A) agrees with that of the strongest diffraction line of Rb_3Sb. Probably, owing to deficiency in the quantity of rubidium, grains could not grow so large in size that they gave the sharp diffraction lines. The origin of the *p*-type conduction in the amorphous state in all kinds alkali antimonides may be assigned to vacancies of alkali atoms in such tiny grains.

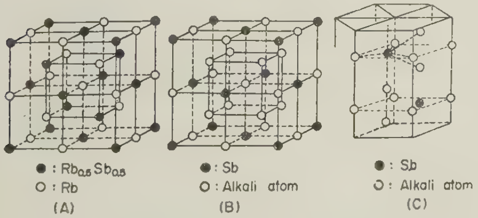

Fig. 5. Unit cells of alkali antimonides. (A): Unit cell of the cubic phase of Rb_3Sb (the same as the unit cell of Cs_3Sb according to Jack and Wachtel). (B): Unit cell of Cu_3Al type (unit cell of Cs_3Sb according to Guntzmann). (C): Unit cell of Na_3As type (unit cell of Na_3Sb, K_3Sb and the hexagonal phase of Rb_3Sb).

§ 4. Discussion

Although many specimens of Rb_3Sb were prepared, we could not make a specimen of the cubic phase which contained no hexagonal phase, so that we could not show experimentally with the pure specimen of the cubic phase that the cubic phase is a *p*-type semiconductor. However, the transition from *p*-type to *n*-type in Rb–Sb occurs rather later than that in K–Sb and Na–Sb in the process of activation with alkali and Cs_3Sb has the cubic structure and is a *p*-type semiconductor. These facts seem to support the conclusion that the cubic phase of Rb_3Sb is a *p*-type semiconductor.

A thick film of the specimen was necessary to obtain X-ray photographs with sharp diffraction patterns. But, in a thick specimen (few microns), the transition of the structure in the process of preparation occurred considerably later than the transition from *n*-type to *p*-type and attainment to the peak resistance. This might be due to the fact that the reaction between alkali metal and antimony proceeded rapidly at the surface of the film and the surface layer of the film had a considerable effect on the electrical properties of the specimens. Therefore, it was desirable to make the specimens as thin as possible. In fact, even with the semi-transparent specimens clear diffraction patterns were obtained, using a thin mica window. It is probable that the specimen containing both the cubic and the hexagonal phase has layer of the hexagonal phase near the surface.

Jack and Wachtel[3)] made X-ray specimens of Cs_3Sb by reaction at 200°∼210°C between antimony powder and cesium vapour, and reported that many specimens gave X-ray photographs with a high background intensity and only one or two broad and diffuse reflexions at low Bragg angle. But we obtained a clearer cubic diffraction pattern with the specimens of Cs_3Sb that were prepared by reaction at 180°C between evaporated thin antimony films and cesium vapour and were not annealed after reaction. This shows that cesium may not easily diffuse into antimony and a highly crystalline specimen of Cs_3Sb can be prepared by diffusing sufficiently cesium into antimony. Therefore, it may be noted that such a thin film of Cs–Sb as a practical photocathode with the maximum photosensitivity just after the establishment of a maximum resistance has the cubic structure, though the relation between the photoemissive properties and the crystal structure is not the main subject in the present work.

Weak Ferromagnetism in β-NaFeO$_2$

By Hiroshi WATANABE
The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai
and Masahiro FUKASE
Konishiroku Photo Industries Company, Limited, Hino-machi, Tokyo

(Received March 3, 1961)

The high temperature modification of sodium ferrite, β-NaFeO$_2$, has weak ferromagnetism, whose Curie temperature is about 450°C. The magnetic property resembles that of LaFeO$_3$. The origin of weak ferromagnetism of β-NaFeO$_2$ can be attributed to the presence of the Dzyaloshinsky type interaction in this compound.

§ 1. Introduction

It is known from the works of French researchers[1)–5)] that sodium ferrite, NaFeO$_2$, crystallizes in two modifications: (1) the low-temperature- or α-modification which is rhombohedral with the space group D_{3d}^5-$R\bar{3}m$[1)], and (2) the high-temperature- or β-modification which is orthorhombic with the space group C_{2v}^9-Pna[2)]. In the present work, thermomagnetic study was made with β-NaFeO$_2$, and it was found that this substance shows weak ferromagnetism when cooled in a magnetic field from temperatures above 500°C. The magnetic property is like that found in LaFeO$_3$ which was studied previously[6)]. The origin of this weak ferromagnetism can be interpreted on the basis of symmetry consideration as due to the presence of the Dzyaloshinsky type interaction[7)] in the compound.

§ 2. Experimental

2.1. *Experimental Procedure*

Powders of Na$_2$CO$_3$ and α-Fe$_2$O$_3$ of average particle size of 0.5 μ in diameter were mixed in the desired proportions, ground in an agate mortar, and sintered at 900°C for 20 hrs in air. The sintered products thus obtained were more stable at room temperature than those with shorter sintering periods. Unstable products were subject to hydration in moist air. Sintering above 1000°C caused sticking of the molten samples to the crucibles.

X-ray powder diffraction patterns were taken of the samples with varying ratios of Na to Fe. Samples ware vacuum-sealed in thin glass tubes.

Samples for thermomagnetic measurements were made in a form of a rectangular prism, 4 mm × 4 mm × 8 mm in size, and were supported by platinum wires, whose one end was buried tight in the sample. Sample mounting as well as the magnetic measurements were made as fast as possible after sintering since even the well-reacted samples were apt to be attacked by moisture.

2.2. *Crystallographic Study*

Fig. 1 shows schematically the positions and intensities of the observed lines on powder photographs. It is seen that samples with $0.9 \leqslant x \leqslant 1.1$ (x denotes Na content: Na$_x$Fe$_{2-x}$O$_{3-x}$) have essentially the same crystal structure, which should correspond to the β-NaFeO$_2$ structure. The pattern was compatible with the structure given by Bertaut and Blum[2)],

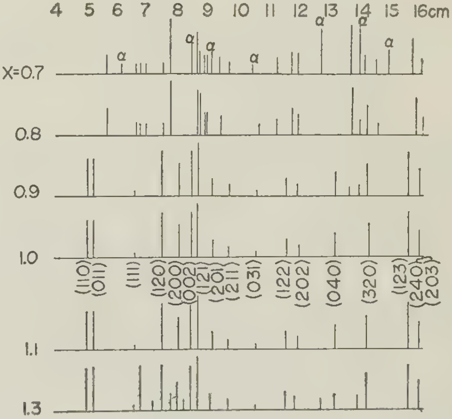

Fig. 1. Schematical representation of the powder diffraction parterns of sintered products of mixtures of Na$_2$CO$_3$ and α-Fe$_2$O$_3$. The abscissa represent the distance between lines of given indices. x stands for the value in the formula Na$_x$Fe$_{2-x}$O$_{3-x}$. Lines with the label α are pertinent to α-Fe$_2$O$_3$. Camera diameter: 114.6 mm. Radiation: FeKα. $x=0.8$ corresponds to 2Na$_2$O$_3$-3Fe$_2$O$_3$, and $x=1.0$ to β-NaFeO$_2$.

except for a small difference in lattice constants from theirs (the present data: $a=5.65$ Å, $b=7.13$ Å, $c=5.37$ Å). Observed and calculated line intensities of β-NaFeO$_2$ are listed in Table I.

Table I. Interplanar distance, d, and observed and calculated line intensities of β-NaFeO$_2$.

For $x=0.8$, there appears a new structure. The composition corresponds approximately to 2Na$_2$O3Fe$_2$O$_3$. According to Collongues and Thery[3], the compound of this composition has a tetragonal structure, and our data are in rough accord with theirs. Samples with $x \leq 0.7$ are mixtures of 2Na$_2$O3Fe$_2$O$_3$ and α-Fe$_2$O$_3$.

For $x \geq 1.3$, additional lines are superposed on the pattern of β-NaFeO$_2$. It is not yet clear whether these lines are due to admixing of a different phase or they are some superlattice lines of the original β-NaFeO$_2$ structure.

2.3. *Magnetic Study*

Thermomagnetic measurements were made of three samples, with $x=1.0$, 1.1 and 0.7. Figs. 2 (a) and (b) show specific magnetization *vs* temperature curves of the samples with $x=1.0$ and 1.1, respectively. The Curie temperature of these samples are 450°C and 550°C, respectively. The dotted curve in (b) seems to indicate that for this sample treating field of 6800 Oe is not sufficiently strong to produce full remanence.

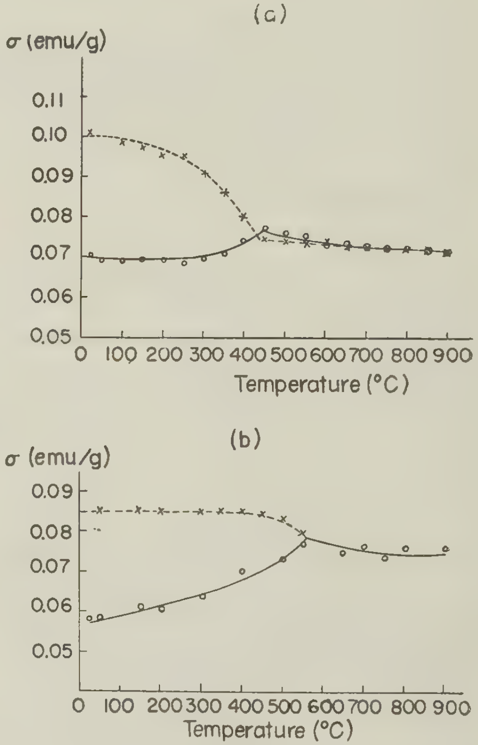

Fig. 2. Specific magnetization σ against temperature of (a) NaFeO$_2$ and (b) Na$_{1.1}$Fe$_{0.9}$O$_{1.9}$. Solid curve: not field-cooled. Dotted curve: cooled from temperatures above 550°C in a field of 6800 Oe. Measuring field: 6800 Oe.

As in LaFeO$_3$, the field-cooled sample has a magnetization *vs* field curve displaced along the magnetization axis. This is shown in Fig. 3. The displacement, however, is very small as compared with the case of LaFeO$_3$. The relation between the remanent magnetization (σ_r) and the field applied during cooling (H_t) is shown in Fig. 4. As is seen from the figure, σ_r is roughly proportional to the square root of H_t. According to Néel's theory of thermoremanent magnetization[8], this behavior corresponds to the case of fine grains with very high coercive force.

Fig. 5 shows the result of the thermomagnetic measurement on a sample with $x=0.7$. As was stated in 2.2, this sample is a mixture of $2Na_2O3Fe_2O_3$ and α-Fe_2O_3. The anomaly in the curve near 650°C may probably corresponds to the Curie temperature of α-Fe_2O_3.* Then the peak at 100°C may be identified with the critical temperature of antiferromagnetic $2Na_2O3Fe_2O_3$.

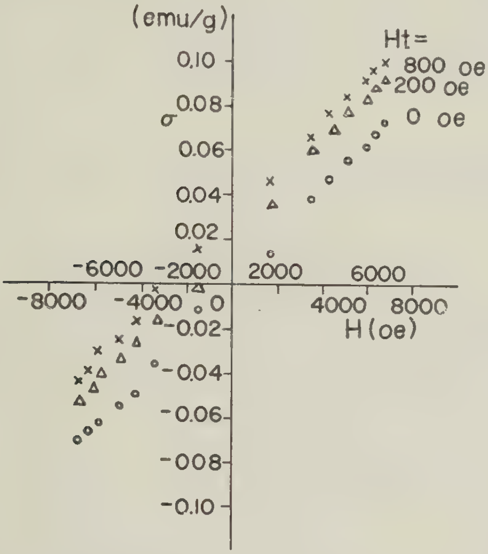

Fig. 3. Specific magnetization (σ) *vs* field (H) curves of field-cooled and not-field-cooled specimens of β-$NaFeO_2$ (at room temperature). H_t: the field during cooling.

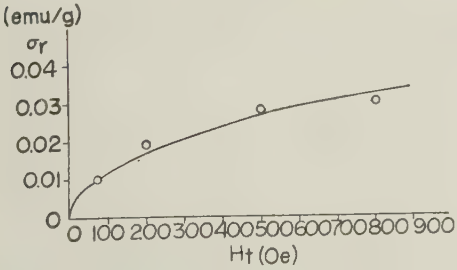

Fig. 4. Thermoremanent magnetization (σ_r) against field applied during cooling (H_t) of β-$NaFeO_2$.

§ 3. Discussion

As was shown in § 2, β-$NaFeO_2$ shows weak ferromagnetism, and it resembles $LaFeO_3$ in that the σ *vs* H curve is shifted along the magnetization axis if it is cooled from temperatures above the Curie temperature of weak ferromagnetism. It has become more and more confirmative that $LaFeO_3$, together with other earth orthoferrites[9], is an intrinsically non-compensating antiferromagnetic because of an angular coupling between almost antiferromagnetically arranged spins. We shall now discuss the possibility of a similar interpretation of weak ferromagnetism in β-$NaFeO_2$.

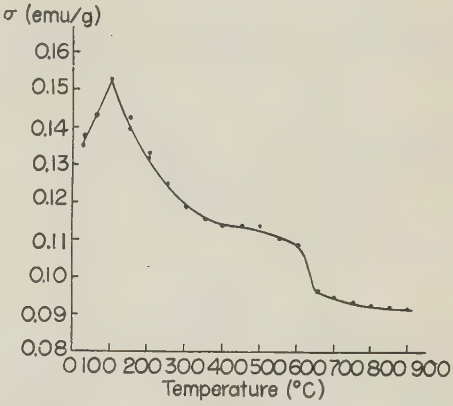

Fig. 5. Specific magnetization (σ) against temperature of $Na_{0.7}Fe_{1.3}O_{2.3}$.

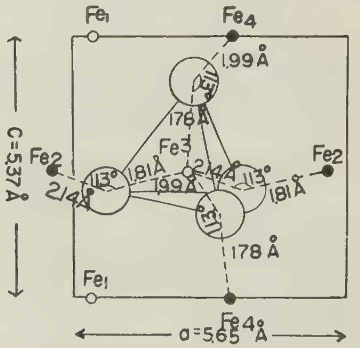

Fig. 6. Environment of an Fe^{3+} ion in β-$NaFeO_2$ structure projected on the *ac*-plane. Large (white) circle: O^{2-} ion. Small white circle: Fe^{3+} ion with + spin. Small black circle: Fe^{3+} ion with − spin.

First of all, Fe^{3+} ions in β-$NaFeO_2$ from a distorted simple monoclinic lattice, so that an antiferromagnetic spin lattice can be formed with antiparallel spin arrangement between near-neighboring Fe^{3+} ions. Each Fe^{3+} ion has four Fe^{3+} neighbors (see Fig. 6). All of them are separated from the central Fe^{3+} ion by intervening O^{2-} ions. Interionic distances and angles Fe–O–Fe are given in the figure. As can be seen, from the figure neighbors of Fe_1 (or Fe_3) are Fe_2 and Fe_4, and those of Fe_2 (or Fe_4) are Fe_1 and Fe_3.

The structure has four screw axes parallel to the c-axis, two planes of gliding reflection n, and two other planes of gliding reflection a. Consideration of these symmetry elements leads to the following relation between the components of $\boldsymbol{S}_i$ (for numbering of spins, see Fig. 6):

---

* Supplementary measurements revealed that this anomaly was absent in a sample with $x=0.8$.

$$\left.\begin{array}{lll} S_{2x}=-\varepsilon S_{1x}\,, & S_{2y}=-\varepsilon S_{1y}\,, & S_{2z}=\varepsilon S_{1z}\,, \\ S_{3x}=-\varepsilon' S_{1x}\,, & S_{3y}=\varepsilon' S_{1y}\,, & S_{3z}=\varepsilon' S_{1z}\,, \\ S_{4x}=\varepsilon\varepsilon' S_{1x}\,, & S_{4y}=-\varepsilon\varepsilon' S_{1y}\,, & S_{4z}=\varepsilon\varepsilon' S_{1z}\,, \end{array}\right\} \tag{1}$$

where ε and ε' take the values ±1. The components of the net moment vector

$$\boldsymbol{m}=\boldsymbol{S}_1+\boldsymbol{S}_2+\boldsymbol{S}_3+\boldsymbol{S}_4$$

can be written as:

$$\left.\begin{array}{l} m_x=(1-\varepsilon)(1-\varepsilon')S_{1x}\,, \\ m_y=(1-\varepsilon)(1+\varepsilon')S_{1y}\,, \\ m_z=(1+\varepsilon)(1+\varepsilon')S_{1z}\,. \end{array}\right\} \tag{2}$$

As mentioned above, $\boldsymbol{S}_1$ and $\boldsymbol{S}_2$ (or $\boldsymbol{S}_3$ and $\boldsymbol{S}_4$) should be nearly antiparallel to each other, while $\boldsymbol{S}_1$ and $\boldsymbol{S}_3$ (or $\boldsymbol{S}_2$ and $\boldsymbol{S}_4$) are parallel, so that the vector

$$\boldsymbol{l}=\boldsymbol{S}_1-\boldsymbol{S}_2+\boldsymbol{S}_3-\boldsymbol{S}_4$$

should have a non-zero absolute value. From (1) it follows that:

$$\left.\begin{array}{l} l_x=(1+\varepsilon)(1-\varepsilon')S_{1x}\,, \\ l_y=(1+\varepsilon)(1+\varepsilon')S_{1y}\,, \\ l_z=(1-\varepsilon)(1+\varepsilon')S_{1z}\,. \end{array}\right\} \tag{3}$$

The case $\varepsilon=\varepsilon'=-1$ is inhibited, because, then, all of the components of $\boldsymbol{l}$ in (3) vanish. Hence we have three cases:

1. $\varepsilon=1$, $\varepsilon'=-1$.

From (3) we have $l_x=4S_{1x}$ and $l_y=l_z=0$ so that the approximate spin direction lies along the a-axis. From (2) $m_x=m_y=m_z=0$ and no net moment appears.

2. $\varepsilon=1$, $\varepsilon'=1$.

$l_x=l_z=0$ and $l_y=4S_{1y}$, so that the approximate spin direction lies along the b-axis. From (2) $m_x=m_y=0$, $m_z=4S_{1z}$ and a small moment appears in the c-direction.

3. $\varepsilon=-1$, $\varepsilon'=1$.

$l_x=l_y=0$ and $l_z=4S_{1z}$, so that the approximate spin direction lies along the c-axis. $m_x=m_z=0$, $m_y=4S_{1y}$ and a small moment appears in the b-direction.

The origin of these non-vanishing net moments may by the Dzyaloshinsky type interaction $\boldsymbol{D}_{ij}[\boldsymbol{S}_i \times \boldsymbol{S}_j]$[7]. The following relation holds between the components of $\boldsymbol{D}_{ij}$'s:

$$\begin{array}{lll} D_{12}(u_x, u_y, 0) & D_{13}(0, v_y, v_z) & D_{14}(-w_x, 0, w_z) \\ & D_{23}(w_x, 0, w_z) & D_{24}(0, -v_y, v_z) \\ & & D_{34}(u_x, -u_y, 0)\,. \end{array}$$

Of these only u_x and w_x are responsible for producing net moments.

Acknowledgements

The authors are indebted to Professor T. Nagamiya and Dr. K. Motizuki of Osaka University for stimulating discussions. One of the authors (M. F.) expresses his thanks to Professor T. Hirone of Tohoku University for providing the facilities to carry out this study in Hirone's laboratory and to Konishiroku Photo Industuries Company for fellowship aid. A part of the expenditure of this study has been defrayed from the Scientific Research Funds of the Ministry of Education.

The Crystal Structure of Chloranil and Bromanil

By Ikuhiko UEDA

General Education Department, Kyushu University, Japan

(Received January 6, 1961)

The Crystal structure of chloranil and bromanil has been determined by X-ray diffraction technique based on the two-dimensional Fourier analysis. Chloranil and bromanil are isomorphous. The cell constants are: $a_0=8.86_2$, $b_0=5.83_7$, $c_0=8.76_3$Å, $\beta=72.6°$ for chloranil and $a_0=8.62_4$, $b_0=6.17_3$, $c_0=9.02_7$Å, $\beta=74.2°$ for bromanil. There are two molecules in the unit cell and the space group is $P\ 2_1/a\ (C_{2h}^5)$. The crystal consists of two layers of substituted halogen atoms which are parallel to the (001) plane, and the skeletons consisting of oxygen and carbon atoms lie between these two layers. The juxtaposition of molecules is such that the dipole interactions between C=O bonds stabilize the structure. There is definite localization of the double bonds in the benzene ring. In the molecule the adjacent halogen and oxygen atoms protrude respectively up and down from the plane of the benzene ring making a puckered form. The thermal motions of the molecules in this crystal have been analysed from the anisotropic thermal parameters of chlorine and oxygen atoms. A theoretical analysis shows that the puckered form is more stable, as a molecule, than the planar form. A clear correspondence is found between this fact and the anisotropic thermal motions of Cl and O atoms.

§ 1. Introduction

Although the molecular shapes of *p*-benzoquinone and its derivatives are symmetrical, they have small but definite values of atomic polarization. Hammick and Coop[1] suggested that this fact was due to the bending effect of the molecule. If it be so, molecules in the crystals may be bended much more by the crystalline field. These effects may become clear by a accurate determination of their crystal structures.

The crystal structure of *p*-benzoquinone was determined by Robertson and Trotter[2]. If this structure is compared to that of chloranil and bromanil, the influence of substitution by halogen atoms to the C=O bond may be estimated. Due to the large size of the halogen atoms the distortion of C=O bonds is expected to be discernible.

Harding and Wallwork[3] determined the crystal structure of the chloranil-hexamethylbenzene complex. According to their results, the oxygen atom and its adjacent two chlorine atoms in the chloranil molecule protruded in the same direction from the plane of the carbon skeleton.

In this paper the detailed crystal structure of chloranil and bromanil will be reported. The structure of chloranil was determined in details which enabled us to discuss the structure of the molecule.

§ 2. Experimental

Both chloranil and bromanil were purified by recrystallizing from saturated benzene solution. Single crystals suitable for X-ray diffraction work were obtained by crystallizing from benzene solution at about 30°C.

The X-ray absorption coefficients of bromanil are $\mu_{\mathrm{Cu}K\alpha}=217\ \mathrm{cm}^{-1}$, $\mu_{\mathrm{Mo}K\alpha}=188\ \mathrm{cm}^{-1}$ and those of chloranil are $\mu_{\mathrm{Cu}K\alpha}=121\ \mathrm{cm}^{-1}$, $\mu_{\mathrm{Mo}K\alpha}=14\ \mathrm{cm}^{-1}$. To minimize the effect of absorption, in the case of bromanil, single crystals were cut and polished to form cylindrical rods 0.2 mm in diameter. The softness and cleavage of these crystals made it very difficult to obtain good samples. Therefore, some systematic error in the intensity data was unavoidable. In the case of chloranil the absorption correction was neglisibly small for Mo*Kα* since we used crystals having a diameter about 0.2 mm.

For the structure determination a complete set of relative intensity for (0*kl*), (*h*0*l*) and (*hk*0) was obtained by integrating Weissenberg goniometer. For chloranil Mo*Kα* radiation and for bromanil Cu$K\alpha$ radiation were used. The relative intensities of reflexions on Weissenberg photographs obtained by the multiple-film technique were measured by visual comparison with an intensity scale.

The crystals were often found twinned in the (001) plane. The temperature factor was fairly large and the reflexions over $\sin\theta/\lambda = 0.8$ Å^{-1} could not be observed. The diffuse scattering was often observed in the cut and polished crystals.

The crystals are monoclinic and the unit cell dimensions determined from high angle reflexions on Weissenberg photographs are:

$$a_0 = 8.86_2 \pm 0.02_5, \quad b_0 = 5.83_7 \pm 0.01_6,$$
$$c_0 = 8.76_3 \pm 0.02_5 \text{ Å}, \quad \beta = 72.6° \pm 0.4°$$
for chloranil

$$a_0 = 8.62_4 \pm 0.01_2, \quad b_0 = 6.17_3 \pm 0.00_9,$$
$$c_0 = 9.02_7 \pm 0.01_3 \text{ Å}, \quad \beta = 74.2° \pm 0.4°$$
for bromanil.

The space group is $P2_1/a$ (C_{2h}^5). The density determined by the floatation method is 1.67 g/c.c. for chloranil and is 3.02 g/c.c. for bromanil. Since the general position in $P2_1/a$ is fourfold and the unit cell contains only two molecules, the centres of gravity of the molecules should occupy a set of twofold special positions. Thus each molecule displays a centre of symmetry in the crystal. Therefore it is clear that their atomic polarization is not due to the asymmetry of the molecules. Since the diffracted intensities of chloranil and bromanil show the same behaviour, both crystals are isomorphous.

§ 3. Structure Determination

From the Patterson maps of the b-projection and a-projection the positions of the heavy atoms were determined. Then the structure factors were calculated with a few models in which the carbon and oxygen skeleton was placed in addition to these heavy atoms. It was possible to arrive at a model which gave fairly good agreement between $F_{cal.}$ and $F_{obs.}$. This was done first with bromanil. In the case of chloranil the model obtained for bromanil was adopted as a starting point.

§ 4. Refinement

In the earlier stage the refinement was repeated by Fourier syntheses. Then, it was followed by subsequent (F_0–F_c) syntheses. In the later stage the thermal anisotropy of heavy atoms and oxygen atom was taken into account. In the structure factor calculation the atomic scattering factors were taken from McWeeny[4] for the light atoms, those from Tomiie and Stam[5] for chlorine, and those from James and Brindly[6] for bromine.

From the ($\rho_0 - \rho_c$) maps the corrections for atomic co-ordinates Δr were estimated by the equation:

$$\Delta r = [d(\rho_0 - \rho_c)/dr]_{r=0} / 2p\rho(0) ,$$

where $\rho(0)$ is the electron density at an atomic centre and p is a constant whose value is deduced from the Fourier map by the equation:

$$\rho(r) = \rho(0) \exp(-pr^2) .$$

The values of $2p\rho(0)$ given by Burbank[7] were used in this refinement but the results of corrections with his values showed some tendency of overestimation.

At this stage of refinement, the temperature factors for each atom were introduced according to the method suggested by Atoji[8] and modified by Sasada[9]. In the final stage

the thermal anisotropy of chlorine and oxygen atoms was taken into account by the method suggested by Schomaker[10] which was modified for the two-dimensional case. By this correction the disagreement factor for each projection was reduced by 2~3% and the positions of light atoms were adjusted slightly. Since in this paper the author wants to discuss small distortion of the C=O bond, even this slight influence should be taken seriously.

Table II. Final atomic parameters and temperature factors of bromanil.

	x/a	y/b	z/c
Br_1	0.4685	0.7203	0.1812
Br_2	0.6970	0.2822	0.1702
O	0.3199	0.8081	0.5087
C_1	0.0983	0.1638	0.4953
C_2	0.4913	0.5634	0.3571
C_3	0.0840	0.0620	0.3505

a-projection $\boldsymbol{B}=6.2$
b-projection $\boldsymbol{B}=6.5$
c-projection $\boldsymbol{B}=5.5$.

The final atomic parameters and temperature factors are shown in Tables I and II. In Table I each atom is assumed to have its stationary scattering factor multiplied by a temperature factor,

$$\exp-[B-\varDelta\sin^2(\phi-\psi)](s/2)^2\ ,$$

where $\boldsymbol{B}$ and $\varDelta$ are constants, ψ is the angle between the direction of maximum vibration and the c^* or a^* axis and $(2s,\ \phi)$ are the polar co-ordinates of a point in each projection plane of the reciprocal lattice. The final structure factors F_{0kl}, F_{h0l} and F_{hk0} are shown in Tables III and IV. The F_0 values have been put on the same scale as the F_c values by making the value of $\sum||F_0|-|F_c||$ minimum. Fig. 1 (a) shows the final *b*-projection of electron density and Fig. 1 (b) shows the *b*-projection of $(\rho_0-\rho_c)$ at the step $R_{h0l}=0.15$.

The disagreement factors $R=\sum||F_0|-|F_c||/\sum|F_0|$ for the refined projections, excluding all reflexions too weak to be observed, are shown below:

$$R_{0kl}=0.09,\ R_{h0l}=0.13,\ R_{hk0}=0.10$$
for chloranil,

$$R_{0kl}=0.13,\ R_{h0l}=0.15,\ R_{hk0}=0.22$$
for bromanil.

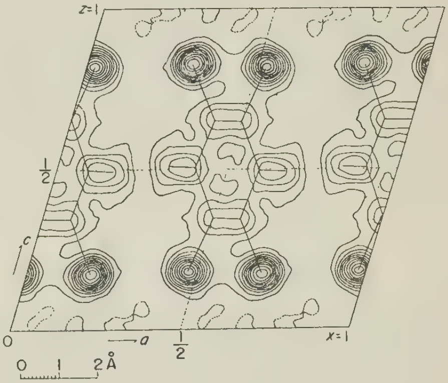

Fig. 1 (a). The final projection of the electron density along the *b*-axis. Contours at intervals of 2 eÅ^{-2}. Contour at 0 eÅ^{-2} is broken.

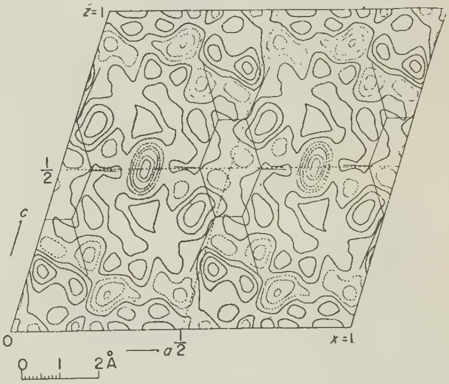

Fig. 1 (b). The $(\rho_0-\rho_c)$ map, (*b*-projection), at the step that the disagreement factors $R=0.15$. Contours at intervals of 0.4 eÅ^{-2}. The negative contours are broken.

§ 5. Accuracy of the Structure Determination

In the case of bromanil the systematic error in the observed structure factors was inevitable because of its large absorption coefficient. Moreover, because of the large atomic number of bromine, the accuracy of the position of light atom was not satisfactory enough to discuss its detailed structure. The standard deviations for atomic positions were calculated by Cruicksnank's[11] method. Those values $\sigma(r)$ were about 0.01 Å for bromine atoms and about 0.1 Å for the light atoms.

In the case of chloranil there is no systematic error except the extinction effect. The standard deviations of atomic positions are: $\sigma(r)=0.003$ Å for chlorine, $\sigma(r)=0.009$ Å for oxygen and $\sigma(r)=0.012$ Å for carbon. Therefore the standard deviations of the bond lengths are: $\sigma=0.017$ Å for the C–C, C=C bonds, $\sigma=0.015$ Å for the C=O bond and $\sigma=0.012$ Å for the Cl–C bond. The average standard deviation of the bond angles is about 1.2°.

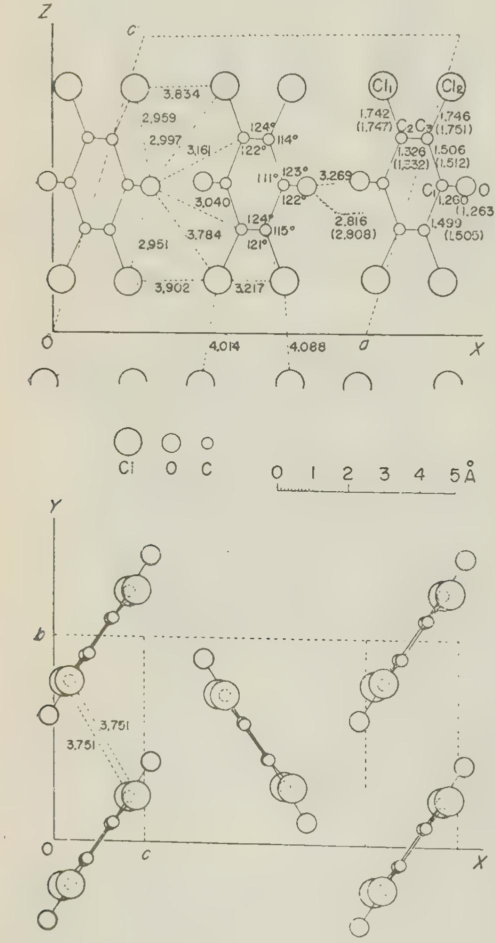

Fig. 2. The arrangement of molecules of chloranil with interatomic distances in Å and bond angles in degrees. The values in the parentheses are the corrected distances by Cruickshank's method.

§ 6. Discussion

(1) Molecular Structure:

The crystal axes were transformed to the orthogonal axes such that a, b axes were parallel to X, Y axes with the common origin. In this orthogonal co-ordinate system the structural calculations of the molecule and the crystal were performed. The results are shown in Fig. 2. The plane through which all carbon atoms in one molecule and its centre of symmetry lie is calculated to be

$$1.0000X+0.6731Y-0.0316Z-7.5584=0\ ,$$

for the molecule at (1/2, 1/2, 1/2). The perpendicular displacements of atoms in this molecule from the above plane are shown in Fig. 3. It is certain that the adjacent chlorine and oxygen atoms protrude respectively up and down from this plane. Moreover the distances between these adjacent oxygen and chlorine atoms are fairly shorter than that expected from the sum of their van der Waals radii. Thus these atoms around the carbon skeleton construct a puckered form.

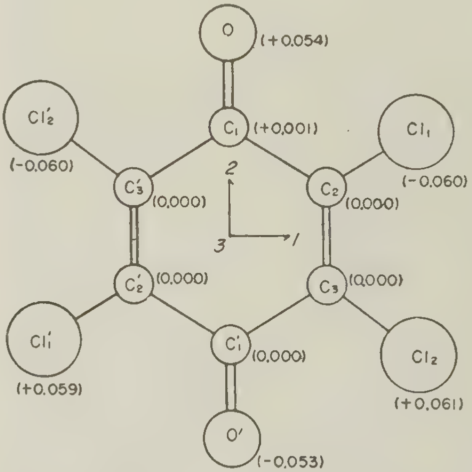

Fig. 3. Molecule of chloranil. The value in the parenthesis for each atom is the perpendicular displacement in Å from the carbon skeleton plane. The axes *1*, *2* and *3* are those concerning U_{ij}.

The bond lengths are found to have fairly typical values, from which it follows that $C_2=C_3$ is the double bond and C_1–C_2, C_2–Cl_1, C_3–Cl_2 are the single bonds. The distance between C_1 and O atoms is somewhat longer than that expected from the C=O bond. Therefore, this bond may have a single bond

(C–O⁻) character to some extent, although it is mainly of double bond character. Thus the $C_1=O$ bond may have a dipole moment. (cf. Figs. 2 and 3.)

(2) Molecular Arrangement:

In the crystal the chlorine atoms form layers parallel to the *XY* plane. The distance between these chlorine layers is slightly larger than that calculated from their van der Waals radii. The cleavage of the (001) plane is well explained by this structure. In these layers the distances between chlorine atoms in adjacent molecules are also slightly larger than that expected from their van der Waals radii. These may indicate that the van der Waals potentials arising from interaction between chlorine atoms are much less than exerting in crystals of usual poly halogenated molecules.

A layer consisting of light atom skeleton lies between these two chlorine layers. In this layer an oxygen atom is found nearest to a carbon atom forming a C=O bond in the adjacent molecule. The distance between these atoms is much shorter than that expected from their van der Waals radii. The two oxygen atoms belonging to these two C=O bonds are even disposed as if they repulse each other. It is suggested that the cohesive factors between molecules arise mainly from the dipole interaction of the C=O bonds. This fact supports Hammick and Coop's[1] theory about the atomic polarization of *p*-benzoquinone and its derivatives. But it cannot be decided whether the bending of the C=O bonds in this crystal is caused by the packing of oxygen to the adjacent carbon and chlorine atoms, or it is due to the interaction between the dipoles of C=O bonds and the crystalline field.

When the structure of molecule as found here is compared with that of Harding and Wallwork[3] from the crystal structure of the chloranil-hexamethylbenzene complex, there is found a remarkable difference in the orientation of the C=O bond relative to the two adjacent chlorine atoms. The chloranil crystal is yellow and that of complex is purple red. In the complex some interaction between the two kinds of molecules should take place resulting the change of electronic state of the molecule of chloranil, which may cause the bending of the C=O bonds.

(3) Anisotropic Thermal Motion:

Using Cruickshank's[12] method the thermal motions of chloranil molecule were analysed from the observed thermal anisotropic parameters of the oxygen and chlorine atoms. The thermal vibration tensors U_{ij}^{obs}'s for Cl_1, Cl_2 and O atoms were calculated from the data of $\boldsymbol{B}$, Δ and ψ in the three projections, such that

$$\overline{u^2}=\sum_{i=1}^{3}\sum_{j=1}^{3}U_{ij}^{obs}l_il_j\ ,$$

where the mean square amplitude of vibrations of these atoms in the direction specified by a unit vector $\boldsymbol{l}=(l_1, l_2, l_3)$. In these calculations the adopted axes are indicated in Fig. 3 and the results are listed in Table V.

The problems to be solved here are the rigid body vibrations of this molecule. The tensors T_{ij}'s of molecular translational vibrations and the tensors ω_{ij}'s of molecular librations about the centre of molecule then can be calculated by the equations:

$$\sum_{i=1}^{3}\sum_{j=1}^{3}U_{ij}^{obs}l_il_j$$
$$=\sum_{i=1}^{3}\sum_{j=0}^{3}[T_{ij}l_il_j+\omega_{ij}(\boldsymbol{l}\wedge\boldsymbol{r})_i(\boldsymbol{l}\wedge\boldsymbol{r})_j]\ ,$$

where $\boldsymbol{r}$'s were the positions of atoms referred to the molecular co-ordinates shown in Fig. 3. These equations were solved under the condition that the molecule was approximately planar, namely $r_3^2=0$. For the small values of r_3's, the value of ω_{12} was rather

Table V. Observed and Calculated U_{ij}.
(Values in 10^{-2} Å^2)

Atom	U_{11}		U_{22}		U_{33}		U_{12}		U_{13}		U_{23}	
	Obs.	Cal.	Obs.	Cal.	Obs.	Cal.	Obs.	Cal.	Obs.	Cal.	Obs.	Cal.
Cl_1	7.33	6.21	6.99	7.76	7.49	7.51	−3.50	−4.87	3.08	3.06	−0.72	−0.86
Cl_2	7.19	6.09	6.08	7.79	6.43	6.46	−0.91	−0.04	3.23	3.11	−0.09	0.10
O	22.06	8.85	3.68	3.68	5.22	5.15	−2.84	−2.38	3.83	3.62	−0.30	−0.29

indefinite. Moreover this affected the values of T_{33}, ω_{11} and ω_{22} very much. Therefore the value of ω_{12} was determined as to give resonable value for T_{33} compared to those of T_{11} and T_{22}. The results are shown in Table VI. From these results the calculated values of U_{ij}^{cal} are compared to those of U_{ij}^{obs} which are shown in Table V.

Table VI. Values of T_{ij} and ω_{ij}.
(Values of T_{ij} in 10^{-2} Å^2 and ω_{ij} in deg^2.)

$$T=\begin{bmatrix} 4.73 & -2.41 & 2.80 \\ & 3.68 & -0.30 \\ & & 4.86 \end{bmatrix} \qquad \omega=\begin{bmatrix} 1.3 & -2.0 & -3.6 \\ & 8.8 & -0.3 \\ & & 18.1 \end{bmatrix}.$$

From these results, it seems certain that the value of ω_{11} is fairly smaller than those ω_{22} and ω_{33}. This means that the libration about the axis *1* is small but those about the axes *2* and *3* are not so much restricted. These facts are consistent with the orientations of the inter-molecular bonds in this crystal, and with the short distance between an oxygen atom in one molecule and its nearest carbon atom in neighbouring molecule. (cf. Figs. 2 and 3.)

The small corrections for atomic positions due to these librations were calculated by Cruickshank's[12)] method. The corrected bond lengths are shown in Fig. 2.

(4) Puckered Molecular Form:

From the results of X-ray analysis it becomes clear that the oxygen and chlorine atoms connected to the benzene ring construct a puckered form. This steric effect is in harmony with the results calculated by the method of Gafner and Herbstein[13)].

a) The angular distortion energy E_1 for each atom is calculated from:

$$E_1=1/2\cdot k(\Delta x)^2\ ,$$

where Δx is the displacement of an atom from the plane of the carbon skeleton and k is the force constant of its displacement. The force constant for out of plane displacement is generally smaller than that for in plane. Accordingly the value of force constant for each atom is assumed to be: $k=0.05\times10^5$ dyne/cm equally.

b) The van der Waals interaction between a pair of adjacent and non-bonded atoms was treated by Hill[14)]. The van der Waals energy E_2 is given by,

$$E_2=\mathcal{E}_a(r_a{}^*/r)^{12}-2\mathcal{E}_a(r_a{}^*/r)^6\ ,$$

where r is the distance between these atoms and $\mathcal{E}_a$, $r_a{}^*$ are energy parameters for this pair of atoms. The distance r depends upon Δx when the adjacent atoms displace antiparallel whereas it is constant when these atoms displace parallel. The values $\mathcal{E}_a$ and $r_a{}^*$ of a single Cl atom have been determined by Hill[14)] and the values of a single O atom are calculated by the method of Hill[14)] from the data of O_2 gas given by Johnston and McCloskey[15)]. The values $\mathcal{E}_a$ and $r_a{}^*$ of a pair of A and B atom are calculated by the formulas: (cf. Hirschfelder, Curtiss and Bird[16)].)

$$\mathcal{E}_a=\{\mathcal{E}_a(A)\cdot\mathcal{E}_a(B)\}^{1/2}\ ,$$
$$r_a{}^*=1/2\{r_a{}^*(A)+r_a{}^*(B)\}\ ,$$

where the value of $r_a{}^*(A)$ or $r_a{}^*(B)$ means the van der Waals diameter of the atom. Since the van der Waals radii have not been determined very accurately and the energy E_2 depends on $r_a{}^*$ strongly, the energy differences E_2's between planar and puckered molecules are calculated for a few different values of $r_a{}^*$, such that:

if Δx's of adjacent atoms are in the opposite direction,

$$E=E_1+1/2\{(E_2-E_0)_{\mathrm{Cl-O}}+(E_2-E_0)_{\mathrm{Cl-Cl}}\}\quad \text{for Cl atom,}$$
$$E=E_1+(E_2-E_0)_{\mathrm{Cl-O}}\quad \text{for O atom,}$$

and if Δx's are in the same direction,

$$E=E_1\ ,\quad \text{for both atoms,}$$

where E_0 is the van der Waals energy at $\Delta x=0$.

The constants used in the calculations are shown in Table VII and VIII. The results are shown in Figs. 4 (a) and (b).

From these results, for the probable values of k, $\mathcal{E}_a$ and $r_a{}^*$, the energy differences E's of Cl and O atoms show the flat valleys in

Table VII. The constants used in the calculations of potential energy differences of Cl and O atoms.

Atoms and pairs		Cl	O	Cl-Cl	Cl-O
$\varepsilon_a \times 10^{15}$ ergs		21.8	7.56	21.8	12.8

	Pauling[17]	3.6	2.8	3.6	3.2
	Author	3.88	—	3.88	—
$k \times 10^{-5}$ dyne/cm		0.05	0.05	—	—

fairly wide ranges of anti-parallel Δx. The condition which gives the minimum of this potential difference is:

$$(r_a^*)^6 = \frac{1}{2} r^6 \left(1 + \sqrt{1 + \frac{kr^2}{12\varepsilon_a}}\right).$$

In these calculations the value of k may have been estimated somewhat less. When the value of r which gives the minimum of the potential difference is kept constant (the observed atomic distance) and let the value of k increase, r_a^* does not increase very much. (cf. Table VIII.) Moreover, the mean value of van der Waals diameter of Cl atom which has been obtained in this X-ray analysis is 3.88 Å. (cf. Table VII.) Now, the exact values of r_a^*'s are not known, the direct correlation between the theoretical calculations and the results of X-ray analysis of chloranil can not be given with high reliabili-

Table VIII. The combinations of k's and r_a^*'s for which the energy differences show minima at the observed atomic distances $r(\text{Cl-Cl}) = 3.217$ and $r(\text{Cl-O}) = 2.955$ Å.

ty. However, from the calculations given above it can be concluded that the puckered form is stable and that the thermal vibrations are pronounced perpendicular to the molecular plane and anti-parallel to each other.

In the above calculations only the adjacent atoms in the same molecule are taken into account. The oxygen atom has another neighbouring carbon atom which belongs to a neighbouring molecule. (cf. Fig. 2.) The influence of the carbon atom to this oxygen atom should be very large and should give the decisive effect in making the puckered form of the molecule. Moreover, the influence may act also co-operatively to make the puckered form of chlorine atoms. Since there is no such influence in the gaseous state, the O and Cl atoms have even chances protruding to the two sides of the carbon skeleton plane so that the positions of these atoms would be diffused by the thermal vibrations in the shallow potential barriers. Therefore chloranil molecules in the gaseous state may look like planar. The influence of the carbon atom may also hinder the thermal vibration of O atom as we see from the fact that the observed values of U_{22} and U_{33} of O atom are smaller than their corresponding values of Cl atoms. (cf. Table V.)

§ 7. Conclusion

Chloranil and bromanil are isomorphous. These crystals form a sandwich type structure which is composed of two layers of halogen atoms parallel to the (001) plane containing light atom skeletons sandwiched between them. The interactions between the molecules are mainly due to the dipole interaction of C=O bonds, which is also supported by the mode of the thermal librations of chloranil molecules in the crystal. The molecule has a centre of symmetry and the oxygen and chlorine atoms around the plane of carbon skeleton are arranged in a puckered form. By a theoretical calculation of potential difference between the planar and puckered molecules, it is shown that the puckered form is more stable. Moreover there are some found correlation between these potential difference valleys and the anisotropic thermal motions of the oxygen and chlorine atoms. Although the bending of C=O bonds as found by the present analysis which is also supported by a theoretical calculation of the molecular structure, there is still a possibility that this bending is caused by the interaction between molecules. The bond lengths found here have normal values except the C=O bond suggesting there is a small contribution of the single bond.

The author wishes to express his sincere thanks to Professor I. Nitta and Professor T. Watanabé for their guidance and encouragement throughout this work. He also thanks Dr. Y. Sasada for his kind advice and Mrs. K. Sugahara for her help in calculations.

Study on Precipitation Phenomena in Thin Films of Supersaturated Gold-Nickel Alloy

By Yasushige FUKANO*

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai

(Received January 7, 1961)

Structure changes of supersaturated gold-nickel alloy after successive agings were studied by means of electron diffraction and electron microscopy. Specimens were prepared by vacuum evaporation and subsequent quenching (Y. Fukano and S. Ogawa, J. Phys. Soc. Japan 14 (1959) 1671). After aging at temperatures lower than 165°C, side maxima appear beside the main spots from the matrix. The side maxima disappear after aging at 250 - 300°C, indicating that they correspond to pre-precipitations. The side maxima were interpreted by assuming a modulated structure similar to that found in Au-Pt alloy by Tiedema et al. (T.J. Tiedema, J. Bouman and W.G. Burgers, Acta Metallurgica 5 (1957) 310). This implies that gold-nickel alloy at the pre-precipitation stage contains a modulated structure similar to that in Au-Pt alloy. After aging at temperatures higher than 300°C, two stable phases with parallel lattices appear. In this state, Widmanstätten structure was found in electron micrographs.

§ 1. Introduction

Since quenching of thin films was difficult so far,[1] aging of alloys has not been studied with thin films prepared by vacuum evaporation. Recently, the present author and Ogawa[2] developed a new technique to quench thin films and studied the aging of Al-Ag alloy. In the present experiment, single crystalline films of Au-Ni alloy were quenched by this technique and structure changes of the films after aging were studied by electron diffraction and electron microscopy.

After aging at temperatures lower than 165°C, side maxima appear at low angle side of main spots from the matrix. The side maxima disappear after aging at 250–300°C. This implies that pre-precipitates formed by low temperature aging are dissolved. The side maxima were explained as a kind of the so-called "side bands" investigated by Daniel and Lipson.[3] After aging at temperatures higher than 300°C, two stable phases with parallel lattices appear. In this state, Widmanstätten structure was found in electron micrographs.

§ 2. Experimental

The present study was carried out using single crystalline films of Au-20 atomic % Ni alloy (Fig. 1) prepared by vacuum evaporation.

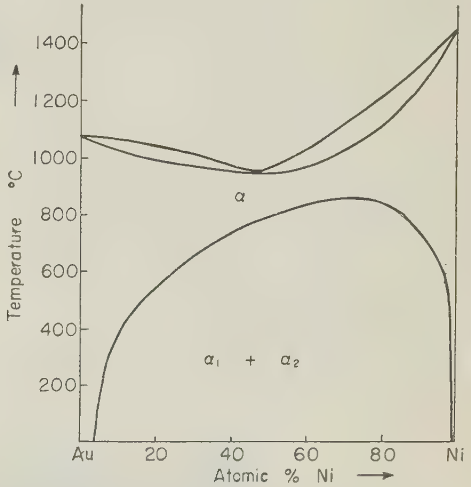

Fig. 1. Equilibrium phase diagram of Au–Ni system.

a) Specimen preparation

The two component metals of this alloy were simultaneously evaporated in vacuum onto fresh cleavage surfaces of rocksalt which were maintained at about 430°C after preheating up to 500°C. The mean thickness of films was about 700 A estimated from the total amount of evaporated metals. Films prepared in this way were well orientated, their surfaces being parallel to (001) plane. It was observed by means of electron microscopy that the thickness of the films were not uniform in most cases. In the present work, however, four most uniform films were selected as specimens. Non uniform films were destroyed during the quenching.

---

* Now at Department of General Education, Nagoya University.

b) Quenching and aging

The specimens were first homogenized by heating in vacua at about 700°C for 2 hr and then quenched to room temperatures by the method described in the previous section. Thus the films of homogeneous supersaturated solid solution were obtained. They were aged in vacua at various temperatures for various periods of time. For temperatures below 165°C, the aging was carried out in the chamber immersed in boiling water or oil bath, and for temperatures above 200°C, in a transparant quartz tube tightly wound by nickrome-wire.

c) Electron diffraction and electron microscopy

The diffraction camera used was a conventional type with a single lens and had camera length about 30 cm. The electron microscope used was Hitachi HU-7. The operating voltage of electron diffraction camera and electron microscope was 50 kV. Electron micrographs were taken at magnification 4,000 X. For the measurement of lattice constants, evaporated gold films aged at about 500°C for 2 hr in vacua were used as standard, adopting lattice constant a=4.070 kX (Wyckoff[4]).

§3. Experimental Results

The four specimens were examined through all the subsequent agings after quenching. The diffraction patterns were taken at various stages of aging. The results are summarized in Table I.

a) Aging at room temperatures

Photo. 1 shows a diffraction pattern of the specimen aged for 2 hr at room temperatures. The pattern shows that the specimen consists of a single phase of the face centered cubic lattice. The lattice constants obtained from all the specimens are listed in Table II. They are independent of the period of aging. The mean value 3.98±0.01 kX agrees with the X-ray value of the homogeneous solid solution of Au-20 atomic % Ni alloy.[5]

Table I. The results obtained from electron diffration patterns at various of aging.

2	10	3.99±0.01
3	24	3.98±0.01
4	72	3.97±0.01
	mean	3.98±0.01

b) Aging at temperatures 100–200°C

The diffraction patterns were taken at the stages of aging for 2 hr, 7 hr and 13 hr at 100°C and for 2 hr at 165°C. Some of the main spots are accompanied by weak side maxima or are pear-shaped. The main spots correspond to the face centered cubic lattice. The lattice constant is 3.98±0.01 kX which is the same as that of the quenched specimen.

Photo. 2 shows a diffraction pattern taken from the specimen aged at 100°C for 2 hr. In Photo. 2 the incident beam is in [001] direction. The (200)-spots are pear-shaped, elongated towards the low angle side. On the original plate of Photo. 2 it can be observed that the (220)-spots and other higher order spots are also elongated towards the low angle side, parallel to the elongation of (200)-spots. When, however, the specimen is

slightly tilted, pear-shaped spots are observed to split into weak side maxima and main spots, although it is difficult to reproduce the details of this splitting on the print. Photo. 3 was taken by rotating the specimen about 45′ around $[1\bar{1}0]$ axis from the position in which Photo. 2 was taken. The spots (200), (020), $(2\bar{2}0)$ and $(\bar{2}20)$ which lie near the boundary of 0-th Laue zone are accompanied by weak side maxima. Photo. 3 is reproduced schematically in Fig. 2, where dots and crosses represent the side maxima. Side maxima corresponding to the dots in

165	2
250—300	1
250—300	4
400—500	1
700	2

Photo. 5. The variation of (200)-spot and the associated side maximum during aging at various temperatures. α, α_1 and α_2 indicate the main spot from α, α_1 and α_2-phases, respectively. Arrows in (b), (c) and (d) indicate the side maxima.

Fig. 2 are reproduced in the enlargements given in Photo. 3. Those corresponding to the crosses are extremely weak and can be observed only on the original plates. The spots $(\bar{2}00)$, $(0\bar{2}0)$ and $(\bar{2}\bar{2}0)$ lie on the Kikuchi bands with the same indices in Photo. 3. The side maxima accompanying these spots are hardly observed. When Bragg condition is exactly satisfied each main spot is so strong that it masks the weak side maxima associated to it. The effect of masking may become serious by the strong diffuse inelastic scattering which accompanies each Bragg spot.

Since it was impossible to observe all the side maxima at the same time, the side maxima around each main spot were investigated by tilting the specimen films. The distance Δr between a main spot and the associated side maximum was measured in many diffraction patterns (Table III). It is found in Table III that the value of Δr is constant independent of the angle of inclination θ. θ is the angle between the normal of the specimen surface and the incident beam. Photo. 4 shows this fact: Distance Δr remains constant, although Photo. 4 (b) and 4 (c) are taken at $\theta=45'$ and $2°10'$, respectively. Based upon the fact that Δr is constant, it is concluded that the intensity regions of the main maximum and the associated side maximum in the reciprocal space are juxtaposed in (010) plane, as illustrated in Fig. 3. The elongation of the region normal to (001) reciprocal plane in Fig. 3 may be caused by bending of the specimen films. For higher order spots the side maxima are not observed although each spot is slightly elongated towards the low angle side. Summarizing the observations, the intensity distribution on the (001) reciprocal plane as shown in Fig. 4 is concluded.

c) *Aging at 250–300°C*

Photo. 5 shows the variation of (200)-spot from the specimen at the various stages of aging. At 250–300°C the side maximum still remains after aging for 1 hr. When, however, the specimen is further aged for 3 hr the side maximum disappears. Thus the diffraction pattern looks similar to that taken just after quenching (Photo. 5 (a)). The lattice constant is also the same as that of the quenched specimen. However, the background of Photo. 5 (e) is much lower than that of Photo. 5 (a), although the change is

hardly recognized in the reproduction. This change indicates that imperfections in the specimen have been decreased. The specimen which has once been aged at 300°C for more than 4 hr and has lost its side maxima shows none of them even when it is again aged at temperatures 100–200°C.

d) *Aging at 400–500°C*

The specimens were successively aged at

Sections of intensity regions cut by Ewald spheres a, b and c.

Fig. 3. The illustration of the intensity region of (200)-spot and the associated side maximum. Sections of intensity regions (a′), (b′) and (c′) correspond to Photos. 4 (a), 4 (b) and 4 (c), respectively.

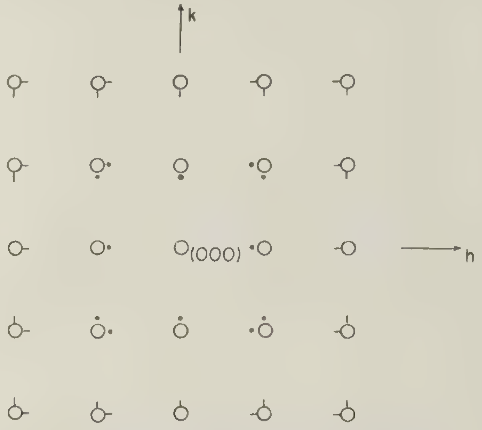

Fig. 4. The illustration of the intensity distribution on (001) reciprocal plane. Open circles and dots indicate main spots and the side maxima, respectively.

high temperatures after the side maxima disappeared. Photo. 6 shows a diffraction pattern taken from the specimen aged at 400–500°C for 1 hr and then cooled slowly to room temperatures. The main spots (α_1 in Photo. 6) correspond to a face centered cubic lattice of lattice constant 4.05±0.01 kX. They are accompanied by weak spots (α_2 in Photo. 6) corresponding to another face centered cubic lattice of lattice constant 3.52±0.01 kX. The two lattices are parallel to each other.

Photo. 7 shows a diffraction pattern of the specimen further aged at 700°C for 2 hr and then cooled slowly to room temperatures. The weak spots in Photo. 6 have become a little stronger in Photo. 7 and spots are multiplied by double reflections. The lattice constant of each lattice remains the same as that given above.

The lattice constants 4.05 kX and 3.52 kX agree respectively with X-ray value of Au-6 atomic % Ni (α_1-phase) and that of Ni-1 atomic % Au (α_2-phase) given by Köster et al.[5] Since the α_2-phase has grown parallel to the matrix phase, it can be expected that there is Widmanstätten structure.

e) *Electron microscopy*

Photo. 8 shows an electron micrograph taken from the specimen aged for 2 hr at 165°C. In this micrograph the images of the modulated structure, details of which will be described later, corresponding to the side maxima are not observed. Small black dots, loops and short lines are visible on the original plate at the locations denoted by a, b and c. They may be images of dislocations.6) 7) Loops have irregular elliptic shapes and the smallest diameter was estimated to be 200 Å. The distribution of loops is not uniform.

Photo. 9 is the electron micrograph corresponding to Photo. 7. White short lines nearly parallel to ⟨100⟩ are visible in Photo. 9. The average dimension of short lines is estimated to be 200 Å in width and 500 Å in length. Some of short lines appear to have L-shape. Since they are not observed in Photo. 8, the appearance of them may be related to the precipitation of α_2-phase. The distribution of white short lines is not uniform. We consider that this pattern corresponds to Widmanstätten structure which is expected from the diffraction pattern (Photo. 7).

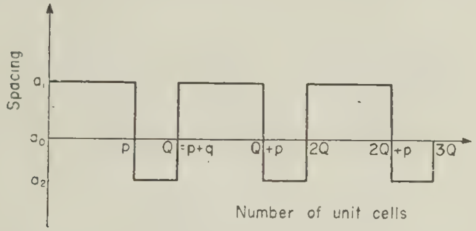

Fig. 5. A model of modulated structure given by Tiedema et al.8)

§ 4. Interpretation of Side Maxima

In interpreting Fig. 4, it might be possible to assume that a new phase with a tetragonal lattice, which is parallel to the lattice of the matrix, had precipitated in the matrix, c-axis taking three orientations parallel to the cubic axes of the matrix. If so, the lattice constant a of the new phase is $a=3.98\pm0.01$ kX, the same as the lattice constant a_0 of the matrix, and the lattice constant c is $c=4.11\pm0.01$ kX calculated from the distance between the incident spot and the side maximum of (200). This tetragonal phase must be either the matrix phase deformed from the face centered cubic lattice or a newly precipitated phase. According to Vegard's law, however, spacing larger than that of gold, $a=4.070$ kX, is impossible in any substitutional solid solution of gold and nickel. Thus the assumption that the new tetragonal phase exists is impossible and the side maxima must be interpreted from a different standpoint.

According to X-ray study of Au-Pt alloy by Tiedema et al.,8) two side bands besides main reflections appear in the early stages of aging and disappear at the later stages. These side bands are attributed to the following modulated structure: The modulation occurs along a cubic axis and its wave-length is Qa_0, where a_0 is the lattice constant of the matrix (Fig. 5). Out of Q layers, p layers are Au rich and q layers are Pt rich, where $q=Q-p$. The spacing of p layers and that of q layers are assumed respectively to be $a_1=a_0(1+q\delta)$ and $a_2=a_0(1-p\delta)$, where δ is a parameter. Ratio p/q is assumed to be the same as that of the amount of the two stable phases which would be obtained at room temperatures.

Au-Ni alloy system studied in the present experiment has the equilibrium phase diagram similar to that of Au-Pt alloy system (Fig. 1). The behavior observed for Au-Ni that the side maxima appear at the early stage and disappear at the later stage of aging is also similar to the behavior for Au-Pt. From these similarities, it is reasonable to attribute the side maxima to the modulated structure as that of Au-Pt alloy. The wave-length of modulation Qa_0 is given by the distance between a main spot and the associated side maxima (Δr of Table III) using the relation

$$\Delta r\cdot Qa_0=\Lambda L, \qquad (1)$$

where Λ is the wave-length of electron wave and L, the camera length. Value of Q turned out to be 17. The ratio p/q is determined from the phase diagram (Fig. 1) and thus $p=14$ and $q=3$ are obtained. It may be reasonable to determine parameter δ by assuming that ratio $(1+q\delta)/(1-p\delta)$ is equal to ratio $a_1/a_2=4.05/3.52$, where a_1 and a_2 are lattice constants of stable α_1 and α_2-phases, respectively. Then δ turns out to be 0.008.

The amplitude of electron wave diffracted by the modulated structure is given by

$$A=\sum_{m=0}^{M-1}\{\sum_{s=0}^{p-1}F_A\exp 2\pi ihs(1+q\delta)+\sum_{t=0}^{q=1}F_B\exp 2\pi iht(1-p\delta)$$
$$\times\exp 2\pi ih\,p(1+q\delta)\}\exp 2\pi ihmQ, \qquad (2)$$

where F_A and F_B are the structure amplitudes of each layer of Au-rich phase and Ni-rich phase, respectively; h, the index of reflection and M, the number of wave-lengths Qa_0. The intensity is, therefore, given by

$$I=\Bigg[\,|F_A|^2\frac{\sin^2\pi hp\,(1+q\delta)}{\sin^2\pi h\,(1+q\delta)}+|F_B|^2\frac{\sin^2\pi hq\,(1-p\delta)}{\sin^2\pi h\,(1-p\delta)}$$
$$+2|F_A|\,|F_B|\,\frac{\sin\pi hp\,(1+q\delta)}{\sin\pi h\,(1+q\delta)}\cdot\frac{\sin\pi hq\,(1-p\delta)}{\sin\pi h\,(1-p\delta)}$$
$$\times\cos\pi hQ\,(1+\delta)\Bigg]\frac{\sin^2\pi MQh}{\sin^2\pi Qh}. \tag{3}$$

The intensity given by the formula (3) has the subsidiary maxima at $h=h_0+\frac{n}{Q}$, where h_0 is the index of main maxima and n, an integer.

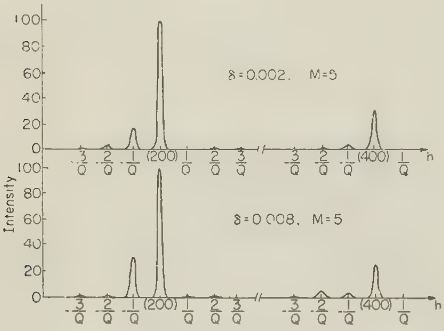

Fig. 6. The calculated intensity curves of (200) and (400)-spots in the reciprocal space.

Fig. 6 shows the intensity curves in the reciprocal space calculated for $\delta=0.002$ and 0.008. Value of M is assumed to be 5. Independent of the value of δ, subsidiary maxima appear only on the low angle side of (200) and (400) main maxima. Subsidiary maxima around (220) are expected to appear on [100] axis similarly to those of (200). The modulated structure in specimen films may be formed along three main axes of the matrix. Thus a diffraction pattern corresponds to the superposition of the intensity regions of three orientations.

The agreement between the observation and the theory is good in the fact that no side maxima is observed in high angle side. It may be reasonable that the second order side maximum at low angle side was not observed, because the expected intensity is too weak. The elongation of (400) spots towards low angle side (Fig. 4) is also in accordance with the theory.

§ 5. Discussions and Conclusions

a) *Side maxima*

The side maxima observed in the present experiment are a kind of the so-called "side bands" investigated by Daniel and Lipson.[3] The side bands observed by them were symmetric across a main reflection and interpreted by assuming sinussoidal modulation of spacing (Fig. 7 (a)). In the case of Al-Cu,

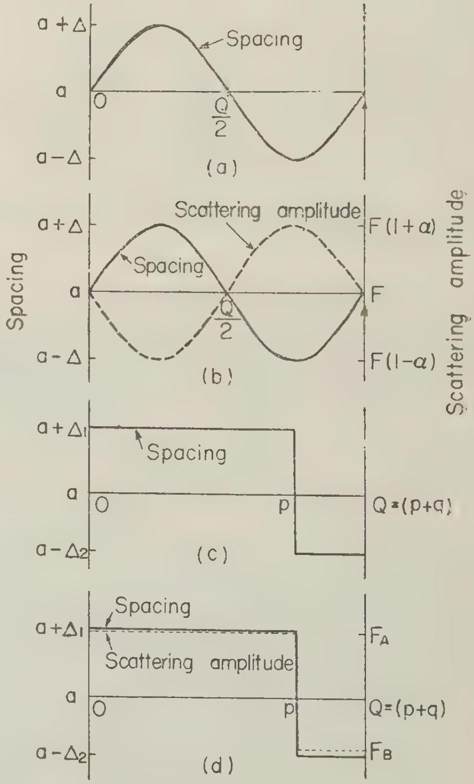

Fig. 7. Modulations given by Daniel-Lipson (a), Wilson (b), Tiedema et al. (c) and the present author (d). Δ and α are amplitudes of the modulation in spacing and scattering amplitude, respectively. Q, p and q are the number of unit cells.

Guinier[9] and Preston[10] observed asymmetric streaks extending towards high angle side. Wilson[11] explained the streaks as follows: Asymmetric side maxima are expected if modulations are assumed both for the spacing and for the scattering amplitude (Fig. 7 (b)). Moreover, the side maximum on low angle side vanishes provided $h_0 Q \Delta = \alpha$, where h_0 is the index of the main reflection and Δ and α are amplitudes of the modulation in spacing and scattering amplitude, respectively. If parameter Q is not a constant, the side maximum extends into a streak. In the case of Au-Pt, Tiedema et al.[8] observed asymmetric side bands. The intensity of the side band on low angle side was stronger than that on high angle side. Tiedema et al. assumed a periodic modulation as illustrated in Fig. 7 (c) to interpret the difference of intensity of both side bands. In the present case of Au-Ni, the side maxima are observed on the low angle side alone. We assumed modulations as illustration in Fig. 7 (d) to interpret the side maximum on low angle side. Each type of the modulations (Fig. 7) depends on the size of atoms and the scattering factor (Table IV).

Table IV. Size and scattering factor of component atoms.

Author	Alloy	Scattering amp.	Size of atoms
Daniel-Lipson	Cu–(Fe–Ni)	$f_{Cu} \sim (f_{Fe}$ or $f_{Ni})$	$r_{Cu} > (r_{Fe}$ or $r_{Ni})$
Wilson	Al–Cu	$f_{Al} < f_{Cu}$	$r_{Al} > r_{Cu}$
Tiedema et al.	Au-Pt	$f_{Au} \sim f_{Pt}$	$r_{Au} > r_{Pt}$
Present author	Au-Ni	$f_{Au} > f_{Ni}$	$r_{Au} > r_{Ni}$

b) *Formation of modulated structure*

For aluminium alloys, the formation of pre-precipitates at low temperatures has been explained as due to quenched-in vacancies which increase the diffusion rate of solute atoms.[12] In the present case of Au- Ni, the formation of modulated structure at low temperatures may also be explained as due to quenched-in vacancies. This explanation is supported by the result that the modulated structure is not produced by re-aging at low temperatures after reversion. Because the excess vacancies have been annealed out in the reversion process, the diffusion rate of Ni-atoms becomes too small to produce pre-precipitates again. The decrease of vacancies in the matrix has been proved also by the decrease of background intensity in diffraction pattern (§ 3(c)).

In the present case, the aging is carried out in the region of temperatures where the second derivative of free energy to composition is negative.[13] The segregates formed in the matrix, therefore, will grow further by mechanism of up-hill diffusion. The surrounding matrix becomes Au-rich. Thus, the modulated structure will be formed by the periodic repetition of the segregation and growth.

Flinn et al.[14] supposed that the homogeneous solid solution of Au-Ni alloy must have a locally ordered structure to reduce the large strain energy in the supersaturated solid solution. In the present experiment, such an ordered structure is not found. The large strain energy may be reduced by the formation of the modulated structure.

Based upon the measurements of electrical resistivity and other physical properties, Sivertsen et al.[15] suggested that metastable precipitates are formed in Au-30 atomic % Ni alloy during aging below 225°C. They supposed that the metastable precipitates are solute rich clusters, solvent-rich clusters or highly ordered regions in the matrix. In the present experiment, it has been made clear that the pre-precipitates have the modulated structure. The pre-precipitates in the present experiment are formed below 300°C while in Sivertsen's experiment, below 225°C. The difference may be due to the difference of compositions of alloys used in both experiments.

c) *True precipitation*

Köster et al.[5] found that the supersaturated solid solution of Au-Ni alloys decomposed by a discontinuous reaction into two phases of an Au-rich solid solution (α_1-phase) and a Ni-rich solid solution (α_2-phase) for aging at temperatures higher than 400°C. According to them, the process of the precipitation proceeds by inhomogeneous precipitation.

In the present work, the homogeneous solid solution of Au-20 atomic % Ni alloy decomposed into two phases of α_1 and α_2 in the whole specimen film after aging at 400–500°C for 1 hr. Since the rate of precipitation in thin evaporated films is larger than that in bulk crystals, we consider that the inhomogeneous precipitation could not be observed in the present experiment.

Tiedema et al.[8] found Widmanstätten structure in Au-Pt alloy. Although Köster et al.[5] did not find Widmanstätten structure in bulk crystals of Au-Ni alloys, the structure is observed in the present experiment (Photo. 9). However, the structure is of dimension several hundred Ångstroms. This may be attributed to the large difference between lattice parameters of two phases, because well-developed Widmanstätten structures are observed for nearly equal lattice parameters.[16] α_2-phase precipitates as the plate parallel to the cubic plane in the matrix. Such a precipitation was also found in Cu-Ag alloys.[17]

Ellwood et al.[18] found from the density measurement that there are very many vacancies in the homogeneous solid solution of Au-Ni alloys, particularly in Au-20 atomic % Ni and Ni-10 atomic % Au. We, therefore, consider that small loops shown in Photo. 8 are dislocation rings which are formed by the collapse of aggregates of vacancies.[7]

§ 6. Acknowledgement

In conclusion the author should like to thank to Prof. S. Ogawa for suggesting this investigation and for guidance throughout the work. Thanks go to Prof. R. Uyeda and Prof. K. Kimoto for helpful discussions.

A Direct Determination of the Crystal Structure of Ethylenediammonium Sulphate

By Kiichi SAKURAI

Department of Physics, Faculty of Science, Osaka University,
Nakanoshima, Osaka, Japan

(Received February 28, 1961)

The Harker-Kasper inequality method was applied successfully to determine most of the signs of structure factors of ethylene diammonium sulphate. Starting from these signs the final Fourier projections on (001) and (100) were obtained. The dimensions of the unit cell containing eight formula units are $a=8.47\pm0.02$ A, $c=18.03\pm0.04$ A, and the space group is $D_4^4-C4_122_1$ or $D_4^8-C4_322_1$. The ethylenediammonium group is of gauche type with an azimuthal angle of 75.7°. The hydrogen bond distances found in this crystal are 2.80 A, 2.81 A, and 2.82 A. The existence of only one kind of two mirror-image configurations of the ethylenediammonium ion in one of the enantiomorphous forms of this crystal may be an important cause of the strong optical rotatory power of the crystal.

§1. Introduction

Crystals of ethylenediammonium sulphate, $(NH_3CH_2CH_2NH_3)SO_4$, are tetragonal and are known for the strong optical rotatory power, 15.5°mm^{-1} for the *D*-line of sodium.[1] In order to obtain a structural basis for the interpretation of the optical activity as well as information on the role of hydrogen bond in this crystal, its structure has been analyzed by X-ray methods. The accurate determination, if possible, of the sulphate and the ethlyenediammonium groups in this crystal is another purpose of this investigation.

From the structure-analytical point of view, this crystal proved to be a suitable example for the application of the inequality method,[2] which permits many of the signs of structure factors to be determined from intensity data. The present author devised a convenient graphical method for applying some important inequalities and used it for the determination of the signs of structure factors $F(hk0)$'s and $F(0kl)$'s of this crystal.[3] The intensity data were also used by Okaya and Nitta as the first example of the application of their linear inequalities.[4]

§2. Experimental

(1) *Unit cell and space group*

The crystallographic description of this substance is given by Groth.[1] Single crystals used in this investigation were obtained by slow evaporation of an aqueous solution at room temperature in a desiccator. Laue photographs showed the tetragonal holohedral symmetry. Oscillation photographs about the *a* and *c* axes, and equatorial Weissenberg photographs about the *c* axis were taken with filtered Cu $K\alpha$ radiation. The diameters of the rod specimens along the *a* and *c* axes used for the oscillation and Weissenberg photograghs were 0.13 mm and 0.22 mm respectively. The dimensions of the tetragonal unit cell obtained from oscillation photographs are $a=8.47\pm0.02$ Å, $c=18.03\pm0.04$ Å. The density given by Burgers[5] is 1.625 g.cm^{-3}, and the value calculated for eight formula units per cell is 1.62 g.cm^{-3}. Systematic absences of reflections are observed in (hkl) when $h+k\neq 2n$, in $(hh0)$ when $h\neq 2n$, and in $(00l)$ when $l\neq 4n$. Hence the space group is $D_4^4-C4_122_1$ or $D_4^8-C4_322_1$. By axial transformation the lattice parameters become $a=5.99$Å, $c=18.03$Å, and the notation of the space group $P4_12_1$ or $P4_32_1$. These crystallographic data are in good agreement with those given by Burgers.[5] In the present investigation the former set of axes was chosen, because it was easier to obtain rod specimens along the *a* axis based on the former axial system.

(2) *Intensity data*

The $(hk0)$ and $(0kl)$ intensities of oscillation photographs were measured with a microphotometer using a standard intensity scale, and the ($hk0$) intensities recorded on multiple-film integrated Weissenberg photographs were estimated visually by comparison with a standard intensity scale. Corrections for polarization and Lorentz factors were applied in the usual way. As the dimensions of the specimens were small, no correction for absorption was considered neccessary. Approximate values for a scale factor and a temperature-factor parameter were obtained by Wilson's method,[6] due allowance being made for overlapping of atoms in the (001) projection as anticipated from the cell dimensions. The value of the temperature-factor parameter was found to be 2.0 Å². The final values of the scale factor and the temperature-factor parameter were determined by comparison of observed structure factors with calculated values.

§ 3. Structure determination

For the space group $D_4^4-C4_122_1$, there exist two sets of positions, special eight-fold and general sixteen-fold position:

$(000:\ \frac{1}{2}\,\frac{1}{2}\,0)+$

8: (a) $x, 0, 0:\ \bar{x}, 0, \frac{1}{2}:\ \frac{1}{2}, x, \frac{1}{4}:\ \frac{1}{2}, \bar{x}, \frac{3}{4}.$

16: (b) $x, y, z:\ \bar{x}, \bar{y}, \frac{1}{2}+z:\ \frac{1}{2}-y, x, \frac{3}{4}+z:$
$\frac{1}{2}+y, \bar{x}, \frac{3}{4}+z:$
$x, \bar{y}, \bar{z}:\ \bar{x}, y, \frac{1}{2}-z:\ \frac{1}{2}+y, x, \frac{3}{4}-z:$
$\frac{1}{2}-y, \bar{x}, \frac{3}{4}-z.$

As the number of formula units in the unit cell is eight, sulfur atoms occupy the special eight-fold positions, and nitrogen, carbon, and oxygen atoms the general positions. The Harker-Kasper inequality method was applied, for it was expected that this structure could be solved by this method. Although the structure does not possess a center of symmetry, its projection on (001) and (100) are both centrosymmetric, and it is sufficient to determine the sings of $F(hk0)$'s and $F(0kl)$'s to obtain the Fourier projections onto these two planes. One of the fundamental set of inequalities[7)]

$$(U_H \pm U_{H'})^2 \leq (1 \pm U_{H+H'})(1 \pm U_{H-H'}),$$

where U_H is the unitary structure factor for the reflection $H=hkl$, was used. The magnitudes of structure factors, $U(hk0)$'s and $U(0kl)$'s, were derived from the structure factors converted into an absolute scale by Wilson's method. The application of the above inequality was carried out using a chart devised by the present author. A detailed description of the use of the chart and the procedure of sign determination has already been published.[3)]

(1) (001) *projection*

The values of the unitary structure factors and the signs determined by the inequality method are given in Table I. An arbitrary parameter ξ is connected with $U(hk0)$'s with h and k both odd, and this corresponds to the arbitrariness of the choice between the two sets of origins (00), ($\frac{1}{2}\frac{1}{2}$) and ($\frac{1}{2}$0), (0$\frac{1}{2}$). Putting $\xi=-1$, a Fourier projection on (001) was synthesized. It is shown in Fig. 1. After the completion of analysis, it was found that the signs of (400), (390), and (570) were wrong. A Fourier projection including all $F(hk0)$'s with their correct signs is shown in Fig. 2. A comparison of these two Fourier maps shows that the inequality method leads to an essentially correct map except minor details. As anticipated from the unit-cell dimensions, there is a considerable overlapping of atoms in the (001) projection, and the parameters of

the atoms other than the sulfur atom cannot be obtained from this projection. However, the symmetry of the structure allows the x and y parameter of the light atoms to be determined simultaneouly from the (100) projection.

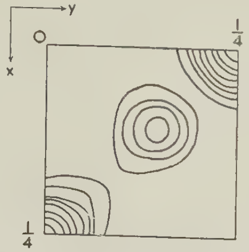

Fig. 1. Fourier projection on (001) based on the signs determined by the inequality method alone. Contours are drawn at equal arbitrary intervals.

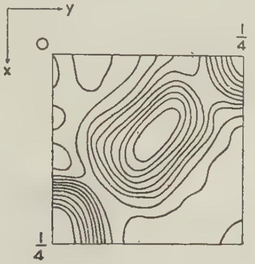

Fig. 2. Final Fourier projection on (001). Contours are drawn at intervals of 2 e.A^{-2}, except around sulfur atom where contours are at intervals of 4 e.A^{-2} starting at 14 e.A^{-2}.

(2) (100) *projection*

The values of the unitary structure factors and the signs determined by the inequality method are given in Table II. In this case two arbitrary parameters, η and ζ, are connected with reflections with $k=2\times$odd, $l=$even and those with $k=2\times$even, $l=$odd respectively. This corresponds to the arbitrariness of the choice of origin out of four points (00), (0$\frac{1}{2}$), ($\frac{1}{4}$0), and ($\frac{1}{4}\frac{1}{2}$). Putting $\eta=+1$ and $\zeta=-1$, a Fourior projection on (100) was synthesized. It is shown in Fig. 3. In this projection all atoms are fairly well resolved, and it was possible to obtain approximate parameter values. From the Fourier projections on (001) and (100) using the signs obtained by the inequality method, it can already be seen that the configuration of the ethylenediammonium ion is gauche. By successive Fourier approximation, the final projection on (100) was synthesized using all the observed F's. It is shown in Fig. 4. In order to refine the struc-

ture, (F_o-F_c) syntheses were calculated, and, after eight successive calaulations, the final atomic parameters and the temperature-factor parameter were determined by the same procedure as mentioned by Cochran.[8] The final difference map is shown in Fig. 5. It shows peaks in the positions expected for the hydrogen atoms from a model of the ethylenediammonium ion, and reasonable parameter values can be assigned to them. Using the formula of Cruickshank[9] for the standard deviation of electron density, $\sigma(\rho_o)$,

$$\sigma(\rho_o)=\frac{1}{A}[\sum(F_o-F_c)^2]^{1/2}$$

where A is the area of the cell in projection, $\sigma(\rho_o)$ for the (100) projection was found to be 0.69 e.Å^{-2}

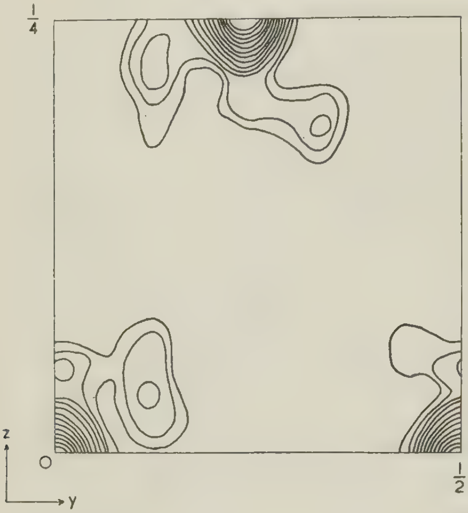

Fig. 3. Fourier projection on (100) based on the signs determined by the inequality method alone. Contours are drawn at equal arbitrary intervals.

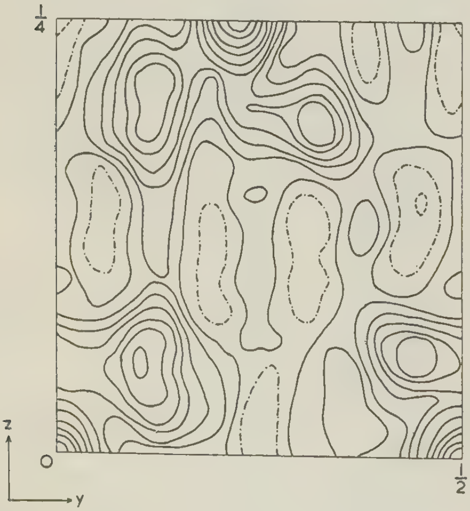

Fig. 4. Final Fourier projection on (100). Contours are drawn at intervals of 2 e.A^{-2}, except around sulfur atom where contours are at intervals of 4 e.A^{-2} starting at 10 e.A^{-2}. Chain lines represent zero contour and broken lines negative contours.

The final atomic parameters are listed in Table III. The observed and calculated structure factors, F_o and F_c, are given in Table IV. The calculated values include the contribution from hydrogen atoms. The average temperature-factor parameter is 1.72 Å^2. The atomic scattering factors used in the calculation are those given in the 'Internationale Tabellen'.[10] The values of R indices for ($hk0$) and ($0kl$) zones are 12% and 16% res-

pectively, non-observed reflections being included.

§ 4. Discussion of the structure

Interatomic distances and bond angles are given in Table V. Owing to the overlapping of atoms, the standard deviations of the interatomic distances cannot simply be estimated by the usual formula,[9] so that any significance cannot be attached to the differences between the values found in the present work and those reported. Therefore a mere comparison of the former with the latter will be made. In the following discussion the sulphate group and the ethylenediammonium group are first dealt with, and then the linkage of ions in the

Table V. Interatomic distances and bond angles.

azimuthal angle 75.7°			

structure is described.

(1) *Sulphate group*

The S–O distance in the sulphate group has been discussed be Wells[11] and Pauling.[12] Pauling has given a value of 1.51 Å as a predicted S–O distance after taking into account the ionic character of σ bond and the amount of π bond character and has stated that this value is in good agreement with an average of observed distances, 1.50Å. The average S–O distance of 1.49 A found in the present investigation is close to this predicted value.

(2) *Ethylenediammonium group*

A striking feature of this crystal structure is that the configuration of the ethylenediammonium group is not trans but gauche with the symmetry C_2. (see Fig. 6.) The azimuthal angle of one half of the group with respect to the other is 75.7°, which is much larger than 60°. This large azimuthal angle may be due to the intramolecular repulsion between two NH_3^+ groups. The C–N^+ distance of 1.49Å is in good agreement with those found in amino hydrohalides, amino acids, and peptides.* The reported values range from 1.46Å to 1.52Å. Cox and Jeffrey[13] have reviewed reported values of the C–N single bond distance and have concluded that they lie within a small range about the average value 1.47Å. Hall and Llewellyn[14] have examined C–N^+ bond distances reported until 1953 and have concluded that the best value is 1.47–1.48 Å. They have also compared C–N^+ distances with C–N distances and have pointed out that there is no evidence of bond shortening of the former, relative to the latter, due to the formal charge effect which is estimated to be about 0.03Å by Pauling. In a review concerning the structural data of amino acids and carboxylic acids published by Hahn,[15] it has been remarked that the C–NH_3^+ distance is 1.50 Å, which is 0.03 Å longer than the normal C–N single bond length.

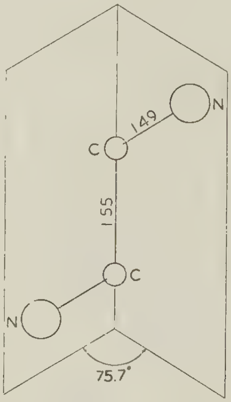

Fig. 6. Structure of the ethylenediammonium group. Bond lengths are given in Angström units.

As the ethylenediammonium ion has the gauche configuration, two mirror-image configurations are possible, and only one kind of the two forms exists in one of the enantiomorphous forms of this crystal. This may be considered to be an important cause of the strong optical rotatory power of this crystal.

(3) *Linkage of sulphate and ethylenediammonium groups*

The structures projected on (001) and (100) are shown in Fig. 7 and Fig. 8 respectively. As can be seen from Fig. 8, the structure can conveniently be described as built up of layers, parallel to (001), containing ethylenediammonium and sulphate groups. Each nitrogen atom is surrounded by six oxygen atoms at distances 2.80, 2.81, 2.82, 3.26, 3.31, and 3.32Å The N-···O distances, 2.80, 2.81, and 2.82Å can be interpreted as hydrogen bonds. These values lie within the range of values reported by Donohue[16] in his list of N–H···O hydrogen bond distances and of those reported later for amino acids and peptides. The arrangement of these three oxygen atoms around the nitrogen atom is shown in Fig. 9, where their positions are projected upon the plane perpendicular to the C–N bond. In this figure the positions of the hydrogen atoms derived from the difference synthesis are also shown. The C–N···O angles are found to be 108.7°, 106.5°, and 103.5°, all being near-tetrahedral value, and the hydrogen atoms lie nearly on the lines connecting the nitrogen and the oxygen atoms. This situation favors the formation of strong hydrogen bonding.16) In each layer ethylenediammonium and sulphate groups are linked by two sets of hydrogen bonds of lengths 2.80, 2.81Å and N···O contacts with distances 3.31, 3.32Å, while these layers are held together by hydrogen bonds of length 2.82A and N···O contacts with a distance 3.26Å. As the number of linkages between layers formed by each nitrogen atom is smaller than that within a layer, a nearly perfect cleavage parallel to (001) can be accounted for by this structure.

---

* The C—N bond considered here refers to the C—NH_3^+ bond of a terminal nitrogen atom.

§ 5. A remark on the use of the inequality method

In this structure the ethylenediammonium ion has the gauche configuration, and this unexpected result has been established unambiguously by the use of the inequality method. This work has thus demonstrated the usefulness of the inequality method in determining a crystal structure in which molecules or molecular ions have an unknown or unexpected strucrure. It will be useful also in determining the average structure of a disordered crystal without any trial-and-error process.

In order that the first Fourier synthesis may

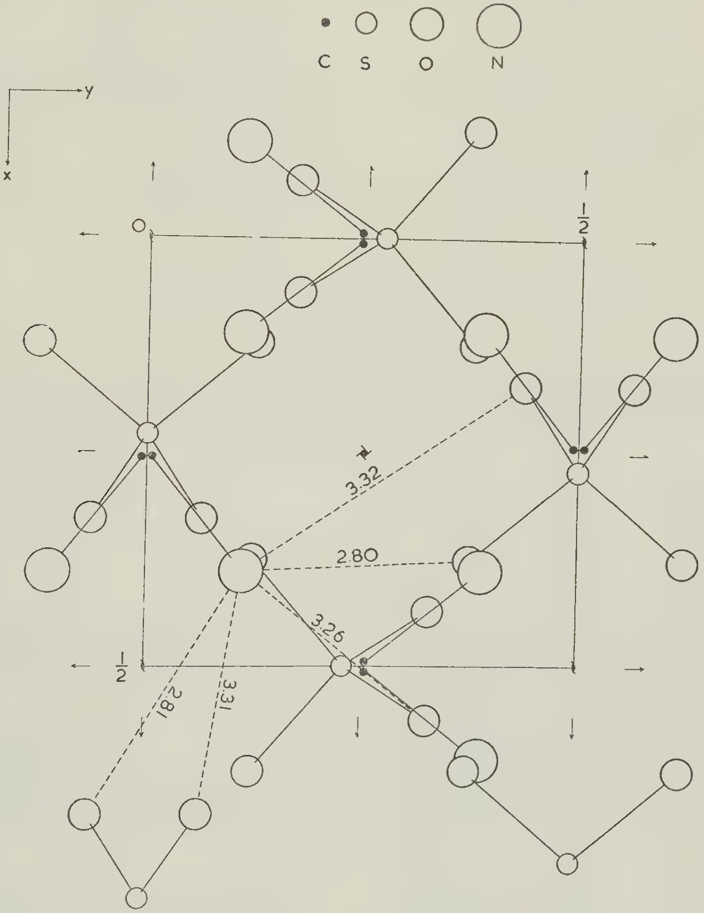

Fig. 7. Projection of the structure on (001). Broken lines represent N-H···O hydrogen bonds and N···O contacts. Interatomic distances are given in Angström units. The N-H···O hydrogen bond of length 2.82 A is not shown owing to the overlapping of participating atoms.

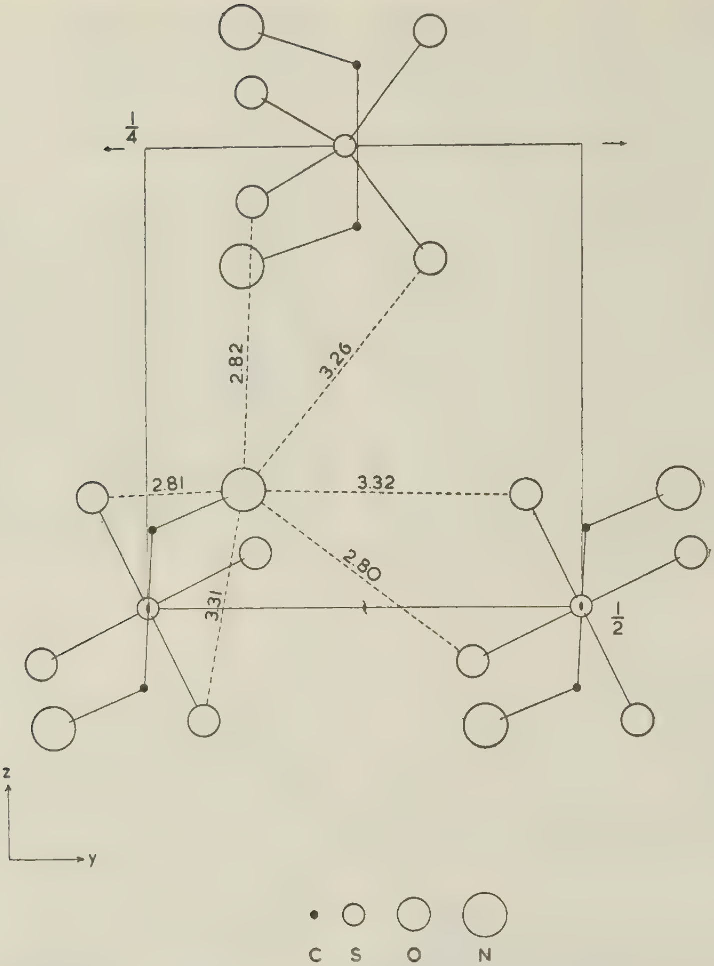

Fig. 8. Projection of the structure on (100). Broken lines represent N–H···O hydrogen bonds and N···O contacts. Interatomic distances are given in Angström units.

give a correct approximate structure, about 20% of larger structure factors must be given their correct signs. In this work the signs of about 70% of the observed structure factors could be determined for the $(hk0)$ and $(0kl)$ reflections, and the minimum magnitudes of $U(hk0)$ and $U(0kl)$ of which the signs could be determined were 0.10 and 0.07 respectively. Obviously the magnitudes of unitary structure factors are important for the successful application of the inequality method. The presence of the comparatively heavy sulfur atom in this structure makes σ, the standard deviation for the Gaussian distribution of unitary structure factors greater, than that expected when the atoms in the unit cell are all equal, and this causes unitary structure factors with large magnitude to be observed. This situation has favored the application of the inequa-

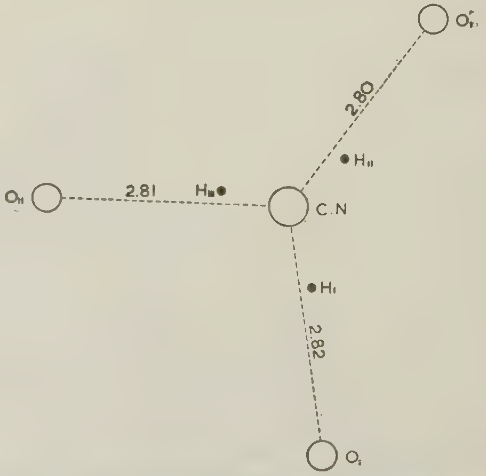

Fig. 9. Arrangement of three hydrogen-bonded oxygen atoms around a nitrogen atom viewed along the C—N bond. The positions of hydrogen atoms are shown by filled circles.

lity method.

The author wishes to express his thanks to Prof. Emeritus I. Nitta and Prof. T. Watanabé for their interest and helpful advice during the course of this investigation. He is also indebted to Dr. Y. Tomiie for his help in experimental work and many tedious calculations.

Study of Metallic Carbides by Electron Diffraction
Part IV. Cobalt Carbides

By Sigemaro NAGAKURA

Tokyo Institute of Technology, Oh-okayama, Meguro-ku, Tokyo

(Received March 3, 1961)

Thin cobalt films formed by evaporation were carburized in town gas at temperatures below 550°C for several hours. Electron diffraction studies of these films confirmed the existence of two kinds of carbide, Co_2C and Co_3C. Co_2C is an orthorhombic crystal with lattice constants $a=2.910$, $b=4.469$ and $c=4.426$ Å, and has a distorted c.p.h. structure. The lattice relation between Co_2C and Co is $(001)_{Co_2C}//(00.1)_{\alpha\text{-}Co}//(111)_{\beta\text{-}Co}$ and $[100]_{Co_2C}//[10.0]_{\alpha\text{-}Co}//[10\bar{1}]_{\beta\text{-}Co}$. Co_2C is formed at temperatures in a range 450°~500°C, and decomposes gradually to α-Co containing stacking faults and graphitic carbon at temperatures in a range 450°~470°C. Co_3C is an orthorhombic crystal with lattice constants $a=4.483$, $b=5.033$ and $c=6.731$ Å and is isomorphous with cementite (Fe_3C). The lattice relation is $(1\bar{2}1)_{Co_3C}//(10.1)_{\alpha\text{-}Co}//(100)_{\beta\text{-}Co}$, and $[111]_{Co_3C}//[0\bar{1}.0]_{\alpha\text{-}Co}//[001]_{\beta\text{-}Co}$. Co_3C is formed at temperatures in a range 450°~500°C and decomposes gradually to α-Co containing stacking faults and to graphitic carbon at temperatures in a range 480°~490°C. The mechanisms of Co_2C and Co_3C formation and decomposition are discussed.

§ 1. Introduction

In the previous papers[1),2),3)] the electron diffraction studies on the nickel and iron carbides were published and it was shown that the method is useful for the study of metallic carbides. The method is applied to the study of cobalt carbides in the present paper.

The cobalt carbide Co_2C was found by Bahr and Jessen,[4)] and Hofer and Peebles[5)] after the CO-gas cementation of cobalt powder at temperatures below 300°C. X-ray studies by Drain,[6)] and Juza and Puff[7)] showed that the

Co_2C is orthorhombic. Juza and Puff carried out the structure analysis, but Clark and Jack[8] reported that their structure was not correct and proposed another structure. Although the above mentioned authors found only the carbide Co_2C, Meyer[9] produced another carbide by the cementation of cobalt bars. His carbide gave the X-ray powder pattern similar to that of cementite, Fe_3C, so that it was considered to be Co_3C. In the present study both kinds of carbide were produced by the cementation of the evaporated cobalt films, and their structures, lattice relation between the carbides and cobalt, processes of carbide formation and decomposition were studied.

§ 2. Experimental

Cobalt films of about 400Å in thickness were prepared on the cleavage faces of rock-salt crystals by the evaporation of electrolytic cobalt. The films were polycrystalline when they were deposited on the faces of rock-salt kept at room temperature, while they were single crystalline on the faces kept at about 500°C. The cementation was carried out according to the method described in the previous paper.[1] The town gas through the converter furnace at about 1000°C was used to carburize the evaporated films. Carburizing temperature was changed in a range from 250 to 550°C. Carburizing period was about 5 hrs., and rate of gas flow was 100~150 cc per min. Composition of the gas was as follows: C: 25, CH_4:5, H_2:40, N_2:30 (in vol %). The electron diffraction patterns were taken by the camera operated at 65kV. The 200kV electron diffraction camera* was used for the measurement of intensities.

§ 3. Results

1. *Evaporated films*

Photo. 1 (a) is an electron diffraction pattern of a cobalt film formed on a surface of rock-salt kept at room temperature. The pattern is due to α-Co crystallites (c.p.h. structure) of random orientation. In the pattern it can be seen that the (hkl) Debye ring having the relation $h-k\neq 3n$ (n: integer) is broad. The breadth increases as the index l becomes higher. The (hkl) ring having the relation $h-k=3n$ is sharp. This shows that many stacking faults are produced on the close packed planes[10] during the deposition. The mean particle size calculated from the half -breadth of the sharp rings was 30Å. When α-Co film was heated in vacuum it transformed to the β-Co film (f.c.c.) gradually, accompanying the crystal growth. Photo. 1 (b) reproduces a diffraction pattern of cobalt film heated at 650°C for 30 min. The mean particle size was 60Å. When the α-Co films were heated in the electron diffraction camera, the transformation from α to β did not occur at the transformation temperature of builk cobalt, 420°C, but occured in a wide temperature range above about 500°C. The amount of transformation depended on the period of heating and on the temperature, and the rate of transformation was very slow at 500°C. The β to α transformation did not take place on cooling.

Photo. 2 reproduces an electron diffraction pattern of a cobalt film with single crystalline orientation prepared on a surface of rock-salt kept at 500°C. The lattice relation was found to be $(00.1)_{\alpha\text{-Co}}//(111)_{\beta\text{-Co}}$ and $[10.0]_{\alpha\text{-Co}}//[10\bar{1}]_{\beta\text{-Co}}$, i.e. the closest packed atomic planes and atomic rows are parallel to each other. The streaks in the pattern can be ascribed to the effect of stacking faults.

2. *Co_2C films*

Photo. 3 reproduces an electron diffraction pattern of a polycrystalline film carburized for 6 hrs. at 500°C. The pattern can be indexed by an orthorhombic unit cell of dimensions

$$a=2.910\,\text{Å},\ b=4.469\,\text{Å}\ \text{and}\ c=4.426\,\text{Å},$$

which agree well with the X-ray data of Co_2C, $a=2.897$ Å, $b=4.447$ Å and $c=4.371$ Å.[8] The mean particle size calculated from the half-breadth of the ring was 40 Å. The patterns of single crystalline film carburized partly and completely are reproduced in Photo. 4 (a) and (b), respectively. The lattice relation is

$$(001)_{Co_2C}//(00.1)_{\alpha\text{-Co}}//(111)_{\beta\text{-Co}}\,,$$
$$[100]_{Co_2C}//[10.0]_{\alpha\text{-Co}}//[10\bar{1}]_{\beta\text{-Co}}\,.$$

The Juza and Puff's structure of Co_2C[7] does not take the positions of carbon atoms into consideration and cannot interpret the reflection (011). According to Clark and Jack,[8] the structure of Co_2C belongs to the space group P_{mnn} and the positions of cobalt atoms are 0, y, z; 0, y, z; 1/2, $1/2+y$, $1/2-z$; 1/2, $1/2-y$,

---

* The author wishes to express his thank to Prof. G. Honjo and Dr. N. Kitamura for giving permission to use the 200 KV camera.

$1/2+z$ with $y=0.347 \pm 0.001$, $z=0.258 \pm 0.002$, and the positions of carbon atoms 0, 0, 0; 1/2, 1/2, 1/2. The structure is illustrated in Fig. 1. Intensities calculated from the model are tabulated in Table I and compared with the observed intensities. The intensity measurement was carried out according to the Karle and Karle's method,[11] and the peak area of Debye ring was measured. Honjo and Kitamura's method[12] was applied to correct the effect of primary extinction using the 200 keV electron diffraction apparatus. The extinction effect was observed in the (002), (111) and (021) rings. The observed intensities agree with the

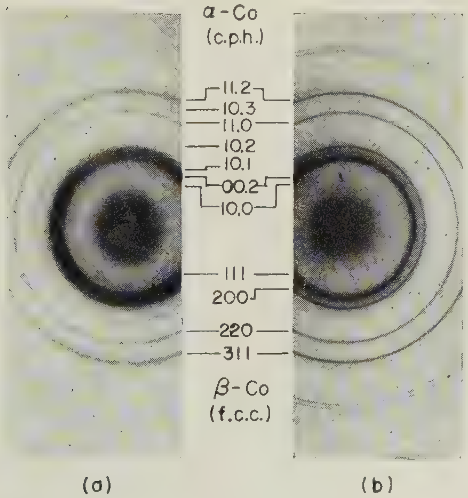

Photo. 1. Electron diffraction patterns of evaporated Co films.
(a) α-Co film deposited on the rock-salt kept at room temperature.
(b) After heating the above film at 650°C for 30 min in vacuum. The pattern is composed of rings due to β-Co and a small amount of α-Co.

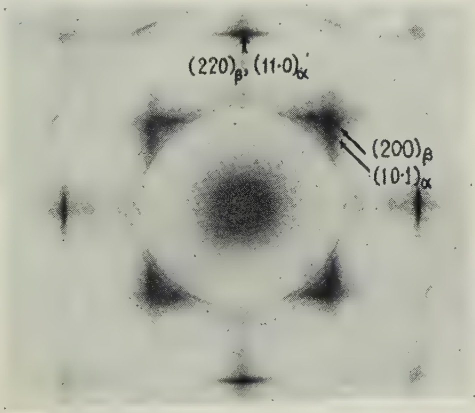

Photo. 2. Electron diffraction pattern of evaporated Co film having single crystalline orientation. Co-existence of α- and β-Co with definite orientation is observed.

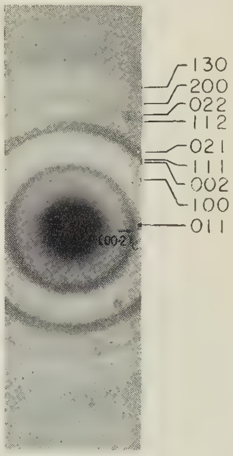

Photo. 3. Electron diffraction pattern of polycrystalline Co_2C film formed by the cementation at 480°C for 8 hrs.

(b) Completely carburized at 450°C for 4 hrs.

calculated in the experimental error.

After carburizing for 5 hrs. the carbide was not produced below 400°C, while the film was carburized to Co_2C at 450°C, leaving small amount of α-Co. The completely carburized films were obtained at 500°C. In this case the deposition of free carbon on the films were observed in many cases. Above 550°C the pattern was composed of Debye rings due to α- and β-Co and graphitic carbon.

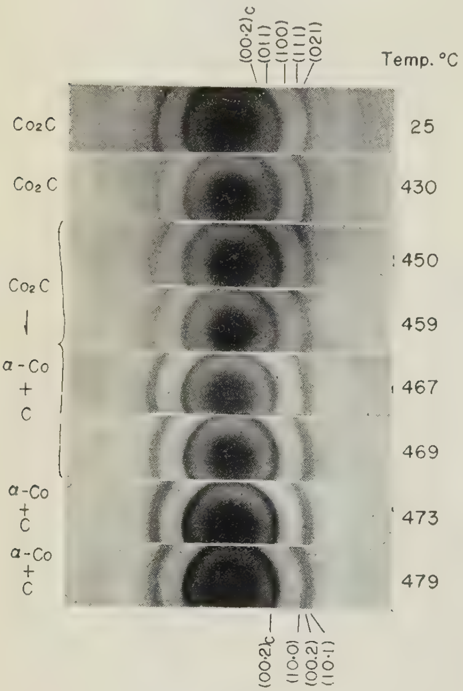

Photo. 5. A series of diffraction patterns showing the decomposition of Co_2C into α-Co and graphitic carbon.

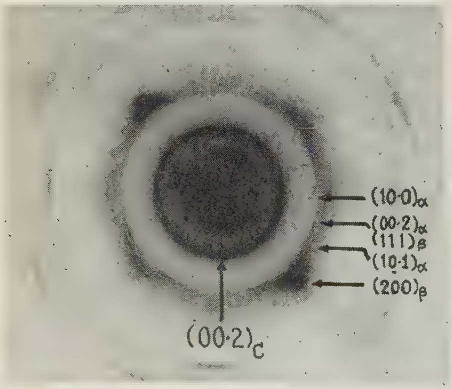

Photo. 6. Electron diffraction pattern after heating the film of Photo. 4 (b) at 500°C for 10 min in vacuum, showing the decomposition of Co_2C to α- and β-Co and graphitic carbon.

When the carburized films were heated in vacuum, Co_2C was found to decompose into α-Co and graphitic carbon. The process of decomposition was continuously observed in the electron diffraction camera. Heating rate was 2°~4°C per min. and the accuracy of temperature was within a few degrees.[1] Photo. 5 reproduces a series of the changes of diffraction patterns. The decomposition began at 450°C and finished at 469°C, leaving the rings due to α-Co and graphitic carbon. α-Co crystallites produced by the decomposition contained the stacking faults as in the evaporated films. Photo. 6 reproduces the diffraction pattern after heating the carburized single cry-

stalline film at 500°C for 10 min. It can be seen that the film is composed of the spots due to α-Co, small amount of β-Co and graphitic carbon without orientation. It is noteworthy that the pattern of cobalt is still single crystalline.

3. Co_3C films

Photo. 7 (a) is an electron diffraction pattern of polycrystalline film carburized at 450°C for 4 hrs. and Photo. 7 (b) is the pattern of cementite, Fe_3C. Their spacings and visual intensities are tabulated in Table II. It is evident from the photographs that the carbide is isomorphous with the cementite and can be identified with Co_3C. The orthorhombic lattice constants are

$$a=4.483\ \text{Å},\ b=5.033\ \text{Å}\ \text{and}\ c=6.731\ \text{Å},$$

which are nearly equal to the lattice constants of cementite, $a=4.516$ Å, $b=5.077$ Å, and $c=6.727$ Å.[13] Photo. 8 reproduces an electron diffraction pattern of Co_3C formed by the cementation of a single crystalline cobalt film. The lattice relation may be

$$(\bar{1}11)_{Co_3C}//(10.1)_{\alpha-Co}//(100)_{\beta-Co}\ ,$$

$$[0\bar{1}1]_{Co_3C}//[01.0]_{\alpha-Co}//[001]_{\beta-Co}\ .$$

This relation is gradually destroyed in the growth stage of carbide crystal.

The temperature range of Co_3C formation was 450~500°C. The diffraction rings of Co_3C are always spotty, showing that the particle size of Co_3C is of the order of several hundred Å. This is much larger than that of α-Co. When Co_3C film was headed in vacuum, it was found that Co_3C decomposes to α-Co and graphitic carbon as in the case of Co_2C. Photo. 9 illustrates the process of the decomposition of Co_3C: the decomposition began at 477°C and finished 491°C. α-Co crystallites produced

by the decomposition contained the stacking faults.

§ 4. Discussion

The c-projection of the structure of α-Co and Co_2C are illustrated in Fig. 1 (a) and (b), respectively. Here, large circles A, B (Fig. 1 (a)) and A′, A″, B′, B″ (Fig. 1 (b)) represent cobalt atoms and small circles (C_1), (C_2) carbon atoms. In the structure of α-Co each close packed atomic plane formed by A and B is parallel to the c-plane, but in the structure of Co_2C atomic planes A′—A″ and B′—B″ make an angle of 17°37′ to the c-plane, since height of each atom is different. In both of the

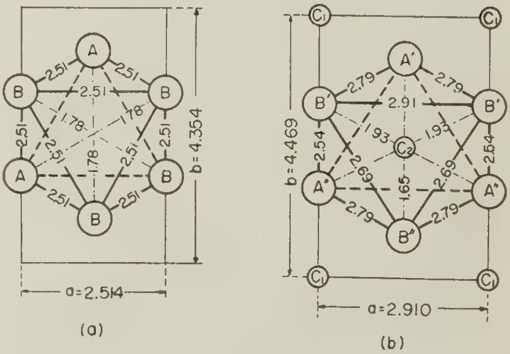

Fig. 1. Structures of α-Co (a) and Co_2C (b) (c-projection). Height of atoms: A: 1/4; B: 3/4; A′: 0.242; A″: 0.258; B′: 0.742; B″: 0.758; C : 0; C_2: 1/2. Heavy lines indicate octahedrons formed by cobalt atoms. Atomic distance is shown in A unit.

structure, however, there are octahedrons formed by cobalt atoms, and in the Co_2C the octahedral interstices are occupied by carbon atoms. Both structures are different only in the orientation of the octahedrons in the lattice. This fact and the lattice relation between α-Co and Co_2C suggest that the Co_2C is formed by the diffusion of carbon atoms into the octahedral interstices of α-Co. By the carbon atom moving in the octahedron, it expanded and distorted in such a way that the distance $A''-A''$ becomes longest and $A''-B'$ shortest. The mean particle size of Co_2C crystallites is nearly equal to that of α-Co and this fact suggests that each crystal of α-Co changes to Co_2C crystal without crystal growth. In the carbide lattice carbon atoms are distributed regularly so as to minimize the lattice distortion. Unlike the case of Ni_3C[2] and ε-Fe_3C, the distribution of carbon atoms in the crystal does not form any sublattice structure. The degree of orientation of α-Co crystallites produced by the decomposition of the single crystalline Co_2C film was not different from the degree of orientation of the original α-Co crystallites. This shows that the decomposition of Co_2C is caused by the carbon atoms moving out of the octahedral interstices of Co_2C. When α-Co films are carburized, the Co_2C may be produced mainly from α-Co even when the carburizing temperature is above the transformation temperature, since the rate of transformation from α- to β-Co is slow. However, Co_2C can be produced also from β-Co and in this case the mechanism can be considered to be similar to the case of Ni_3C formation from nickel.[1]

The arrangement of cobalt atoms in Co_3C crystal has no simple relation to the atomic arrangement in α- or β- crystal and the particle size of Co_3C is much larger than that of α- or β-Co. These situations are similar to the case of Fe_3C (cementite) formation from α-Fe. In contrast to the case of Co_2C, therefore, Co_3C may be formed in such a way that nuclei of Co_3C are produced on the cobalt surface and grow up gradually at the expense of cobalt crystal.

The temperature range of Co_2C and Co_3C formation were nearly same. Therefore, it could not be predicted which carbide would be produced by the cementation. It is worthwhile to mention that the decomposition product of both carbides was mainly α-Co but not β-Co, in spite of the fact that the decomposition temperature is higher than the transformation temperature of bulk cobalt. This may be due to the fact that the atomic arrangement of cobalt atoms in the carbides is more closely related to that of α-Co than that of β-Co.

The author should like to express his thanks to Professors S. Oketani and G. Honjo for their valuable discussions. This work was partly supported by a Grant in Aid for Fundamental Scientific Research from the Ministry of Education.

Study on the Internal Motions of Some Acryl- and Methacryl-group High Polymers by Pulsed NMR Method

By Takao KAWAI

Yoshida College, Kyoto University

(Received February 1, 1961)

The internal motions of some high polymers were investigated by measuring the spin-lattice relaxation time (T_1) together with its minima ($T_{1\,\mathrm{min}}$) in proton resonance in the temperature range from liquid air up to about 300°C by pulsed NMR method at 25 Mc/sec. For acryl-group high polymers (PMA, PEA, PBA), two minima of T_1 were observed, one at higher temperature corresponding to the segmental motion and the other at lower temperature to the internal motion of side chain ester alkyl group. For methacryl-group high polymers (PMMA, PEMA, PBMA), three minima of T_1 were observed, of which one at the highest temperature corresponds to the segmental motion, the next at the middle temperature to the internal motion of both main chain methyl group and side chain ester alkyl group and the last at the lowest temperature to the internal motion of the latter group alone.

Thus, we could definitely separate the internal motion of amorphous high polymers. The rigorous analysis of the behavior is considered to be a rather difficult problem, because of the complexity of the circumstances and the lack of both existing suitable formulas and precise experimental data.

§1. Introduction

Nuclear magnetic resonance (NMR) methods have been widely applied to investigate the internal motion of high polymers. Some researches are summarized in a recent review by Sauer and Woodward.[1] However, the methods which have been widely used are steady state methods to measure the line width, the second moment, or the line shape. Relatively few works have been performed on the spin-lattice relaxation time (T_1) of high polymers.[2,3,4,5] We have undertaken a systematic investigation about the internal motion of some high polymers, by measuring T_1 in proton resonance in the temperature range as wide as possible. Some preliminary results were already published.[6] In the present study, we have succeeded in separating clearly the internal motion of high polymer into the segmental motion and the component motions of side chain. The samples used, the experimental methods and results, and discussions will be given in detail below.

§2. Samples

We have investigated the internal motion of the amorphous high polymers but not of the the partially crystalline ones, because the formers are fit to simple analyses. As to the partially crystalline high polymers, the investigations

Table I. Samples used.

will be done in a near future.

Six samples were used, as tabulated in Table I.

All samples were kindly supplied by Asahi Kasei Mfg. Co. and some were polymerized by Prof. Kozasa at Kyoto University who measured the average polymerization factors for PMA and PEA by Ostwald's viscometer and found them to be about 4600 and 5560 respectively. The samples are otherwise thought to be of commercial grade.

§ 3. Experimental Method and Results

To measure T_1, a standard 90°~90° pulse method was used.[7,8] The experiments were performed at 25 Mc/sec, using the apparatus already reported.[9] Some improvements were made, however, in order to increase the stability, to obtain stronger *r.* f. pulse, to measure T_1 at lower temperatures and to observe spin echo decay time. All the modifications will be reported in detail elsewhere. The obtained data on the temperature dependence of T_1 for six amorphous high polymers are given in Figs. 1~6.

The estimated error in the measured T_1 is about ±10% above−50°C, but for lower temperature range, it grows worse up to about ±30%. This inaccuracy may be due partly to weak signal and short free induction decay time (T_2*) at lower temperatures and partly to the transition between the modes of internal motion which mainly determine T_1. The error in measuring the temperature T is about ±1°C through nearly the whole range but about ±3°C for lower temperature range, due to the performance of the modified Gutowsky type cryostat[10] which was used.

Some remark must be made about the amplitude of the nuclear signal just after the first pulse (y_1). In principle, y_1 is proportional to the number of resonant nuclei. As already pointed out,[9] however, our apparatus cannot detect the nuclear resonance signal due to protons in the rigid state. So y_1 may be considered to be a rough measure of the number of moving protons. The results of measurement of the temperature dependence of y_1 for PMA and PMMA are shown in Figs, 7 and 8 respectively. The interpretion of y_1 as being proportional to the number of moving protons may contain some errors, because y_1 will be very sensitive to the adjustment of 90°~90° pulse condition, to the change of the "Q" of

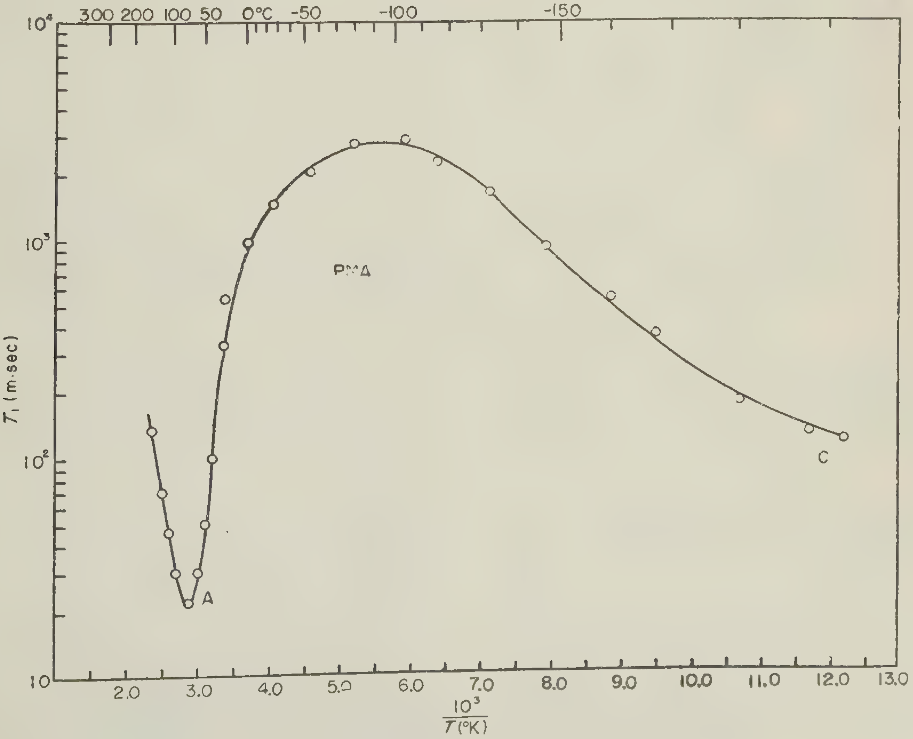

Fig. 1. Temperature dependence of T_1 of proton in PMA.

the sample coil with temperature and to the change of the filling factor of the sample at high temperature, where the sample is in viscous liquid state. However, Figs. 7 and 8 are considered to be useful supports for the interpretation of the data on T_1, as will be shown in the next section.

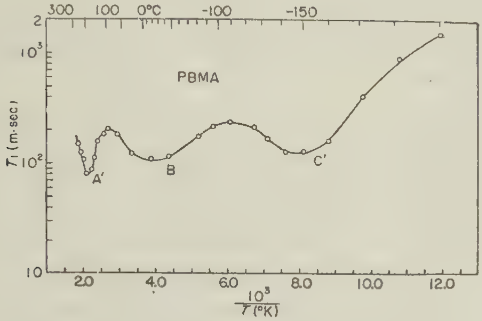

Fig. 6. Temperature dependence of T_1 of proton in PBMA.

§ 4. Interpretation of Data

To interpret the data on T_1, we follow the BPP theory[11] and consider that one mode of the internal motion corresponds to one V-shaped part of the curve T_1 versus $1/T$. But we do not directly apply their formula, which is based on the assumption of a single correlation time.

Thus, first, the V-shaped curves at highest temperatures, maked with *A* and *A'* in Figs. 1~6, obviously correspond to the segmental motions. The data in this temperature range for PMA and PMMA were already published,[6] having been analysed tentatively by using the BPP formula. Recently, A. Miyake used these published data to obtain a distribution spectrum of the correlation time and succeeded in interpretation.[12]

Second, the V-shaped curves marked with *B*, in which a minimum of T_1 occurs at about -10°C for three methacryl-group samples as seen in Figs. 2, 4 and 6, are due to the existence of main chain methyl groups. This conclusion can be derived by comparing the data for each methacryl-group high polymer with those for corresponding acryl-group. In this temperature range, we can consider that in methacryl-group high polymers, both the side chain ester alkyl group and the main chain methyl group are moving and that the magnetic interaction between these two groups are rather strong, for otherwise we would be able to observe two T_1's separately as in the study of the sorbed water.[13]

Third, the V-shaped curves at lowest temperatures marked with *C* and *C'* in Figs. 1~6, can be considered, of course, to correspond to the motions of side chain ester alkyl groups. At the present stage, however, we cannot decide by NMR whether only alkyl groups or the whole C–O–O–R groups are moving. As to the solution of this problem, the study of β transition by dielectric relaxation experiments may be useful. For PMA and PMMA, the V-shaped curves are not completed, which show that the side chain methyl groups are moving even at the liquid air temperature. It is reasonable to consider that it is not so easy for the ethyl buthyl and perhaps propyl radicals to move as for the methyl radicals.

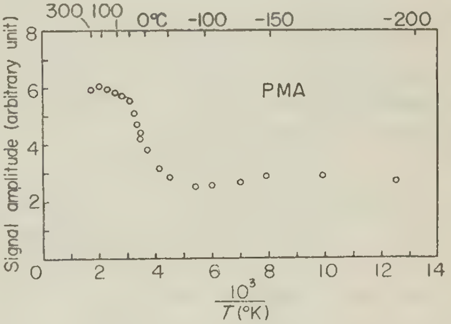

Fig. 7. Signal amplitude (arbitrary unit) *versus* $1/T$ for PMA.

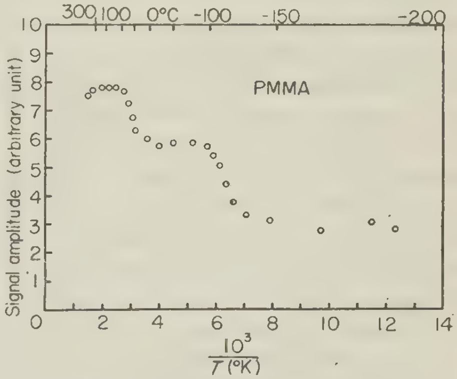

Fig. 8. Signal amplitude (arbitrary unit) *versus* $1/T$ for PMMA.

Finally, we consider the data shown in Figs. 7 and 8. As already pointed out in the preceding section, y_1 is a measure of the number of moving protons. According to the above interpretation of the data on T_1, the respective y_1's should be in the ratio of 6:3 in the temperature ranges corresponding to A and C for PMA, and 8:6:3 in the temperature ranges corresponding to A′ B and C′ for PMMA, considering the molecular structure of each polymer (Table 1). As seen in Figs. 7 and 8, these expectations are fairly satisfied, showing the correctness of the above interpretation.

§ 5. Discussions

Here we consider the use of the BPP formula[11,14] based on the "single correlation time (τ_c)." According to it, the relation between T_1 and τ_c can be represented as follows:

$$\frac{1}{T_1}=\frac{3}{10}\frac{\gamma^4\hbar^2}{b^6}\left(\frac{\tau_c}{1+\omega^2\tau_c^2}+\frac{4\tau_c}{1+4\omega^2\tau_c^2}\right),$$

where b is the "effective" interproton distance, that is an appropriate average of the distances between propons which are effective for the relaxation. Further, if we consider the internal motion of high polymers as an activation process, we have

$$\tau_c=\tau_0\exp(\Delta E/RT).$$

If we use the above formula, we can analyse the data on the temperature dependence of T_1, taking b, τ_0 and ΔE as three adjustable parameters. Then the minimum of T_1 gives b and the temperature dependence gives τ_0 and ΔE. These processes were, indeed, carried out for the segmental motions of PMA and PMMA previously.[6] For other modes of the internal motion, we have tried these analyses for the two representative cases, that is, for the V-shaped curve marked with B for PMMA, and for that marked with C for PEA. It would be desirable to treat the V-shaped curve marked with C for PMA, since it corresponds to the motion of methyl group, which has been widely studied. Unfortunately, however, we could not attain the temperature where the minimum of T_1 for that mode occurs.

The results of the analyses are as follows: $b=2.1$Å, $\tau_0=3.5\times10^{-12}$ sec and $\Delta E=3.6$ Kcal/mol for curve B of PMMA, $b=2.2$Å, $\tau_0=4.5\times10^{-12}$ sec and $\Delta E=1.9$ Kcal/mol for curve C of PEA. The plots of τ_c *versus* $1/T$ are shown on semilogarithmic scale in Fig. 9 (a) and (b) for these two cases respectively, where open circles (for PMMA) and filled circles (for PEA) are derived from the data on T_1, using the BPP formula, and the straignt lines connecting these give $\tau_c=\tau_0\exp(\Delta E/RT)$.

For the curve B of PMMA in Fig. 2, where not only main chain methyl groups but also side chain ester methyl groups are moving and further there are strong coupling between both, the circumstances are very complicated.

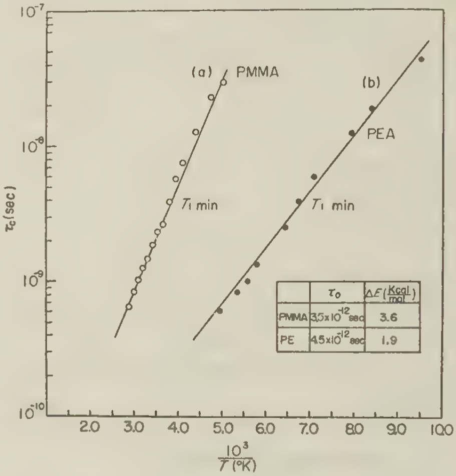

Fig. 9. Plot of τ_c against $1/T$ for PMMA (a) and PEA (b).

But we notice that the value of 2.1Å is somewhat larger than that estimated from the molecular structure (about 1.8Å for H—H distance in methyl group). The same can be said about b for the curve C of PEA in Fig. 3. As for the activation energy ΔE, the values derived above seem to be a little smaller than that derived from T_1 for methyl groups in smaller molecules.[5] It may perhaps be unnecessary to confirm the existence of the distribution of correlation times, though in general, both the increase in the value of $T_{1\,min}$ (which is equivalent to the increase in the apparent value of b) and the flatness of the V-shaped curve (which is equivalent to the decrease in the apparent activation energy) are the results which are expected when we take the distribution of correlation times into account.

§ 6. Conclusions

We could definitely separate the various modes of the internal motion of amorphous high polymers, by measuring T_1 in proton resonance by pulsed NMR method. Recently, the similar investigations were performed by Odajima, Woodward, and Sauer, by measuring the second moment by steady state method.

Our results are excellently consistent with theirs, and we think our results are more direct. We could not discuss our data quantitatively, because of the complexity of the affairs, the lack of both the suitable formula for analysis and the precise experimental data. For further discussions, the progress in the theory of T_1 of high polymers and the measurements of T_1 at various frequencies would be necessary.

Acknowledgements

The author would like to express his sincere gratitude to Professor I. Takahashi for his continual interest and discussions. The author is also indebted to Professor H. Kozasa for his kindness of making and testing the samples. The author's thanks are also due to Dr. A. Hirai for his helpful assistance throughout this investigation and to Dr. S. Ishida of Asahi Kasei Co. for his kindness of providing the samples.

Mechanical Dispersions and Transition Phenomena in Semicrystalline Polymers

By Yasaku Wada

Department of Applied Physics, Faculty of Engineering, University of Tokyo, Bunkyo-ku, Tokyo, Japan

(Received March 3, 1961)

The existing data of mechanical dispersions in seven semicrystalline polymers (polyethylene, polypropylene, polyethylene terephthalate, polytrifluoromonochloro ethylene, polyamide, polyurethane and polytetrafluoroethylene) are compiled and the frequency dependence of loss peak temperature ("transition map") is illustrated. The primary and secondary dispersions occuring in the amorphous regions are identified on the basis of these results. The correspondence of the mechanical dispersions to dielectric ones, transition temperatures found in dilatometric measurements and change in NMR line width with temperature is discussed for these polymers.

§ 1. Introduction

A mechanical dispersion phenomenon in amorphous polymer is observed above glass transition temperature T_g: the mechanical loss exhibits a maximum at a temperature T_r higher than T_g, the temperature gradient of storage modulus has a discontinuity at T_g[1] and the modulus largely decreases in the vicinity of T_r from the order of 10^{10} to 10^6 or 10^7dyn/cm^2.

Recent investigations about the glass transition of amorphous polymers have revealed that the transition occurs in a rather broad temperature range.[2] In many amorphous polymers the upper limit of this range, $T_g{}^+$, is about twenty or thirty degrees higher than the lower limit, $T_g{}^-$.[1]

The temperature dependence of volume, elastic modulus and loss factor in the vicinity of the transition region, is schematically illustrated in Fig. 1. As is apparent in the figure, the glass transition temperature T_g in existing literatures which was determined as an intersection of two straight line portions in the volume-temperature curve lies between $T_g{}^+$ and $T_g{}^-$, being rather nearer to $T_g{}^+$.

It should be particularly mentioned here that the transition region and the dispersion region are not identical, though closely related to each other.[2] The former is determined by the interrelation between frequency of external excitation and temperature dependence of relaxation time, while the latter is determined by the relation between cooling or heating rate of the sample and the temperature dependence of the relaxation time. The glass transition temperature depends indeed on the cooling rate, but it can be taken practically as a material constant, since the cooling rate cannot be varied in the order of magnitude in usual experiments.

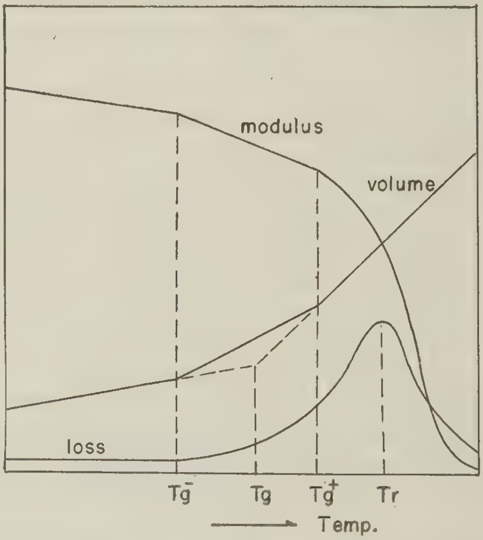

Fig. 1. Schematical representation of the temperature dependence of the volume, the mechanical loss factor and the storage modulus near the glass transition temperature.

In the case of semicrystalline polymers also, the glass transition has been believed to take place in the amorphous part and the associated mechanical dispersion has been observed. This dispersion is usually termed "primary disper-

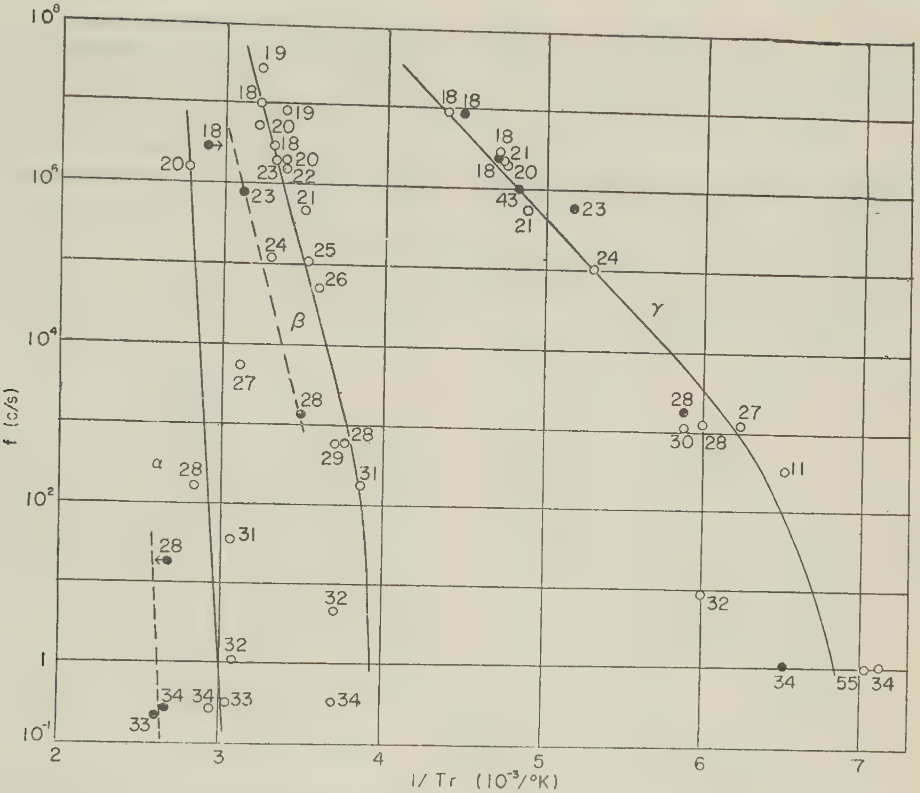

Fig. 2. Transition map of polyethylene. (Circle and dot represent values for branched and linear polyethylene respectively.)

sion." Besides this there has been found in lower temperatures another dispersion associated with the local motion of chain molecules in the amorphous part, named "secondary dispersion." Furthermore, a third dispersion originating from the crystalline part has been also exhibited in some polymers.

Owing to the complicated behavior abovementioned, there is even at present a large scatter of the opinion among authors about the problem which dispersion should correspond to the primary or the secondary dispersion. It is our purpose here to compile the existing data on the mechanical dispersion of semicrystalline polymers and to identify the primary and the secondary dispersions. The data of the thermal expansion, dielectric dispersion and nuclear magnetic resonance will be also referred to.

Seven kinds of semicrystalline polymer are dealt with in this paper:

(1) Polyethylene (PE)
(2) Polypropylene (PP)
(3) Polyethylene terephthalate (PET)
(4) Polytrifluoromonochloroethylene (PTFMCE)
(5) Polyamide (PA)
(6) Polyurethane (PU)
(7) Polytetrafluoroethylene (PTFE)

Nylon 6 and nylon 66 among many modifications of PA have been most extensively studied and are the subjects of the present study. In the case of PU the data are available only for polytetramethylene-hexamethy-

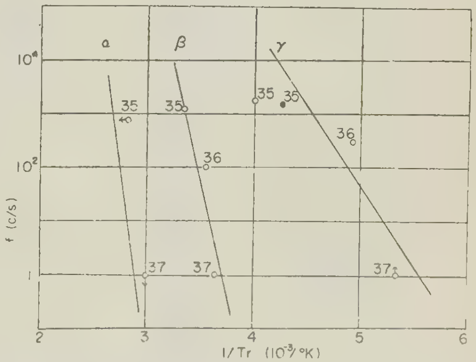

Fig. 3. Transition map of polypropylene. (Circle and dot represent isotactic and atactic polymers respectively.)

lene-urethane. Polymers other than these seven are not treated here because the available data have been too scanty up to the present.

§ 2. Transition Maps of Semicrystalline Polymers

The frequency dependence of the temperature of loss factor maximum T_r is illustrated in Figs. 2 to 8 for seven kinds of polymers. Numbers in the figures indicate the reference numbers. The names of dispersion follow mostly the nomenclature in the review article by Woodward and Sauer,[3] in which the upswing, not the peak, of damping near the

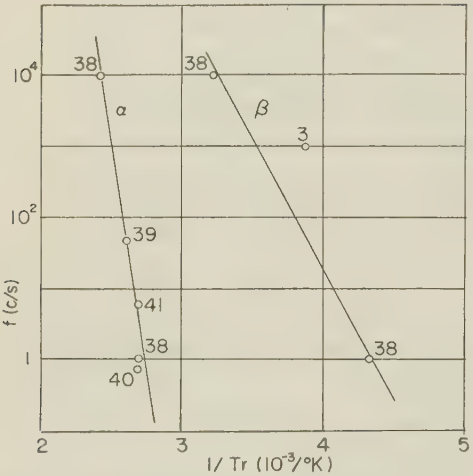

Fig. 4. Transition map of polyethylene terephthalate.

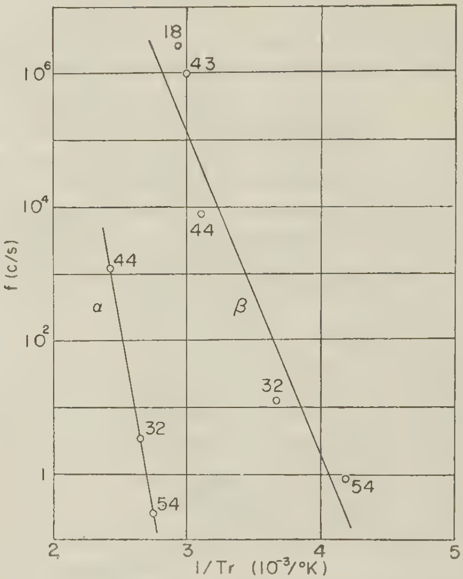

Fig. 5. Transition map of polytrifluoromonochloroethylene.

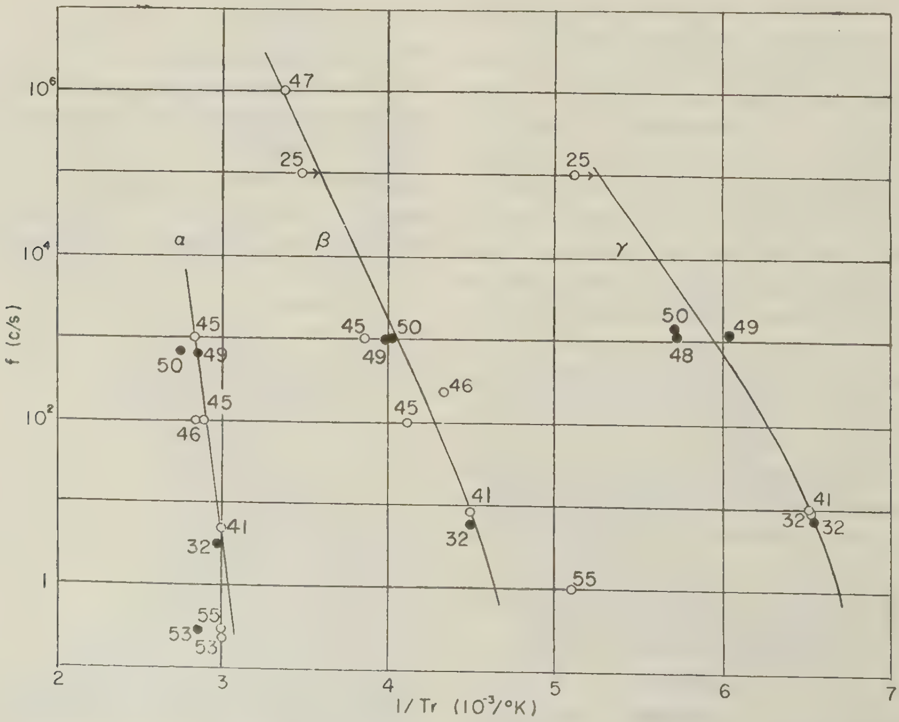

Fig. 6. Transition map of polyamide. (Circle and dot represent nylon 6 and nylon 66 respectively.)

melting point was often called "α peak" and the peak just below was called "α′ peak." This α′ peak is named "α peak" in this paper and the name "α′" is not used.

It is apparently seen from these transition maps that the relation between log *f* and $1/T_r$ is linear in most of the dispersions, though in some cases the linear relation does not hold in low frequencies. The apparent activation energy *E* is calculated from the straight line portion by

$$E=-2.30R\frac{\partial \log f}{\partial(1/T_r)}, \tag{1}$$

where *R* is the gas constant. The values of *E* are listed in Table I, together with T_r values at 1 cps frequency. The values of PE in this table are related to the branched polymer.

The relationship between transition phenomena and dielectric dispersion in polar polymers has been the subject of many papers. The data of dielectric dispersion are shown in Table I for comparison, reproduced from the very extensive study by Nakajima and Saito.[4] The values of PE was obtained with an oxidized sample. T_r in Table I is not to be directly compared with ε'' maximum temperature, since the loss factor corresponds to $\varepsilon''/\varepsilon'$, rather than ε'' in dielectric property. The ε'' maximum temperature should be higher than T_r, if the mechanical and dielectric dispersions are associated with the same mole-

Table I.

Polymer	T_m (°K)	Dispersion	Mechanical		Dielectric		T_k (°K)
			E (kcal/mole)	T_r at 1 cps (°K)	E (kcal/mole)	ε'' max. temp. at 1 cps (°K)	
PE	370	α	130	333			
		β	34	250	26	265	253[5]
		γ	9.5	145	13		140[5]
PP	440	α		345			
		β	40	275			250[6,7]
		γ	13	178			
PET	537	α	65	365	100	420	340,[8,13] 360[9]
		β	17	230	18	200	
PTFMCE	483	α	50	370	60	380	320[9,10,11]
		β	21	248	18	240	
PA	496, 538	α	62	330	48	310	330[9]
		β	21	214	17	220	
		γ	16	148	9		
PU	450	α	43	310			
		β	20	200			
		γ	10	140			
PTFE	600	α	170	400			400[9]
		β	70	300			
		γ	20	180			160[12]

cular mechanism. Taking this into consideration, one sees in Table I that the values of mechanical dispersion are in a satisfactory agreement with those of the dielectric one.

The last column of Table I shows the temperature T_k where the volume-temperature curve was found to exhibit a discontinuity in slope

§ 3. Criteria for Primary and Secondary Dispersions

The primary dispersion, being caused by movements of large sections of chain molecules in the amorphous phase, may be expected to follow the criteria below:

(1) The loss peak height should increase with increase in the fraction of the amophous phase.

(2) The activation energy should be relatively large, say several tens kcal/mole as estimated from that of perfectly amorphous polymers, owing to the large unit of motion.

(3) The thermal expansion curve should have a point of discontinuity in slope (T_g) in the vicinity of the loss peak temperature at a very low frequency.

(4) T_g should be roughly two-thirds of crystalline melting temperature T_m, when measured in absolute temperature scale.[14,15] This relationship is only an empirical one, but has been confirmed for many substances exhibiting the glass transition. Fig. 9 represents the relation of break temperatures in thermal

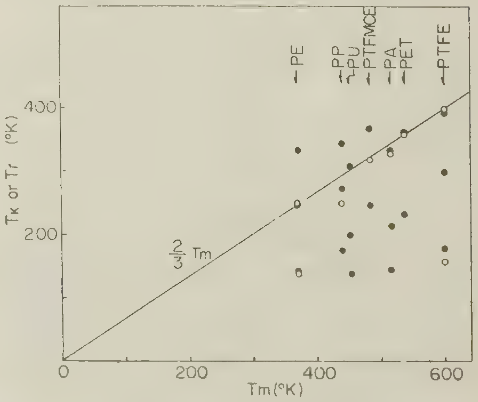

Fig. 9. Break points in thermal expansion curves (circle) and loss peak temperatures at 1 cps (dot) plotted against melting points.

expansion curves (T_k) and loss peak temperatures at 1 cps (T_r) against T_m for seven polymers.

Recently some theoretical studies have been made on the mechanism of the secondary dispersion,[16,17] the conclusion being not yet arrived. Okano[17] attributed this dispersion to the vibration of chain segments and achieved a qualitative agreement with experiment. It may be inadequate at the present stage to ascribe the secondary dispersion of a specific polymer to the rotation of a specific group of atoms in a chain molecule.

In any case, since it is at least valid that the secondary dispersion comes from the local motion of segments in the amorphous phase, the dispersion may be expected to obey the following criteria:

(5) The loss peak height should increase with increase of the relative amount of the amorphous phase.

(6) The dispersion should be observed at lower temperatures than the primary one.

(7) The activation energy should be smaller than that of primary disperson, roughly estimated as ten kcal/mole or so.

Identification of the primary and secondary dispersions for specific polymers will be made in the next section on the basis of the above criteria.

§ 4. Discussions on Specific Polymer

Polyethylene

The peak height of β dispersion is very small, often undetectable in linear PE which has a small fraction of the amorphous regions. Further, the increase in the amorphous regions by irradiation brings about the increase in height of the β peak of PE.[29] It is apparent from Table I and the above facts that the β dispersion fulfils all the criteria for the primary dispersion.

It is seen from Table I that the γ dispersion fulfils the criteria for the secondary dispersion except (5). The loss peak height of this dispersion is almost the same in branched PE as in linear PE.[18,28] This discrepancy may be explained under the assumption that some of the so-called crystalline regions in linear PE may be in an intermediate state between the crystalline and the amorphous states and the local motion of molecules which contributes to the secondary dispersion can take place also in this intermediate region.

The change in shape of the proton magnetic resonance absorption line of PE with temperature seems to support the view of regarding the β and γ dispersions as primary and secondary ones respectively. The narrow line component, caused by moving protons in the amorphous regions, at first appears at 200°K or below, then begins to become rapidly narrower at about 250°K.[29]

Many investigators have agreed in attributing the α dispersion of PE to the presence of the crystalline regions.[28,29]

Polypropylene

The behavior of the mechanical dispersions in PP is closely similar to PE so far as the data available at present concern.[57] A similar assignment of mechanisms to the dispersions as given to PE applies seemingly to PP.

Two extra loss peaks (δ and ε peaks) have been found in this polymer at very low temperatures and have been attributed to the rotation of methyl groups in the crystalline and amorphous regions respectively.[37] This explanation seems, however, not easy to understand. The rotation of such an axially symmetrical group as methyl group can result in no strain in the polymer and hence may not bring about any mechanical relaxation. In any cases, it may be important to explore the mechanical response over an extremely low temperature range for other polymers also.

Polyethylene terephthalate

The α dispersion of this polymer, the loss peak height of which was found to increase with increase of the amorphous regions,[39] satisfies well the criteria (1) to (4). According to the study of dielectric properties,[4] the relaxation strength of this dispersion begins to fall at about 100°C with decreasing temperature. This is indicative of the fact that the segmental motions of molecules begin to be "frozen-in" from this temperature. This temperature therefore can be regarded as the upper limit of glass transition region.

Polytrifluoromonochloroethylene

As is apparent from Table I, the criteria (2) to (4) hold true well for the α dispersion. Nakajima and Saito[58] have investigated the dielectric dispersion of this polymer in detail. According to them the relaxation strength of both α and β dispersions increases almost linearly with increasing fraction of the amorphous regions. Further, the relaxation strength of α dispersion falls rapidly from 50°C with lowering temperature. This indicates definitely that this temperature is the upper limit of glass transition region. They also found that the narrowing in the distribution of relaxation times for the β dispersion starts at 20°C with increasing temperature. This behavior can be accounted for by considering that the local motion of segments is modified above this temperature by the rotationary motion of segments.[59] This temperature therefore can be regarded as the starting point of glass transition, i.e. the lower limit of the transition region.

The γ dispersion satisfies the criteria (5) to (7) and can be safely concluded to be the secondary dispersion.

The temperature dependence of maximum slope width of magnetic resonance absorption line of fluorine nuclei in PTFMCE supports our conclusions. According to Nishioka,[65] narrowing occurs slightly first at around 240°K, then falls rapidly from 340°K.

Polyamide

The mechanical dispersion of polyamides has been most fully investigated by Woodward, Crissman and Sauer.[50] According to them, three loss peaks, α, β and γ, are all affected in height and/or peak temperature by absorbed water, hence all of them are considered as contribution of the amorphous regions. It was further verified that the β dispersion disappears for polymers perfectly free from water. It may be quite natural to say, on the basis of these facts and the data in Table I, that the α and γ dispersions correspond to the primary and secondary dispersions respectively.

One possible explanation for the appearance of the β dispersion may be that the amorphous regions are microscopically separated into two phases, one including water molecules, the other not. The local motions in the former phase contribute to the β dispersion, those in the latter to the γ dispersion. As is widely known,[60] absorbed water in polymers at low temperatures hinders the molecular motion, hence the β dispersion is located at a higher temperature. The primary dispersion results from the motions in regions including both phases and may not be separated into two peaks.

Investigation of the dielectric dispersien of nylon 6[4] shows that the relaxation strength of α dispersion falls from 75°C with decreasing temperature. This indicates that this temperature is the upper limit of glass transition region.

The line width of nuclear magnetic resonance absorption in dry nylon 6 first decreases slightly from ca. 150°K with increasing temperature, then rapidly from 310°K;[61] this is favorable to our conclusions.

Polyurethane

Behavior of the mechanical dispersions of PU very much resembles to PA, reflecting the similarity in chemical structures. With less uncertainty a similar assignment of mechanisms as given for PA appears to apply to PU.

Polytetrafluoroethylene

Many authors have confirmed[62,63,64] that the β dispersion of PTFE comes from the crystalline phase transition.

The α dispersion, though very well fits the criterion (4) as seen in Fig. 9, cannot be regarded as the primary dispersion on account of the following reasons. First, the apparent activation energy is too large as seen in Table I. Secondly, change in the X-ray pattern has been observed at elevated temperatures, being correlated with this dispersion.[64] Though some discrepancies exist among the data of nuclear magnetic resonance study in PTFE, it may be at least valid that the line width of the narrow component caused by moving fluorine nuclei in the amorphous regions exhibits narrowing far below room temperature,[52] indicating the glass transition located at low temperatures.

Taking the above facts into consideration, it may be reasonable to regard the γ dispersion as the primary one. Indeed, McCrum[56] has found that the loss peak height of γ dispersion decreases with increasing crystallinity and the storage shear modulus falls in this dispersion range from 2×10^{10} to 4.5×10^{9} dyn/cm^2 for the sample of 45% crystallinity. The γ dispersion thus satisfies well the criteria for the primary dispersion except (4). The definite explanation about the misfit of the criterion (4) to PTFE cannot be given here, but some remarks must be added. Nonpolar polymers such as PE and PP have generally lower glass transition temperatures than polar ones as PA, PTFMCE and PET, owing to the larger chain flexibility. Then the low transition temperature of PTFE may be reasonable. The misfit therefore seems to be due to the *too* high melting point, presumably resulting from the crystal structure of PTFE. If we take the crystalline phase transition temperature (285°K) as a hypothetical melting point, the criterion (4) applies very well also to this polymer.

It is not unreasonable to compare the α dispersion of PTFE to those of PE and PP.

§ 5. Conclusion

In this paper we have correlated the dynamic mechanical behavior of seven semicrystalline polymers with other types of behavior such as the dielectric, thermal and magnetic ones and classified the transition or dispersion regions without considering the specific chemical structures of polymers.

The conclusions are shown in Table II, the upper and lower limits of glass transition region being also listed. Of course values are only approximate ones. The glass transition temperature is affected by degree of crystallinity, degree of orientation, cooling rate and other numerous factors and varies from sample to sample by ten degrees or so.

Table II. Classification of dispersions

Polymer	Disperision due to crystalline region	Dispersion due to amrphous region		Glass transition region (°K)
		Primary	Secondary	
PE	α	β	γ	220—250
PP	α	β	γ	230—260
PET		α	β	340—360
PTFMCE		α	β	290—320
PA		α	β^*, γ	310—340
PU		α	β^*. γ	ca. 310
PTFE	α, β	γ		150—180

* Observed only for polymers including water.

Microwave Spectrum of Formaldehyde
III. Vibration-Rotation Interaction

By Takeshi OKA and Yonezo MORINO

Department of Chemistry, Faculty of Science,
The University of Tokyo, Tokyo, Japan

(Received, November 15, 1960)

The centrifugal distortion constants and the inertia defects necessary for the analysis of the microwave spectrum of formaldehyde molecule were calculated by the vibration-rotation theory.

Nielsen's formulation was used throughout together with the useful relations found by the present authors. The calculated centrifugal distortion constants, inertia defects and Coriolis coupling constants fit well to the experimental values.

§ 1. Quantum Mechanical Hamiltonian

The quantum mechanical Hamiltonian for a vibrating rotator was derived by Wilson and Howard as follows,[1)]

$$H=\frac{1}{2}\sum_{\alpha,\beta}\mu^{1/4}(P_\alpha-p_\alpha)\mu_{\alpha\beta}\mu^{-1/2}(P_\beta-p_\beta)\mu^{1/4}+\frac{1}{2}\mu^{1/4}\sum_s p_s\mu^{-1/2}p_s\mu^{1/4}+V \tag{1}$$

where P_α's are the components of the rotational angular momentum along the molecule-fixed axes and p_s's are momenta of vibration. p_α's are components of the angular momentum due to the vibration and can be written in terms of p_s as

$$p_\alpha=-\sum_s\sum_{s'}{}'\,\zeta_{ss'}{}^{(\alpha)}Q_sp_{s'}$$

where Q_s are normal coordinates of vibration and $\zeta_{ss'}{}^{(\alpha)}$ are Coriolis coupling constants. μ is the inverse of the inertia tensor and when the moments of inertia are expanded in terms of the normal coordinates, its determinant μ and components $\mu_{\alpha\beta}$ are vibrational operators.

$$\mu_{\alpha\beta}=\mu_{\alpha\beta}{}^{(e)}-\mu_{\alpha\alpha}{}^{(e)}\mu_{\beta\beta}{}^{(e)}\Big[\sum_s a_s{}^{(\alpha\beta)}Q_s+\sum_s\sum_{s'}\Big\{\Big(A_{ss'}{}^{(\alpha\beta)}-\sum_{s''}\zeta_{ss''}{}^{(\alpha)}\zeta_{s's''}{}^{(\beta)}\Big)-\sum_\xi\mu_{\xi\xi}{}^{(e)}a_s{}^{(\alpha\xi)}a_s{}^{(\beta\xi)}\Big\}Q_sQ_{s'}\Big]$$

$$\mu=\mu^{(e)}\Big[1-\sum_s\sum_\alpha\mu_{\alpha\alpha}{}^{(e)}a_s{}^{(\alpha\alpha)}Q_s+\sum_s\sum_{s'}\sum_\alpha\Big\{\mu_{\beta\beta}{}^{(e)}\mu_{\gamma\gamma}{}^{(e)}a_s{}^{(\beta\gamma)}a_{s'}{}^{(\beta\gamma)}-\mu_{\alpha\alpha}{}^{(e)}\Big(A_{ss'}{}^{(\alpha\alpha)}-\sum_{s''}\zeta^{(\alpha)}{}_{ss''}\zeta^{(\alpha)}{}_{s's''}\Big)\Big\}Q_sQ_{s'}\Big]$$

where $a_s{}^{(\alpha\beta)}$ and $A_{ss'}{}^{(\alpha\beta)}$ are expansion coefficients of the moments of inertia and are defined as follows;

$$I_{\alpha\beta}=I_{\alpha\beta}{}^{(e)}+\sum_s a_s{}^{(\alpha\beta)}Q_s+\sum_s\sum_{s'}\Big\{A_{ss'}{}^{(\alpha\beta)}-\sum_{s''}\zeta^{(\alpha)}{}_{ss''}\,\zeta^{(\beta)}{}_{s's''}\Big\}Q_sQ_{s'}\,.$$

V is the potential energy of vibration composed of harmonic quadratic terms and anharmonicity terms;

$$V=\sum_s\frac{\lambda_s}{2}Q_s{}^2+hc\sum_s\sum_{s'}\sum_{s''}k_{ss's''}q_sq_{s'}q_{s''}+hc\sum_s\sum_{s'}\sum_{s''}\sum_{s'''}k_{ss's''s'''}q_sq_{s'}q_{s''}q_{s'''} \tag{4}$$

When these expressions are substituted into Eq. (1) and appropriate Van Vleck's transformation which eliminates the first order off-diagonal terms is carried out[2)], the rotational Hamiltonian for an asymmetric rotor can be written as

$$H=\frac{1}{2}\sum_{\alpha,\beta}\sigma_{\alpha\beta}P_\alpha P_\alpha+\frac{1}{4}\sum_{\alpha,\beta,\gamma,\delta}\tau_{\alpha\beta\gamma\delta}\,P_\alpha P_\beta P_\gamma P_\delta \tag{5}$$

with

$$\frac{h}{\hbar^2}\frac{1}{2}\sigma_{\alpha\beta}=\frac{1}{2}[I^{-1}]_{\alpha\beta}+\sum_s\left[\frac{1}{4\pi}\sqrt{\frac{h}{c}}\left\{\frac{3k_{sss}}{\omega_s^{3/2}}a_s^{(\alpha\beta)}+\sum_{s'}{}'\frac{k_{sss'}}{\omega_{s'}^{3/2}}a_{s'}^{(\alpha\beta)}\right\}\right.$$
$$\left.+\frac{h}{8\pi^2c}\left\{4\sum_{s'}{}'\frac{\omega^2_{s'}}{\omega_s(\omega_s^2-\omega_{s'}^2)}\zeta_{ss'}^{(\alpha)}\zeta_{ss'}^{(\beta)}+3\frac{A_{ss}}{\omega_s}\right\}\right]\frac{(v_s+\frac{1}{2})}{I_{\alpha\alpha}^{(e)}I_{\beta\beta}^{(e)}}$$

and

$$\frac{h}{\hbar^4}\tau_{\alpha\beta\gamma\delta}=-\sum_s\frac{a_s^{(\alpha\beta)}a_s^{(\gamma\delta)}}{8\pi^2c^2\omega_s^2}\cdot\frac{1}{I_{\alpha\alpha}^{(e)}I_{\beta\beta}^{(e)}I_{\gamma\gamma}^{(e)}I_{\delta\delta}^{(e)}}$$

For a planar molecule $I_{cc}^{(e)}-I_{aa}^{(e)}-I_{bb}^{(e)}=0$ but $\Delta=I_{cc}-I_{aa}-I_{bb}$ is not equal to zero due to the additional terms in the expression of $\sigma_{\alpha\beta}$ in Eq. (5). The formula for this quantity, inertia defect, was derived by the present authors from Eq. (5) by using properties of vibration-rotation quantities as[3)]

$$\Delta=\frac{h}{\pi^2c}\left[\sum_s\left(v_s+\frac{1}{2}\right)\sum_{s'}{}'\frac{\omega_{s'}^2}{\omega_s(\omega_s^2-\omega_{s'}^2)}\{(\zeta_{ss'}^{(a)})^2+(\zeta_{ss'}^{(b)})^2-(\zeta_{ss'}^{(c)})^2\}\right.$$
$$\left.+\frac{3}{2}\sum_t\frac{1}{\omega_t}\left(v_t+\frac{1}{2}\right)\right]-\tau_{abab}\left(\frac{3}{4}\frac{I_{cc}}{C}+\frac{I_{bb}}{2B}+\frac{I_{aa}}{2A}\right)$$
$$-\frac{m}{M}[I_{cc}g_{cc}-I_{bb}g_{bb}-I_{aa}g_{aa}] \tag{6}$$

where t expresses the out-of-plane vibration and $g_{\alpha\alpha}$ are the components of the g-tensor for the rotational magnetic moment of the molecule. The purpose of this report is to evaluate the centrifugal distortion constants $\tau_{\alpha\beta\gamma\delta}$ and the inertia defects $\varDelta$ for the formaldehyde molecules.

§2. *l* Matrix

In order to calculate the vibration-rotation interaction, the transformation which relates the Cartesian displacements of atoms with the normal coordinates of vibration is necessary. This is the $\boldsymbol{l}$ matrix used by Nielsen and his coworkers, the elements of which are defined by

$$\sqrt{m_i}\,\delta\alpha_i=\sum_s l_{is}^{(\alpha)}Q_s \tag{7}$$

where $\delta\alpha_i$ represents the Cartesian displacement of the i-th atom. Eq. (7) can be written in matrix form as

$$\boldsymbol{x}=\boldsymbol{M}^{-2/1}\,\boldsymbol{l}\boldsymbol{Q} \tag{8}$$

where $\boldsymbol{M}$ is a 3N×3N diagonal matrix and $\boldsymbol{x}$ and $\boldsymbol{Q}$ are vectors with 3N and 3N−6 elements, respectively.

The $\boldsymbol{l}$ matrix can be calculated if the normal vibration treatment is completed. Thus, if we define the internal coordinates and the symmetry coordinates by $\boldsymbol{R}$ and $\boldsymbol{S}$, respectively, and the transformation matrices between them as

$$\boldsymbol{x}=\boldsymbol{AR},\quad \boldsymbol{R}=\boldsymbol{U'S}\ \text{and}\ \boldsymbol{S}=\boldsymbol{LQ}\ , \tag{9}$$

the $\boldsymbol{l}$ matrix is expressed as

$$\boldsymbol{l}=\boldsymbol{M}^{\frac{1}{2}}\boldsymbol{AU'L}. \tag{10}$$

$\boldsymbol{L}$ matrix can be obtained from the normal vibration calculation $(\boldsymbol{GF}-\lambda_k\boldsymbol{E})\boldsymbol{L}_k=0$. $\boldsymbol{A}$ matrix for such molecules as formaldehyde can be derived analytically by inverting the $\boldsymbol{B}$ matrix ($\boldsymbol{R}=\boldsymbol{Bx}$) with the Eckart's condition. For HDCO, where the symmetry is low, it can be obtained from the relation

$$\boldsymbol{A}=\boldsymbol{M}^{-1}\boldsymbol{B'G}^{-1} \tag{11}$$

where G^{-1} denotes the inverse of the G matrix calculated with respect to the internal coordinates. From the properties of these matrices and the $\boldsymbol{e}$ matrix which represents the normalized Eckart's condition, following relations are obtained[3].

$$\begin{aligned} \boldsymbol{l}'\boldsymbol{l} &= \boldsymbol{E}_{3N-6} \\ \boldsymbol{l}'\boldsymbol{e} &= \boldsymbol{e}'\boldsymbol{l} = 0 \\ \boldsymbol{l}\boldsymbol{l}' &= \boldsymbol{E}_{3N} - \boldsymbol{e}\boldsymbol{e}' \end{aligned} \tag{12}$$

They are expressed in scalar form as

$$\begin{aligned} &\sum_i \sum_\alpha l_{is}{}^{(\alpha)}\, l_{is'}{}^{(\alpha)} = \delta_{ss'} \\ &\sum_i \sqrt{m_i}\, l_{is}{}^{(\alpha)} = 0 \\ &\sum_i \sqrt{m_i}\, (\gamma_i\, l_{is}{}^{(\beta)} - \beta_i\, l_{is}{}^{(\gamma)}) = 0 \\ &\sum_s l_{is}{}^{(\alpha)}\, l_{js}{}^{(\alpha)} = \delta_{ij} - \sqrt{m_i m_j} \left(\frac{1}{M} + \frac{\gamma_i \gamma_j}{I_{\beta\beta}} + \frac{\beta_i \beta_j}{I_{\gamma\gamma}} \right) \\ &\sum_s l_{is}{}^{(\alpha)}\, l_{js}{}^{(\beta)} = \frac{\sqrt{m_i m_j}}{I_{\gamma\gamma}}\, \alpha_j \beta_i \quad (\alpha \neq \beta) \end{aligned} \tag{13}$$

They can be used for checking the calculated $\boldsymbol{l}$ matrix as well as for obtaining useful relations between the vibration-rotation quantities. Attention must be paid in calculating the $\boldsymbol{l}$ matrix to the fact that the Cartesian coordinate is fixed to the molecule along of the principal axes of inertia. Thus for the case of HDCO where the a-axis of the inertia tensor does not coincide with the C=O axis, a slight modification is necessary, because the $\boldsymbol{B}$ matrix, independent of the masses of the atoms, is common to all isotopic species and was calculated with respect to the coordinate along the C=O axis. The matrix Θ which expresses the rotation of the molecule-fixed coordinate must be multiplied. It is easily seen that the Θ matrix and the $\boldsymbol{M}^{2/1}$ matrix commute each other, and the $\boldsymbol{l}'$ matrix related to the principal axes of inertia can be expressed by

$$\boldsymbol{l}' = \Theta \boldsymbol{l} \tag{14}$$

The quantities $a_s{}^{(\alpha\beta)}$, $A_{ss}{}^{(\alpha\beta)}$ and $\zeta_{ss'}{}^{(\alpha)}$ are expressed by the components of $\boldsymbol{l}$ matrix as follows.[2]

$$\begin{aligned} &a_s{}^{(\alpha\alpha)} = 2 \sum_i \sqrt{m_i}\, (\beta_i\, l_{is}{}^{(\beta)} + \gamma_i\, l_{is}{}^{(\gamma)}) \\ &a_s{}^{(\alpha\beta)} = -2 \sum_i \sqrt{m_i}\, \alpha_i\, l_{is}{}^{(\beta)} = -2 \sum_i \sqrt{m_i}\, \beta_i\, l_{is}{}^{(\alpha)} \qquad (\alpha \neq \beta) \\ &A_{ss'}{}^{(\alpha\alpha)} = \sum_i (l_{is}{}^{(\beta)}\, l_{is'}{}^{(\beta)} + l_{is}{}^{(\gamma)}\, l_{is'}{}^{(\gamma)}) = \delta_{ss'} - \sum_i l_{is}{}^{(\alpha)}\, l_{is'}{}^{(\alpha)} \\ &A_{ss'}{}^{(\alpha\beta)} = -\sum_i l_{is}{}^{(\alpha)}\, l_{is'}{}^{(\beta)} \qquad (\alpha \neq \beta) \\ &\zeta_{ss'}{}^{(\alpha)} = \sum_i (l_{is}{}^{(\beta)}\, l_{is'}{}^{(\gamma)} - l_{is'}{}^{(\beta)}\, l_{is}{}^{(\gamma)}) \end{aligned} \tag{15}$$

It is obvious from the third formula of Eq. (15) and the first formula of Eq. (13) that the following relations exist for a planar molecule.

$$\left.\begin{aligned} &A_{ss}{}^{(aa)} + A_{ss}{}^{(bb)} = A_{ss}{}^{(cc)} = 1, \\ &a_s{}^{(aa)} + a_s{}^{(bb)} = a_s{}^{(cc)}, \end{aligned}\right\} \quad s\text{: in-plane vibration}$$

and

$$\left.\begin{aligned} &A_{ss}{}^{(aa)} = A_{ss}{}^{(bb)} = 1, \ A_{ss}{}^{(cc)} = 0, \\ &a_s{}^{(aa)} = a_s{}^{(bb)} = a_s{}^{(cc)} = 0. \end{aligned}\right\} \quad s\text{: out-of-plane vibration} \tag{15'}$$

It can be seen from Eq. (15) using Eq. (13) that the following relations exist:[3]

$$
\begin{aligned}
&\sum_{s} \zeta_{ss'}{}^{(\alpha)} \zeta_{ss'}{}^{(\beta)} = A_{ss'}{}^{(\alpha\beta)} - \frac{1}{4} \sum_{\xi} \frac{a_s{}^{(\alpha\xi)}\, a_{s'}{}^{(\beta\xi)}}{I_{\xi\xi}} \\
&\sum_{s} (a_s{}^{(\alpha\alpha)})^2 = 4I_{\alpha\alpha} \\
&\sum_{s} (a_s{}^{(\alpha\beta)})^2 = \frac{I^2{}_{\gamma\gamma} - (I_{\alpha\alpha} - I_{\beta\beta})^2}{I_{\gamma\gamma}} \\
&\sum_{s} (a_s{}^{(\alpha\alpha)}\, a_s{}^{(\beta\beta)}) = 2(I_{\alpha\alpha} + I_{\beta\beta} - I_{\gamma\gamma})
\end{aligned}
\qquad (16)
$$

These relations can be used to check the calculation.

§ 3. Symmetry Considerations

In applying the formulation given above to actual molecules many terms are shown to vanish from the symmetry considerations. Among many quantities appearing in Eq. (5), only those terms which are totally symmetric with all symmetry operations remain. For example, k_{sss} is non-vanishing only when s belongs to the totally symmetric species, because otherwise $k_{sss}\, q_s{}^3$ is antisymmetric with some symmerty operations. In the same way, whether $a_s{}^{(\alpha\beta)}$ $A_{ss}{}^{(\alpha\beta)}$, and $\zeta_{ss'}{}^{(\alpha)}$ vanish or not are determined from the symmetry properties of $q_s P_\alpha P_\beta$, $q_s{}^2 P_\alpha P_\beta$, and $q_s q_{s'} P_\alpha$, respectively.

Table I

Character Table for C_s symmetry

C_s	I	$\sigma\ (ab)$	
A'	$+1$	$+1$	R_c
A''	$+1$	-1	R_a, R_b

Table II

k_{sss}	$s \subset A'$	
$k_{sss'}$	$s' \subset A'$	s arbitrary
$A_{ss}{}^{(\alpha\alpha)}$ and $A_{ss'}{}^{(ab)}$	s arbitrary $\alpha = a, b, c,$	
$\zeta_{ss'}{}^{(c)}$	$s \subset A'$ and $s' \subset A'$ or $s \subset A''$ and $s' \subset A''$	
$\zeta_{ss'}{}^{(a)}$ and $\zeta_{ss'}{}^{(b)}$	$s \subset A'$ and $s' \subset A''$ or $s \subset A''$ and $s' \subset A''$	
$a_s{}^{(\alpha\alpha)}$ and $a_s{}^{(ab)}$	$s \subset A'$ $\alpha = a, b, c$	
$(a_s{}^{(bc)}$, $a_s{}^{(ac)})$	$s \subset A''$	

i) C_s symmetry, HDCO

The character for C_s symmetry is shown in Table I, in which the c-axis is taken as the out-of-plane axis. Non-vanishing elements are listed in Table II. $a_s{}^{(bc)}$ and $a_s{}^{(ac)}$ are shown to be zero from Eq. (15) for a planar molecule.

ii) C_{2v} symmetry, H_2CO

The character for C_{2v} symmetry is shown

Table III

Character Table for C_{2v} symmetry

C_{2v}	I	$C_2(a)$	$\sigma(ab)$	$\sigma(ac)$	
A_1	$+1$	$+1$	$+1$	$+1$	
A_2	$+1$	$+1$	-1	-1	R_a
B_1	$+1$	-1	$+1$	-1	R_c
B_2	$+1$	-1	-1	$+1$	R_b

Table IV

Non-vanishing elements for C_{2v} symmetry

k_{sss}	$s \subset A_1$	
$k_{sss'}$	$s' \subset A_1$	s arbitrary
$A_{ss}{}^{(\alpha\alpha)}$	s arbitrary, $\alpha = a, b, c$	
$\zeta_{ss'}{}^{(c)}$	$s \subset A_1$ and $s' \subset B_1$, ($s \subset A_2$ and $s' \subset B_2$)	
$\zeta_{ss'}{}^{(b)}$	$s \subset A_1$ and $s' \subset B_2$, ($s \subset A_2$ and $s' \subset B_1$)	
$\zeta_{ss'}{}^{(a)}$	$s \subset B_1$ and $s' \subset B_2$, ($s \subset A_1$ and $s' \subset A_2$)	
$a_s{}^{(\alpha\alpha)}$	$s \subset A_1$ $\alpha = a, b, c$	
$a_s{}^{(ab)}$	$s \subset B_1$	
$(a_s{}^{(bc)})$	$s \subset A_2$	
$(a_s{}^{(ac)})$	$s \subset B_2$	

in Table III. Non-vanishing elements are listed in Table IV. The rotational Hamiltonian described in the previous report was derived from these considerations.[5]

§ 4. Centrifugal Distortion Constants

The centrifugal distortion constants defined in Eq. (5) are calculated if the $\boldsymbol{l}$ matrix is obtained. Since they are expressed by $a_s^{(\alpha\beta)}$'s the non-vanishing constants are shown to be $\tau_{\alpha\alpha\alpha\alpha}$, $\tau_{\alpha\alpha\beta\beta}$ and τ_{abab} for C_{2v} planar molecules and $\tau_{\alpha\alpha\alpha\alpha}$, $\tau_{\alpha\alpha\beta\beta}$, τ_{abab} and $\tau_{\alpha\alpha ab}$ for C_s planar molecules.

The centrifugal distortion constants are calculated directly from Eq. (5), which can be transformed into a more convenient form. When Eq. (15) is substituted for example to the expression of $\tau_{\alpha\alpha\alpha\alpha}$ in Eq. (5), it is seen that

$$\begin{aligned}\tau_{\alpha\alpha\alpha\alpha} &= -\frac{1}{2(I_{\alpha\alpha}^{(e)})^4}\sum_s \frac{(a_s^{(\alpha\alpha)})^2}{\lambda_s} \\ &= -\frac{2}{(I_{\alpha\alpha}^{(e)})^4}\sum_i\sum_j \sqrt{m_i m_j}\left[\beta_i\beta_j\sum_s \frac{l_{is}^{(\beta)}\,l_{js}^{(\beta)}}{\lambda_s} + \beta_i\gamma_j\sum_s \frac{l_{is}^{(\beta)}\,l_{js}^{(\gamma)}}{\lambda_s}\right. \\ &\qquad\left. + \gamma_i\beta_j\sum_s \frac{l_{is}^{(\gamma)}\,l_{js}^{(\beta)}}{\lambda_s} + \gamma_i\gamma_j\sum \frac{l_{is}^{(\gamma)}\,l_{js}^{(\gamma)}}{\lambda_s}\right]\end{aligned}$$

The terms appearing in the bracket can be written in a matrix form. If we define a matrix X which is a square diagonal matrix with the equilibrium coordinates of particles as the diagonal elements, the following relation exists

$$\sqrt{m_i m_j}\,\alpha_i\beta_j\sum_s \frac{l_{is}^{(\alpha)}\,l_{js}^{(\beta)}}{\lambda_s} = |\boldsymbol{X'M^{1/2}\,l\lambda^{-1}\,l'M^{1/2}X}|_{\alpha_i\beta_j} \tag{17}$$

where the suffix represents the $\alpha_i\beta_j$-th component of the matrix. When the Eqs. (10) and (11) and the familiar relation $\boldsymbol{F}^{-1} = \boldsymbol{U'L\lambda^{-1}L'U}$ are substituted, the matrix appearing in the right hand side of Eq. (17) becomes $\boldsymbol{X'MAF^{-1}A'MX} = \boldsymbol{K}$. The matrices $\boldsymbol{X}$, $\boldsymbol{M}$, and $\boldsymbol{A}$ can be calculated from the masses of the atoms and the geometry of the molecule without solving the normal coordinate problem. Thus the centrifugal distortion constants can be used to determine the potential constants when there is not sufficient vibrational frequencies. The centrifugal distortion constants can be represented by the K matrix as

$$\begin{aligned}\tau_{\alpha\alpha\alpha\alpha} &= -\frac{2}{(I_{\alpha\alpha}^{(e)})^4}\sum_i\sum_j (K_{\beta i\beta j}+K_{\beta i\gamma j}+K_{\gamma i\beta j}+K_{\gamma i\gamma j}) \\ \tau_{\alpha\alpha\beta\beta} &= -\frac{2}{(I_{\alpha\alpha}^{(e)})^2\,(I_{\beta\beta}^{(e)})^2}\sum_i\sum_j (K_{\beta i\gamma j}+K_{\beta i\alpha j}+K_{\gamma i\gamma j}+K_{\gamma i\alpha j})\end{aligned} \tag{18}$$

This equation is essentially the same as the one derived by Kivelson and Wilson but is more straightforward.[6]

For a planar molecule such as formaldehyde, c elements of the X matrix vanish and $K_{\alpha icj} = 0$. Thus the following relations which was pointed out by Kivelson and Wilson are valid for all planar molecules.

$$\begin{aligned}\tau_{cccc} &= \tau_{aaaa}\frac{C^4}{A^4} + 2\,\tau_{aabb}\frac{C^4}{A^2B^2} + \tau_{bbbb}\frac{C^4}{B^4} \\ \tau_{bbcc} &= \tau_{bbbb}\frac{C^2}{B^2} + \tau_{aabb}\frac{C^2}{A^2} \\ \tau_{aacc} &= \tau_{aaaa}\frac{C^2}{A^2} + \tau_{aabb}\frac{C^2}{B^2}\end{aligned} \tag{19}$$

This relation can also be derived from the definition of the centrifugal distortion constants and the relation between $a_s^{(\alpha\beta)}$ in Eq. (15′).

§ 5. Calculation

i) Normal vibration

The formaldehyde molecule has six modes of vibration. In the cases of H_2CO and D_2CO, three of them belong to A_1, two to B_1 and one to B_2 species and in the case of HDCO five of them belong to A' and one to A'' species. An elaborate normal vibration treatment for the formaldehyde molecule was given by Miyazawa[7] using Urey-Bradley potential field. His potential constants were slightly modified in order to fit the calculated values to the values recently observed by Blau and Nielsen.[8] Internal coordinates were taken as shown in Fig. 1. The following equilibrium structure was assumed:

$$C=O=1.21\ A,\ C-H=1.08\ A,\ <HCO=120°.$$

The observed and calculated vibrational frequencies are listed in Table V, together with the potential constants. The agreement is satisfactory. $\boldsymbol{l}$ matrix was calculated from the $\boldsymbol{L}$ matrix obtained in the course of normal vibration treatment. The calculated $\boldsymbol{l}$ matrix was checked by Eq. (13).

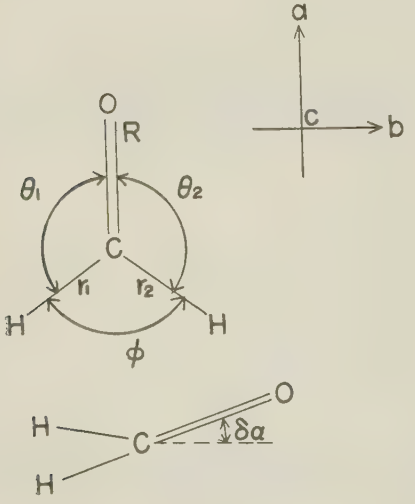

Fig. 1

ii) $a_s^{(\alpha\beta)}$, $A_{ss}^{(\alpha\beta)}$, and $\zeta_{ss'}^{(\alpha)}$

$a_s^{(\alpha\beta)}$, $A_{ss}^{(\alpha\beta)}$, and $\zeta_{ss'}^{(\alpha)}$ were calculated from Eq. (15). It was seen that the calculated values of these constants satisfied the relations in Eq. (16). Some of them are written here.

$$H_2CO: \quad (\zeta_{16}^{(b)})^2+(\zeta_{26}^{(b)})^2+(\zeta_{36}^{(b)})^2=1$$

$$(\zeta_{46}^{(a)})^2+(\zeta_{56}^{(a)})^2=1$$

$$(\zeta_{1s}^{(c)})^2+(\zeta_{2s}^{(c)})^2+(\zeta_{3s}^{(c)})^2=1 \quad (s=4,\ 5)$$

$$HDCO \quad (\zeta_{16}^{(\alpha)})^2+(\zeta_{26}^{(\alpha)})^2+(\zeta_{36}^{(\alpha)})^2+(\zeta_{46}^{(\alpha)})^2+(\zeta_{56}^{(\alpha)})^2=1 \quad (\alpha=a,\ b,\ c)$$

$$\sum_s\sum_{s'}(\zeta_{ss'}^{(\alpha)})^2=4 \quad (s,\ s'=1,\ 2,\ 3,\ 4,\ 5)$$

iii) Centrifugal distortion constants

The centrifugal distortion constants are calculated either by Eq. (5) or by Eq. (15). The explicit formula by Eq. (5) was given by Silver.[9] The calculated values are listed in

Table VI

Table VI.

iv) Inertia defect

The inertia defect was calculated as shown in Table VII. It depends on the vibrational states of the molecule. The additional terms which come from the centrifugal effect and electronic interaction are given separately. The effect of elentrons is not very small. This is due to the out-of-plane π electrons of the C=O bond. In calculating the electronic interaction the g-values listed in Table I of II were used.

§ 6. Discussions

The calculated constants of vibration-rotation interaction are compared with the observed ones in Table VIII. There is only one experimental value for the Coriolis coupling constant.[8] This value has been obtained from infra-red spectrum. Since ν_5 and ν_6 vibrations have nearly equal frequencies, the two levels $v_5=1$ and $v_6=1$ mix through $\zeta_{56}^{(a)}$.

* Blau and Nielsen (8).

§ The quoted error came from the experimental error of g-factor (5).

The calculated value is found to be in good agreement with the experimental value.

The calculated centrifugal distortion constants were used in the analysis of the K-type doubling spectra in the first part of this series of reports. As was shown there, the observed frequencies were fit with the calculated ones by a small adjustment on τ_{bbbb}. The calculated values and observed ones are listed in Table VIII.

Since the frequencies for the R-type transition were available only for H_2CO and HDCO, the observed inertia defects are listed only for these two species. They agree with the calculated values within the probable error. The rotational constants for other isotopic species were computed using the calculated inertia defects. The measurement of $1_{01} \leftarrow 0_{00}$ lines for these isotopic species would be of interest to test the accuracy of the present result.

Double Quantum Transition in Electron Spin Resonance of Diphenyl-Picryl Hydrazyl at Low Magnetic Fields

By Tsuneo HASHI

Department of Physics, Faculty of Science, Kyoto University

(Received February 3, 1961)

Two radiation fields (ν_1 of about 150 Mc and ν_2 of 30, 20, and 15 Mc) are applied at static fields of about 50 gauss. The line shape, the peak position, and the intensity of the signal are well interpreted on the basis of the Bloch phenomenological equation choosing $T=4.8\times10^{-8}$ sec, except for slight discrepancies near $H_0=\omega_1/|\gamma|$. Some experimental results at $\nu_2=4.5$ Mc are also given.

§ 1. Introduction

When a two-level system of energy separation $h\nu_0$ is simultaneously irradiated by two radiation fields of different frequencies ν_1 and ν_2 ($\nu_1>\nu_2$), the double quantum transition can take place[1,2,3] under the condition of conservation of energy ($\nu_0=\nu_1-\nu_2$ or $\nu_0=\nu_1+\nu_2$) and that of angular momentum. In the case of $\nu_0=\nu_1-\nu_2$, a quantum with frequency ν_1 is absorbed and a quantum with frequency ν_2 simultaneously emitted, while in the case of $\nu_0=\nu_1+\nu_2$, two quanta with frequencies ν_1 and ν_2 are simultaneously absorbed. Though each process is accompanied by the inverse process, the weight of the inverse process is smaller by the population ratio of the two energy levels. The net emission at the frequency ν_2 in the case of $\nu_0=\nu_1-\nu_2$ is of particular interest, since this mechanism can be used to realize a maser on a system with the positive temperature,[3] and recently much attention has been paid to the role of the double quantum transition in the masers.[3,4,5]

The present paper is concerned with this type of double quantum transition associated with the electron spin resonance of diphenyl-picryl hydrazyl (DPPH) at low magnetic fields. In the field of the magnetic reasonance, the experimental work reported by Winter[2] seems to be the only one as the experimental work on such a double quantum transition.[*] He observed a double quantum transition in DPPH at high magnetic fields, but gave no detailed descriptions of characters of the transition such as the line shape, the peak position and the intensity of the signal. The aim of the present work consists in the detailed study on the double quantum transition relating to the relaxation in the non-isolated system.

We used two radiation fields of the frequency ν_1 of about 150 Mc and of the frequency ν_2 in the range of 4.5 Mc to 30 Mc, and the static magnetic field of about 50 gauss. The signals were observed at the frequency ν_2. The low field magnetic resonance is particularly suitable for the study of the line shape, since the sufficient field strength of rf magnetic field is readily obtainable and the inhomogeneity of the static magnetic field is easily reduced to such an amount that the line shape is not seriously affected by it.

The description of the apparatus, the experimental results and the comparison with the calculations based on the Bloch phenomenological equation[6] are given in the following.

§ 2. Apparatus and Experimental Procedure

The block diagram of the apparatus is shown in Fig. 1. The directions of three magnetic fields (H_0, $2H_1\cos\omega_1t$ and $H_2\cos\omega_2t$) are so arranged that the conservation of the angular monentum is preserved for the double quantum transition, as shown in Fig. 2.

The static magnetic field H_0 of about 50 gauss is produced by a Helmholtz coil which

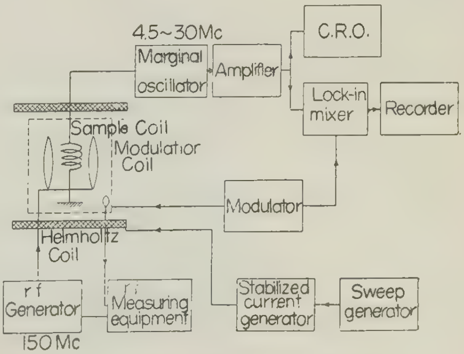

Fig. 1 Block diagram of apparatus

is supplied by a low voltage stabilized current generator using power transistors. At the same time, this generator gives a gradual change in the magnetic field drived by sweep generator of the Miller integrator type. The value of H_0 is measured by an ordinary absorption signal of DPPH using a low field electron spin resonance spectrometer operating in the range of 10 Mc to 200 Mc, which is not shown in Fig. 1.

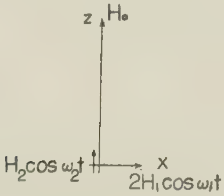

Fig. 2. Arrangement of magnetic fields.

The rf magnetic field $2H_1\cos\omega_1t$ ($\nu_1\simeq150$Mc) perpendicular to the static magnetic field H_0 is produced by a Helmholtz coil with diameter of 3 cm supplied by an rf generator constructed by the stage of master oscillator and that of power amplifier. The maximum available value of H_1 is about 4 gauss. The value of H_1 is measured by a pickup coil-VTVM system. It is also chequed by use of the pulsed pure quadrupole resonance of Br^{81} in $NaBrO_3$,[7] as follows. A single crystal of $NaBrO_3$ is inserted in the coil and the frequency of the rf generator is set at the pure quadrupole reasonance frequency of Br^{81}, i.e. about 150Mc which is also the frequency of the radiation field used throughout the present experiment. The rf generator is then operated in pulsed fashion and the signal from Br^{81} is detected in a usual way as in the standard pulsed pure quadrupole reasonace experiment (the details of the calibrating apparatures are not given in Fig. 1.). From the observed 90° pulse-width t_w and the relation $\sqrt{3}\gamma_{Br}H_1t_w=\pi/2$, the value of H_1 is obtained.

The rf magnetic field $H_2\cos\omega_2t$ ($\nu_2=4.5\sim30$ Mc) parallel to the static magnetic field H_0 is produced by a marginal oscillator of Pound-Knight type.[8] The marginal oscillator serves also as a detector for the double quantum transition, whose output is amplified and coherently detected in the same manner as in the usual magnetic resonance experiment.[9]

The 32c modulation field is produced by an auxiliary coil parallel to the static magnetic field H_0 and the peak-to-peak amplitude used for all of the measurements is 0.1 gauss or less. The frequency modulation and frequency sweep scheme is more desirable than the present magnetic field modulation and magnetic field sweep scheme, but it is not practical because a relatively wide frequency range must be swept. Since our main purpose is the detailed study of the line shape, particular attention was paid to the setting of modulation amplitude, the linearity of the sweep, the balancing of lock-in mixer, and the homogeneity of magnetic fields H_0 and H_1.

The sample consisted of approximately 0.3 g of polycrystalline diphenyl-picryl hydrazyl. All measurements were made at room temperatures.

§ 3. Experimental Results and Discussion

The measurements were made at the frequencies ν_1 of about 150 Mc and ν_2 of 30, 20,

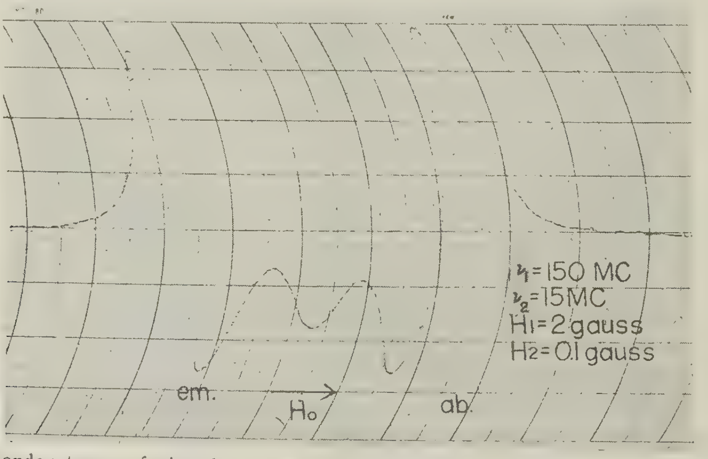

Fig. 3. A typical recorder trace of signal at $\nu_1=150$Mc, $\nu_2=15$Mc $H_1=2$ gauss and $H_2=0.1$ gauss.

15 and 4.5 Mc for various values of H_1 from 1 to 3 gauss. The value of H_2 was fixed at 0.1 gauss.

First we shall show the experimental results at $\nu_2=30$, 20 and 15 Mc. A typical recorder trace and its integrated curve at $\nu_2=15$ Mc and $H_1=2$ gauss are represented in Figs. 3 and 4. All of the integrated curves of the signals obtained at $\nu_2=30$, 20 and 15 Mc have the similar profile. The characteristic features of the curve are as follows. The curve shows opposite polarities on both sides of the magnetic field $H_0=\omega_1/|\gamma|$. By comparing it with the polarity of the ordinary absorption signal obtained by the same apparatus at the frequency ν_2, it was decided that the emission takes place below that field value (i.e. $\omega_0<\omega_1$) and the absorption above it (i.e. $\omega_0>\omega_1$). The fact that the emission takes place in the present case was also confirmed by detecting it with the aid of a high gain regenerative amplifier, in which the oscillation occurred when coupled with it in the case of 2 g of DPPH.

The emission and the absorption parts of the integrated curve are similar in form except for the polarities. More precisely, however, the height of the absorption curve is slightly larger than that of the emission curve. The ratio of the two peak heights is equal to that of the values of H_0 at which the peaks appear. If the curves are transformed by dividing the ordinate by the corresponding abscissa, the emission and the absorption curves become coincident in form. So, in the following, we deal with only the half of the whole curve obtained by the above procedures.

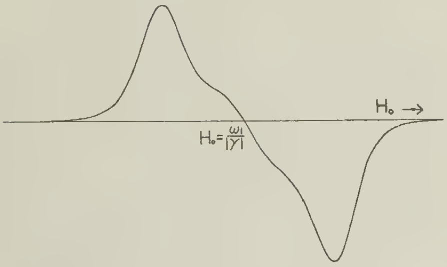

Fig. 4. Integrated curve of the signal given in Fig. 3, the left-hand half showing the emission and the right-hand one absorption.

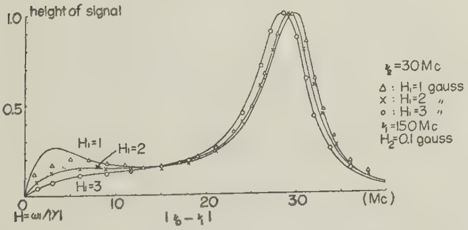

Fig. 5. Calculated half line shapes and experimental points at $\nu_1=150$Mc, $\nu_2=30$Mc, $H_1=1$, 2, 3 gauss and $H_2=0.1$ gauss. The formers are obtained by using (8) and normalizing the peak to unity, and the latters obtained by the procedures stated in the text.

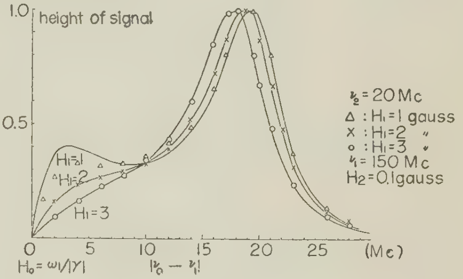

Fig. 6. Calculated half line shapes and experimental points at $\nu_1=150$Mc, $\nu_2=20$Mc, $H_1=1$, 2, 3 gauss and $H_2=0.1$ gauss. These are obtained in the same way as in Fig. 5.

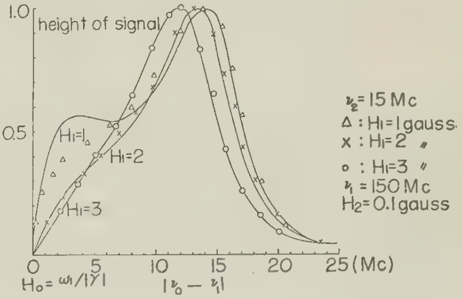

Fig. 7. Calculated half line shapes and experimental points at $\nu_1=150$Mc, $\nu_2=15$Mc, $H_1=1$, 2, 3 gauss and $H_2=0.1$ gauss. These are obtained in the same way as in Fig. 5.

The transformed emission (or absorption) curve is not symmetrical with respect to its peak axis, but some bulges or bumps appear on the higher (or lower) field side. The detailed line shapes are given by experimental points in Figs. 5∼7 for various values of ν_2 and of H_1.

The positions of the peaks do not coincide exactly with the field values $H_0=(\omega_1\pm\omega_2)/|\gamma|$, shifting to the higher field side in the case of emission (lower field side in the case of absorption). The amount of the shift is approximately proportional to H_1^2.

The variation of the peak height (signal intensity) with H_1 is shown in Fig. 8 (where the heights are not divided by the corresponding values of H_0). It is proportional to H_1^2 at $\nu_2=30$ Mc, but at $\nu_2=15$ Mc, the increase of it becomes more gradual than H_1^2 for larger values of H_1. Since it is difficult to maintain the equal sensitivity of the spectrometer at different frequencies, the precise comparison between peak heights at different frequencies was not made. But it was observed that the peak height is approximately proportional to $1/\nu_2^2$ at the fixed values of H_1.

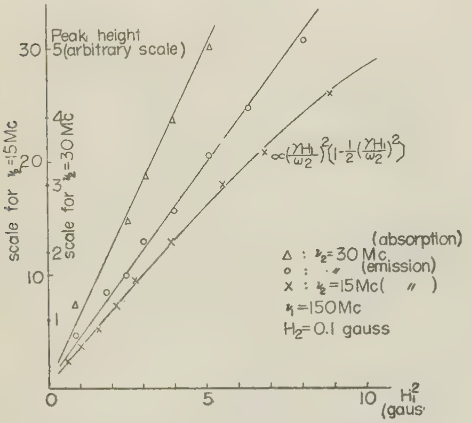

Fig. 8. Variation of peak height with H_1 at $\nu_2=$ 30Mc, 15Mc, $\nu_1=150$Mc and $H_2=0.1$ gauss. ∘, Δ, × are experimental points corresponding respectively to emission and to absorption at $\nu_2=30$Mc and to emission at $\nu_2=15$Mc. Curves are obtained by using (10) and multiplying by appropriate factors for best fits. Different multiplication factors are used for $\nu_2=30$Mc and $\nu_2=15$Mc.

The signal intensity decreases as $\cos^2\theta$, if the direction of the field $H_2\cos\omega_2 t$ is rotated by the angle θ in the zx plane (Fig. 2). No signals could be obtained when the direction of $H_2\cos\omega_2 t$ became perpendicular to both H_0 and H_1. We tried to observe, in this case, the signals due to the higher order transitions at the field $H_0=(2\omega_1\pm\omega_2)/|\gamma|$, but without success.

Now, we shall compare the above results with the calculations based upon the Bloch phenomenological equation.

In non-diluted DPPH, the strong exchange coupling markedly narrows the resonance lines,[10] so the application of the Bloch equation was justified[11] from the microscopic point of view. It holds in the present case of the double quantum transition. Further we assume $T_1=T_2$ after Lloyd and Pake,[10] though recently it was pointed out[12] that in some cases the relation $T_1=T_2$ does not hold exactly for non-diluted DPPH.

The Bloch equation is

$$\frac{d\boldsymbol{M}}{dt}=\gamma(\boldsymbol{M}\times\boldsymbol{H})-\frac{1}{T}(\boldsymbol{M}-\boldsymbol{M}_0)\,. \qquad (1)$$

In the present case, $\boldsymbol{H}$ consists of three components H_0, $2H_1\cos\omega_1 t$ and $H_2\cos\omega_2 t$, namely

$$\boldsymbol{H}=(H_0+H_2\cos\omega_2 t)\boldsymbol{k}+(2H_1\cos\omega_1 t)\boldsymbol{i}\,. \qquad (2)$$

Using a coordinate system rotating about H_0 with angular frequency ω_1, the phenomena described by Eqs. (1) and (2) can regarded as a kind of magnetic resonance in the rotating coordinate system, "nutation resonance." The time dependent magnetization M_z of frequency ν_2 obtained from the equation is

$$M_z=(\chi' H_2\cos\omega_2 t+\chi'' H_2\sin\omega_2 t)\,, \qquad (3)$$

with

$$\chi''=\frac{1}{2}|\gamma|M_0 T\frac{(\omega_0-\omega_1)(\gamma H_1)^2}{\omega_e^3}\cdot\frac{4\omega_e\omega_2}{(\omega_e+\omega_2)^2+1/T^2}\cdot\frac{1}{1+(\omega_e-\omega_2)^2T^2}\,, \qquad (4)$$

where

$$\omega_e=|\gamma|H_e=\sqrt{(\omega_0-\omega_1)^2+(\gamma H_1)^2}\,,$$

and further, following assumptions have been made:

$$|\gamma|H_2\ll\left|\frac{\omega_e^2}{(\omega_0-\omega_1)}\right|,\quad \gamma^2H_2^2\ll\frac{1}{T^2}\,. \qquad (5)$$

Using the values of T already reported,[10,12,13,14] it can be shown that the inequalities (5) hold under the present experimental conditions. In addition, $\omega_2 T\gg1$ at $\nu_2=30$, 20 and 15 Mc, so that Eq. (4) becomes

$$\chi''=\frac{1}{2}|\gamma|M_0T\frac{(\omega_0-\omega_1)(\gamma H_1)^2}{\omega_e^3}\frac{4\omega_e\omega_2}{(\omega_e+\omega_2)^2}\frac{1}{1+(\omega_e-\omega_2)^2T^2}\,. \qquad (6)$$

The power absorbed by the sample is

$$P=\frac{1}{2}\omega_2 H_2^2\chi''\,. \qquad (7)$$

According to the formulas (4) and (7), P becomes negative for $\omega_0<\omega_1$ and positive for $\omega_0>\omega_1$, corresponding to the experimentally observed facts.

Since the line shapes in Figs. 5~7 are obtained from the experimental curves devided by the corresponding value of H_0 and normalized as the peak height becomes unity, they should be compared with a factor

$$\frac{|\omega_0-\omega_1|(\gamma H_1)^2}{\omega_e^3}\cdot\frac{4\omega_e\omega_2}{(\omega_e+\omega_2)^2}\frac{1}{1+(\omega_e-\omega_2)^2T^2} \quad (8)$$

appeared in (6).

Best fits are obtained by choosing the value of T as 4.8×10^{-8}sec. The solid curves in Figs. 5~7 are the polts of the factor for various values of H_1 using the above value of T. The same value of T was also obtained by use of ordinary absorption signal of the same sample at the frequency of about 150 Mc. The signal was obtained in the course of measuring H_0.

The asymmetry in the line shape is mainly due to the factor $\frac{|\omega_0-\omega_1|(\gamma H_1)^2}{\omega_e^3}$ which can be written as $\cos\Theta\ \sin\Theta$ and has the peaks at $H_0=\frac{\omega_1}{|\gamma|}\pm\frac{H_1}{\sqrt{2}}$, where Θ is the angle between H_0 and H_e in the coordinate system rotating about H_0 with the angular frequency ω_1. If the resonance lines were traced using the frequency modulation and frequency sweep technique, the asymmetry in the line shape would not appear.

The factor $\frac{4\omega_e\omega_2}{(\omega_e+\omega_2)^2}$ represents the fact that the magnetic field causing the transition is linearly polarized rather than circularly.

As will be seen in Figs. 5~7, the agreement between the experimental points and the calculated curves is nearly satisfactory. In the region near $H_0=\omega_1/|\gamma|$, however, some disagreements appear, especially for the case of $H_1=1$ gauss. They may be attributed to the experimental error due to the poor signal-to-noise ratio, frequently encountered in the case of lower H_1 and to the rather crude assumption that $T_1=T_2$. The rf field $2H_1\cos\omega_1 t$ is "on resonance" in the region near $H_0=\omega_1/|\gamma|$, so that the direct transition (not the double quantum transition) is strongly saturated. At first sight, the saturation might be considered to be an origin of the disagreements. However, the effects of the saturation caused by the rf field $2H_1\cos\omega_1 t$ on the line shape of the double quantum transition are already taken into account when the Bloch equation is used. So, the anomalous saturation effect which cannot be described by the Bloch equation, if any, might be another origin of the disagreements in the region near $H_0=\omega_1/|\gamma|$. The study of the double quantum transition under the saturation condition which is closely related to the "rotary saturation"[15] is now under way on diluted DPPH, where $T_1\fallingdotseq T_2$ and the applicability of the Bloch equation is doubtful.

It is difficult to calculate the exact values of H_0 at which the factor (8) is maximum. But considering the fact that the first two factors of (6) are rather slowly varying functions of H_0 near the peak, the approximate peak position is obtained as

$$H_0=\frac{\omega_1}{|\gamma|}\pm\frac{1}{|\gamma|}\left(\omega_2-\frac{1}{2}\frac{(\gamma H_1)^2}{\omega_2}-\frac{1}{8}\frac{1}{\omega_2T^2}\right). \quad (9)$$

The term $\frac{1}{8|\gamma|}\frac{1}{\omega_2T^2}$ is about 0.1 gauss or less in magnitude under the present experimental conditions and it cannot be detected by the used experimental apparatus. The term $\frac{1}{2|\gamma|}\frac{(\gamma H_1)^2}{\omega_2}$ becomes of the order of one gauss and gives a main contribution to the shift of the peak position from $H_0=(\omega_1\pm\omega_2)/|\gamma|$, which agrees with the experimental results.

The approximate peak value of χ'' is calculated from (6) by putting $\omega_e=\omega_2$, as:

$$\frac{1}{2}|\gamma|M_0T\left(\frac{\gamma H_1}{\omega_2}\right)^2\left[1-\frac{1}{2}\left(\frac{\gamma H_1}{\omega_2}\right)^2\right], \quad (10)$$

which explains the experimental variation of the peak height with H_1 at the fixed ν_2 as shown in Fig. 8, and that with ν_2 at the fixed H_1. The difference between the gradients of two curves for $\nu_2=30$ Mc in Fig. 8 can be interpreted by the difference between the values of $M_0=\chi_0H_0$ at which the peaks appear.

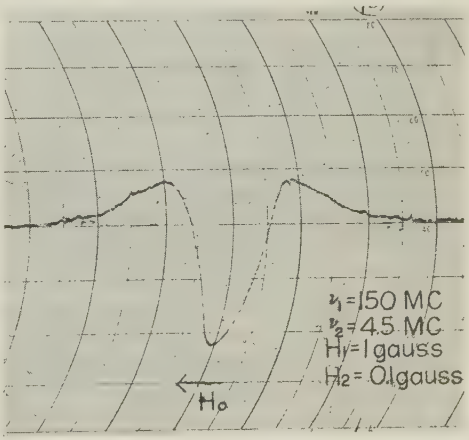

Fig. 9. A recorder trace of signal at $\nu_1=150$Mc, $\nu_2=4.5$Mc $H_1=1$ gauss and $H_2=0.1$ gauss.

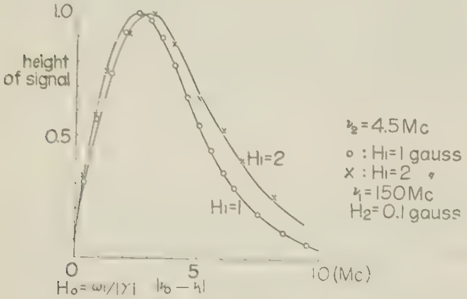

Fig. 10. Calculated half line shapes and experimental points at $\nu_1=150$Mc, $\nu_2=4.5$Mc, $H_1=1$, 2 gauss and $H_2=0.1$ gauss. These are obtained in the same way as in Fig. 5.

Next we shall mention about the signal at the frequency ν_2 of 4.5 Mc. One of the recorder trace of the signals is shown in Fig. 9. The integrated curve is similar in form to the ordinary dispersion signal. Though it seems to have different profile from the results observed at $\nu_2=30$, 20 and 15 Mc, it consists of two parts, emission and the absorption part. After the treatment described above, the line shape becomes the same as those at the higher ν_2 frequencies. The half of the whole line shape is shown by experimental points in Fig. 10. The rf field $2H_1 \cos \omega_1 t$ is always "on resonance" over the whole curve, but as mentioned above, Eq. (4) can be used for analysis. Two calculated line shapes at $H_1=1$ and $H_1=2$ gauss are shown in Fig. 10, where $T=4.8\times10^{-8}$sec is used. So far as the curves in Fig. 10 are concerned, the agreement between the experimental and the calculated line shapes is satisfactory. The observed variations in the position and in the height of the peak are different from those at $\nu_2=30$, 20 and 15Mc, and are rather complicated functions of H_1. The peak height is proportional to H_1^2 up to the field $H_1=0.5$ gauss, but for heigher values of H_1 the increase in the peak height becomes more gradual. For the values of $H_1>1$ gauss, the peak position lies on the lower (or higher) field side for higher values of H_1 in the case of the emission (or absorption). Though these features can be interpreted qualitatively by the expression (4), no precise comparison has been made as yet. The detailed study of the case of $\nu_2=4.5$ Mc will be published in a near future.

Acknowledgement

The author would like to express his sincere thanks to Prof. I. Takahashi and Prof. K. Tomita for their continued interest and discussion. The author's thanks are also due to the members of our laboratory for their assistance. The samples were kindly supplied by Mr. Y. Deguchi of the Department of Chemistry of this University.

On the Pendent Drop, I

By Ko TAMADA
Department of Aeronautical Engineering, Faculty of Engineering, Kyoto University
and Yoshio SHIBAOKA
Department of Physics, Faculty of Science, Osaka City University

(Received February 27, 1961)

In the present paper is discussed the equilibrium of a pendent drop which appears on the film of water covering a horizontal surface. It is found that the volume of the drop takes a maximum value at a special configuration of $D/H \cong 3$, where D is the diameter and H the depth, of the drop. The solutions for the equilibrium beyond this maximum cannot be realized in the actual drop, since there is slight but steady current of water into the drop from the surrounding film. The drop, in reality, will become unstable for external disturbance and collapse just before the said limit is reached.

An analytical solution is obtainable for the case of a two-dimensional drop, the cross sectional area of which is also seen to attain a maximum at $D/H \cong 1.9$.

§ 1. Introduction

When a glass or metal plate is wetted fully by water and set horizontally, there will soon appear pendent drops on the lower surface of the plate. As far as the present writers are aware, the theoretical consideration concerning the pendent drop of this kind was first made by S. Moriguchi.[1] He linearized the fundamental equation of equilibrium for small thickness of the drop at its initial stage of formation, and determined the diameter of the drop as a characteristic value of the equation. In the present paper is considered the more developed and thick drop on the basis of the equilibrium equation in its full nonlinear form. The process of growth and breakdown of the drop will be of special interest.

As the result of calculation, it turns out that the volume of the drop attains a maximum at a special geometry $D/H \cong 3$, where D is the diameter and H the depth, of the drop. This may be regarded as the final stage of equilibrium for an actual drop, since its volume must increase monotonously owing to the inflow of water induced by the negative pressure at the base of the drop.

The drop, in reality, will collapse just before the said limiting stage is reached. The discussion of the dynamical instability of the drop will however be given in a subsequent paper.

§ 2. Fundamental Equation

The shape of the pendent drop in question is symmetric about a vertical axis and we take it as the z-axis (positive direction downward) of the cylindrical coordinates (r, z) (Fig. 1).

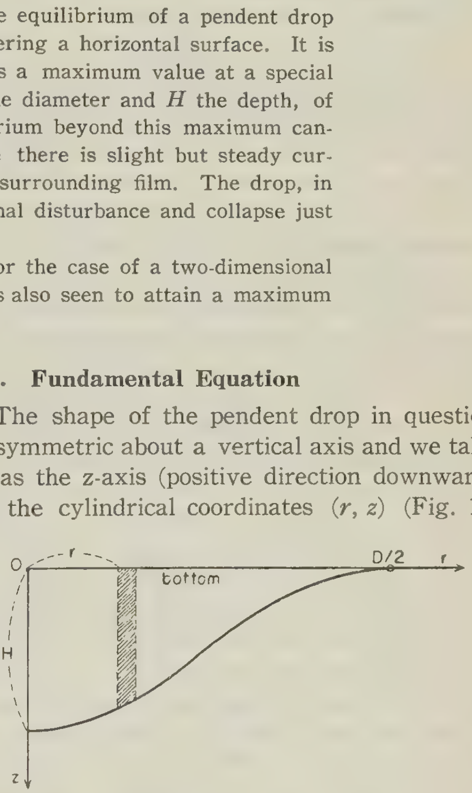

Fig. 1

Let $z(r)$ be the surface of the drop, T the surface tension, ρ the density of water, g the accelaration of gravity and p the excess pressure of the surrounding air over the pressure of water at the bottom $(z=0)$ of the drop. Then, by considering equilibrium of the mass of water contained between the two coaxial cylinders r and $r+dr$, we may write down the equation of equilibrium in the following form:

$$T\frac{d}{dr}\left\{\frac{r\,dz/dr}{\sqrt{1+(dz/dr)^2}}\right\}+r(\rho gz-p)=0 . \qquad (1)$$

Putting here

$$\sqrt{\frac{T}{\rho g}}=l , \quad r=l\xi , \quad z-\frac{p}{\rho g}=l\eta , \qquad (2)$$

we reduce Eq. (1) to a nondimensional form

$$\frac{1}{\xi}\frac{d}{d\xi}\left\{\frac{\xi d\eta/d\xi}{\sqrt{1+(d\eta/d\xi)^2}}\right\}+\eta=0\,. \tag{3}$$

The parameter l is the representative length of the present problem, whose value is determined by the physical constants T, ρ and g. Assuming, for example, $\rho=1\,\mathrm{gr/cm^3}$, $T=73\,\mathrm{dyne/cm}$ and $g=980\,\mathrm{cm/sec^2}$ for water, we obtain the result $l=0.27\,\mathrm{cm}$.

Appropriate boundary conditions for the present problem may be such that

$$\text{at } \xi=0 \text{ and } \xi=\alpha \quad d\eta/d\xi=0\,. \tag{4}$$

Here α is the nondimensional radius of the rim of the drop, which may be taken as the characteristic value of Eq. (3). As is shown below, it may take finite values. This might be seen somewhat unnatural, since any observed drop continues smoothly to the surrounding film of water and hence has no difinite radius. The discrepancy may however be explained as follows: Since the surface tension acts horizontally at the rim $\xi=\alpha$, the weight of the drop as a whole must be sustained by the sum of the pressure difference p. Therefore the pressure of water at the bottom $z=0$ of the drop must be lower than the air pressure, while the pressure in the thin film of water surrounding the drop is obviously equal to the air pressure. The result will be slight but steady inflow of water into the drop from the surrounding. Thus, the actual drop is never in equilibrium in the strict sence, and precise argument about the shape of the drop near the rim will call for the consideration of the inflow of water (viscosity will be important) mentioned above. However, for the case of very slow growth, the shape of the drop may be expected to agree practically with the profile of equilibrium to be determined by (3) and (4).

Since the drop is relatively flat at its initial stage of formation, we may safely neglect the term $(d\eta/d\xi)$ in Eq. (3). Then, it reduces to the Bessel equation of the zero order. This is the case treated by S. Moriguchi. The radius α is determined as the first characteristic value of the equation for the boundary condition (4).* Now, for the consideration of the drop at its intermediate and final stages, it seems to be impossible to make any neglect in Eq. (3). Further, owing to its nonlinearity, it is difficult to obtain analytical solution of the full equation (3), and so we shall appeal to a method of numerical integration in the following section.

§ 3. Integration of the Equation

Let $\Delta\xi$ be a small increment of ξ and $\xi_j=j\Delta\xi$ $(j=0, 1, 2, \ldots)$. Then, Eq. (3) may be approximated by the difference equation

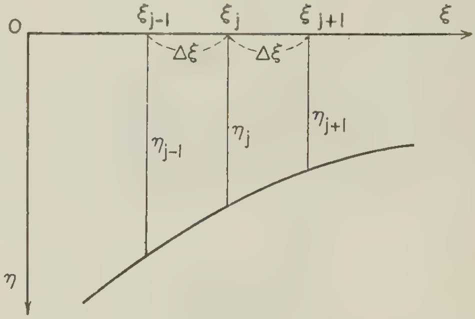

Fig. 2

$$(\xi_j\Delta\xi)^{-1}(\zeta_{j+1/2}-\zeta_{j-1/2})+\eta_j=0\,, \tag{5}$$

where

$$\left.\begin{aligned}\zeta_{j+1/2}&=\frac{1}{2}(\xi_{j+1}+\xi_j)\,\frac{\eta_{j+1}-\eta_j}{\Delta\xi}\times\\&\qquad\left\{1+\left(\frac{\eta_{j+1}-\eta_j}{\Delta\xi}\right)^2\right\}^{-1/2}\\\zeta_{j-1/2}&=\zeta_{(j-1)+1/2}\,,\quad \eta_j=\eta(\xi_j)\end{aligned}\right\} \tag{5a}$$

Solving for η_{j+1} we get

$$\left.\begin{aligned}\eta_{j+1}&=\eta_j+k(1+k^2)^{-1/2}\Delta\xi\,,\\k&=\frac{2j-1}{2j+1}\frac{\eta_j-\eta_{j-1}}{\sqrt{(\Delta\xi)^2+(\eta_j-\eta_{j-1})^2}}+O(\Delta\xi)\end{aligned}\right\} \tag{6}$$

This formula enables us to calculate η_{j+1} with the known data η_j and η_{j-1}. For the starting value η_0 and η_1 we use the power series solution

$$\eta=\eta_0\left\{1-\frac{1}{4}\xi^2+\frac{1}{64}(1-\eta_0^2)\xi^4-\frac{1}{4608}(2-20\eta_0^2+9\eta_0^4)\xi^6+\cdots\right\} \tag{7}$$

which satisfies the initial condition $\eta=\eta_0$ and $d\eta/d\xi=0$ at $\xi=0$. By means of (6) and (7) we may calculate the successive values of η_j until $d\eta/d\xi=0$ at $\xi=\alpha$. This α may be taken as the radius of the drop. Further, the numerical result thus obtained may be refined in the following way. We first integrate once the equation (3) formally and obtain

---

* $\alpha\cong3.83$ and the diameter of the drop $2l\alpha\cong2\,\mathrm{cm}$ for water.

$$d\eta/d\xi = -\left\{\xi^2 - \left(\int_0^\xi \xi\eta\, d\xi\right)^2\right\}^{-1/2} \int_0^\xi \xi\eta\, d\xi\,. \quad (8)$$

Then, inserting the values of $\eta(\xi)$ previously obtained into the right hand side, and carrying out numerical integration,* we can obtain the second approximation for $\eta(\xi)$. We repeat the process till the result converges.

§ 4. Result and Discussion

Fig. 3 shows the calculated profiles of the pendent drop for several values of the parameter η_0. The diameter-depth ratio D/H for each case is tabulated in Table I.

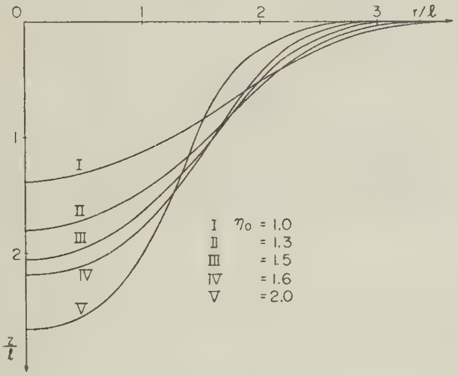

Fig. 3

Table I.

η_0	1	1.3	1.5	1.6	2
D/H	5.173	3.786	3.175	2.924	2.092

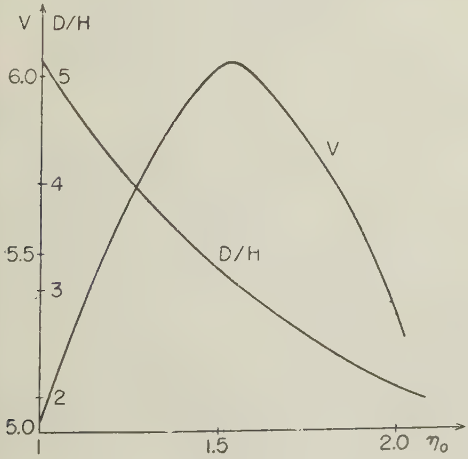

Fig. 4

Now, the volume V of water contained in the drop is obviously given by the equation

$$V = 2\pi \int_0^{D/2} r z(r) dr \qquad (9)$$

Evaluating the integral numerically for each values of η_0, we obtain the relation between V and D/H as shown in Fig. 4. As is seen in the figure, the volume of the drop becomes maximum at about $D/H \simeq 3$. This stage of the maximum volume may be taken as the static limit of the actual drop, since as mentioned before the volume of the drop must increase steadily.** As a matter of fact, the drop will break down just before the said stage is attained owing to its instability for external disturbances.

§ 5. Two-dimensional Case

The corresponding problem for the two-dimensional case seems to be rather artificial, yet it may be of some interest since exact analytical treatment is possible. The result turns out to be qualitatively similar to that of the preceding case.

Taking the rectangular coordinates (x, y) in place of (r, z) and applying the corresponding transformation (2), the fundamental equation becomes

$$\frac{d}{d\xi}\left\{\frac{d\eta/d\xi}{\sqrt{1+(d\eta/d\xi)^2}}\right\} + \eta = 0\,. \qquad (10)$$

Solving this equation under the conditions (4), we get

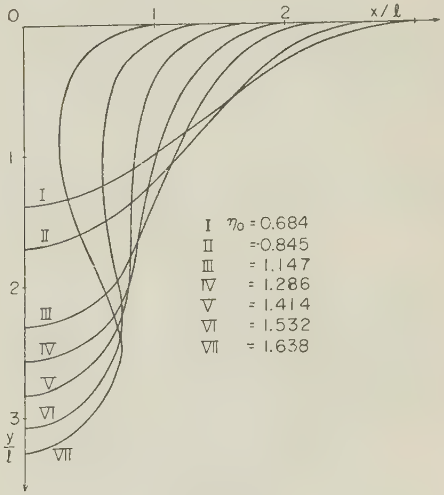

Fig. 5

---

* We have used the formula $\int_{xj-1}^{xj} y dx = \frac{1}{12}(5y_{j-1} + 8y_j - y_{j+1}) \Delta x$

** Part of the profile for $D/H < 3$ can be realized in a pendent drop from the lower tip of a vertical capillary (Reference 2).

$$\left.\begin{aligned} \eta &= \eta_0 \cos\theta\,, \\ \xi &= 2E(\eta_0/2, \theta) - F(\eta_0/2, \theta) \end{aligned}\right\} \quad (11)$$

where $F(\lambda, \theta)$ and $E(\lambda, \theta)$ are respectively the elliptic integral of the first and the second kinds. Since $\eta(\xi) = -\eta(\alpha - \xi)$ in this case, the reduced radius α of the drop is given by the expression

$$\begin{aligned} \alpha &= [\xi]_{\theta=\pi/2} = 4E(\eta_0/2) - 2K(\eta_0/2) \\ &= \pi\left\{1 - \frac{3}{16}\eta_0^2 - \frac{15}{1024}\eta_0^4\right. \\ &\qquad \left. - \frac{35}{16384}\eta_0^6 - \frac{1575}{4194304}\eta_0^8 - \cdots\right\} \quad (12) \end{aligned}$$

where K and E are the complete elliptic integrals. Further, the volume (or cross sectional area, to be exact) S of the drop is $S = 2\alpha\eta_0$, and it can be shown that S becomes maximum for $\eta_0 \simeq 1.187$. Corresponding value of $D/H = \alpha/\eta_0$ is found to be about 1.85. In Fig. 5 are shown some of the calculated shapes of the two-dimensional drop. The value of D/H for each case is given in Table II.

Table II.

η_0	0.684	0.845	1.147	1.286	1.414	1.532	1.638
D/H	4.174	3.187	1.976	1.554	1.198	0.882	0.589

After completing the present work, the writers became aware of the paper due to S. Fordham,[2)] in which are given detailed results of calculation for the shapes of pendant drops. Fordham's work however concerns the determination of surface tension from measurements of pendant drops and hence the calculation of the shape of drop was carried out only up to the point of inflexion on the profile of the drop.

Observation of Dislocations in Germanium Single Crystal

By Masakazu SHOJI, Shoji TAUCHI,
Tomokuni MITSUISHI and Masami TOMONO
Hitachi Central Research Laboratory
Kokubunji, Tokyo

(Received February 28, 1961)

It is well known that the density of small etch pits of germanium revealed by slow etching is several orders of magnitude larger than that of CP–4 etch pits[1),2)]. These small etch pits were believed to be screw dislocations[1),2)], but their high density has not been explained. Correspondence between the dislocation line and etch pits was reported[3),4)], although above-mentioned point is not decided.

In this experiment, dislocation lines in germanium were observed by the method of Borrmann[4)] and the density of etch pits was compared with that of X-ray images. From the crystal ingots two groups of specimen A and B were taken very near to each other as shown in Fig. 1(a).

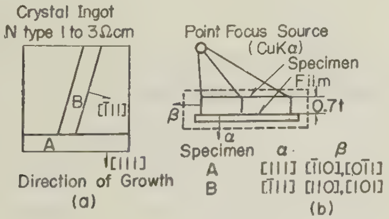

Fig. 1. Orientation of the specimen and the method for X-ray observation.

Nearly isotropic distribution of the direction of Burgers vector was assured by the comparison of X-ray photographs taken for the specimen A and B as shown in Fig. 1(b). After the X-ray observation, CP–4 etch pits and small spiral etch pits reported by Rhodes et al.[2)] were revealed successively. The density of the latter was considerably larger than that reported. The density of etch pits was compared with that of X-ray images obtained for one of the (110) planes. The result is shown in Fig. 2. This might be a extension of the data of Kurtz et al.[5)]

Agreement between the density of X-ray images and that of CP–4 etch pits becomes good because both of them are underestimated. Factor of underestimation in X-ray observation must be smaller than six because one of the six <110> is perpendicular to the diffracting plane. This is shown by *L* in the figure. For the etch pit, this factor must be smaller than four[5)] in the worst case[6)]. This is given by *H*. Overlapping of images prevents precise determination of the density.

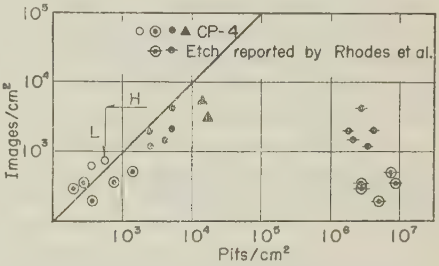

Fig. 2. Comparison of the density of images and that of etch pits.

Density of small etch pits was nearly uniform all over the ingots from which specimen A and B were taken. If these pits correspond to the dislocation lines, some of the photographs taken for different (110) planes must show their images. But the densities of images determined from several photographs agreed within the factor six and the density of small pits was about 10^3 times larger than these. So these small etch pits never correspond to the usual dislocation lines.

They may be clusters of vacancies, some kind of defects related to the impurity[2)], or loops of dislocation which are too small to be resolved. Relation to the rocking curve data[1)] is not clear at present.

The authors wish to express their thanks to Dr. H. Hagihara and Professor K. Kohra for their kind advice and encouragement.

Anomalous Temperature Dependence of Lattice Constants of Ferroelectric Sodium Nitrite

By Sadao HOSHINO and Iwao SHIBUYA

Institute for Solid State Physics
The University of Tokyo, Tokyo

(Received March 18, 1961)

In order to study the mechanism of the ferroelectric phase transition in $NaNO_2$, the temperature dependence of lattice constants was measured precisely by x-ray diffraction methods. $NaNO_2$ is ferroelectric below 160°C[1] with the space group I*m*2*m*[2]. The spontaneous polarization along the orthorhombic *b* axis disappears above the Curie point as the space group becomes I*mmm*[3].

Single crystals grown from aqueous solution were used throughout the experiment. In the preliminary stage of the experiment, back reflection photographs were taken at various temperatures with a high temperature x-ray camera. The result suggested the existence of a weak anomaly just above the Curie point in addition to the expected one at the Curie point. Because the accuracy of the film method was not sufficient for the present study, additional precise measurements were made using an x-ray diffractometer with an electric furnace. The distance from the specimen to the receiving slit in front of the G–M counter was 200 mm, considerably longer than the radius of the camera previously used (50 mm). The resolving power for measuring the change of diffraction angles was quite high, so that even a small change of the unit cell dimensions (about 0.0001Å) could be detected. Special care was taken for temperature control of specimens; the maximum error of temperature measurements did not exceed ±0.2°C. A very slow heating rate of at least ten minutes per degree was chosen to attain thermal equilibrium of the specimen. Results obtained are shown in Fig. 1.

As is shown, the *c* axis decreases its length moderately with increasing temperature, while the *a* and *b* axes increase their magnitudes. In the figure, one can observe two anomalies at 163°C and 178°C, respectively. The one at 163°C apparently corresponds to the known transition point where the spontaneous polarization disappears, while the other at 178°C has not been reported previously. If the second anomaly observed in this thermal expansion experiment corresponds to a new phase transition, it should indicate the existence of an unknown phase between the well-known ferro- and para-electric phases, although no indication of such an anomaly was shown in the dielectric[1] and specific heat[4] measurements. Recently, Tanisaki[5] discovered the presence of a microdomain structure just above 163°C. Referring to his result, one might call $NaNO_2$ in the new phase region as antiferroelectric. However, no perfectly ordered state would be attained in this phase range, therefore, further structural investigations together with the evaluation of the pair-correlation function illustrated recently[6,7] appear to be necessary for the detailed discussion on the phase transition mechanism of this crystal.

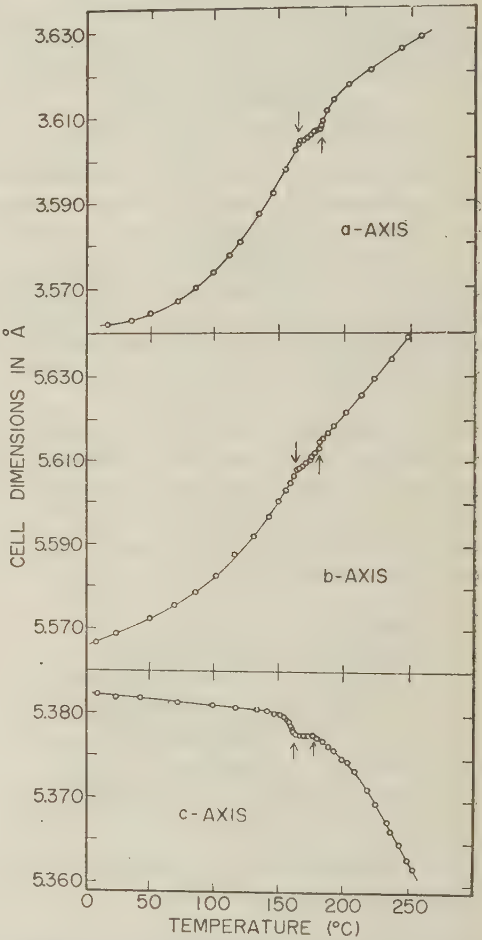

Fig. 1. Temperature dependence of the *a*, *b*, and *c* axes obtained by measuring temperature variations of diffraction angles of (*400*), (*060*), and (*006*) Bragg reflections, respectively.

The phase transition at 163°C was deduced to be of the first order[1], however, the results of the present investigation seem to contradict the above statements, since no appreciable jump in the temperature variation of the cell constants was observed at the transition point (Fig. 1).

A part of this work (film method) was made at the Tokyo Institute of Technology getting assistances of Messers Y. Takeuchi and T. Kato to whom the authors' thanks are due.

Moving Striation in Microwave Discharge Plasma

By Mikio TAKEYAMA,
Yoshida College, Kyoto University
Tanehiro NAKAU, Sōzaburo YAMASAKI
Osaka University of Liberal Arts and Education
and Takeshi ISA
Himeji Technical College

(Received February 23, 1961)

Recently many investigations[1,2] have been carried out on the moving striation in glow discharge plasma. The present note reports that a similar sonic wave can also be observed in stationary microwave discharge plasma under certain conditions.

The experimental apparatus and procedures are as follows: A JRC-2M10 magnetron (maximum output power is 200 W C.W. at 2450 Mc/s) was mounted in a rectangular waveguide (72×34 mm). The discharge tube 20 mm in diameter was placed 2 cm apart from one end of the guide, in the first case, perpendicular and in the second case, parallel to the microwave electric field, as shown respectively in Figs. 1 and 2. Commercial pure argon gas of 8 mmHg pressure was sufficiently cleaned off active gases and used.

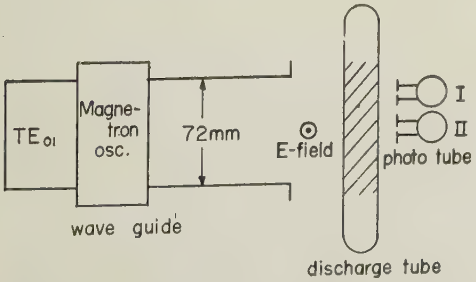

Fig. 1. Microwave electric field perpendicular to plasma column.

The power and the heater supplies for the magnetron oscillator were well regulated to make stable the plasma excited by microwave. In the first case (Fig. 1), we could observe a sonic wave in a plasma under certain condition, when the discharge tube was placed unsymmetrical to the waveguide. The plasma light intensity when the sonic wave was excited was detected by the photomultiplier tubes I and II placed apart from each other in Fig. 1. The output signals from the photo tubes were observed on an oscilloscope. In Photo. I, we can recognize a phase difference between the waves detected by the photo tubes I and II, that is, the existence of progressing wave. We also observed that the amplitude of oscillation built up with wave progression. The frequency shifted from ~500 c/s to ~900 c/s with the change in microwave power, the wave velocity was about 20 m/s, and the wave length about 4 cm. This wave might be so-called "moving striation".

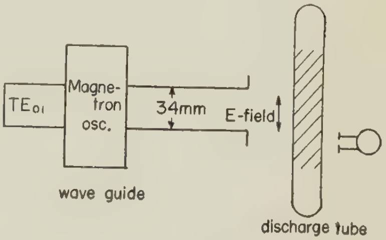

Fig. 2. Microwave electric field parallel to plasma column.

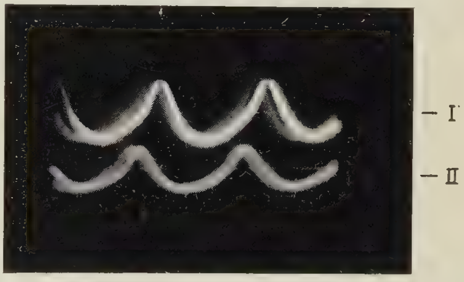

Photo. I. Moving striation pattern in microwave discharge.

In the second case (Fig. 2), on the contrary, any sonic wave was not observed.

The authors wish to thank Prof. I. Takahashi and Prof. K. Mitani at Kyoto University, and Prof. H. Takeyama at Hiroshima University for their kind advices and discussions.

Electron Spin Resonance of Manganese in $MgCl_2$

By Kuniya FUKUDA, Hiroaki MATSUMOTO,
Toru TAKAGI and Yoichi UCHIDA

*Department of Physics, Faculty of Science,
Kyoto University*

(Received January 23, 1961)

Electron spin resonance of manganese ion in $MgCl_2$ single crystal has been measured at room temperature by using 1.2 cm wavelength microwave.

The material of $MgCl_2$ containing one mole percent of $MnCl_2$, after having been thoroughly baked and sealed in a quartz tube under vacuum of about 10^{-3} mmHg, was heated up to 800°C and then slowly cooled down to room temperature at a rate of 20°C per hour. $MgCl_2$-Mn crystal obtained in this way has a layer structure. From its Laue pattern in Fig. 1, it is seen that the crystal is single and has a three-fold symmetry axis (c-axis) perpendicular to the cloven plane. $MgCl_2$ single crystals as well as $MnCl_2$ belong to $CdCl_2$ crystal type and have a trigonal symmetry about the c-axis[1].

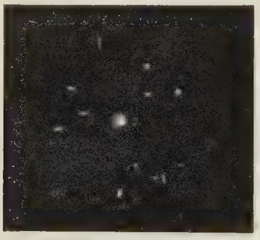

Fig. 1. Laue pattern of $MgCl_2$-Mn. Incident X-ray is perpendicular to the cloven plane of a sample (parallel to the c-axis).

Electron spin resonance was measured by rotating the static magnetic field around the c-axis in the plane perpendicular to it. Resonance spectra are independent of the direction of static magnetic field in this plane within experimental error and they consist of a broad line of about 450 oe. peak to peak width and many sharp lines of about 40 oe. peak to peak width, as shown in Fig. 2.

The sharp lines can be analyzed with the spin Hamiltonian:

$$\mathscr{H} = g\beta \boldsymbol{HS} + \boldsymbol{D}S_z^2 + \boldsymbol{E}(S_x^2 - S_y^2) + \boldsymbol{ASI}\,,$$

where $A = (-82 \pm 4) \times 10^{-4}\,\mathrm{cm}^{-1}$, $|D| = (140 \pm 10) \times 10^{-4}\,\mathrm{cm}^{-1}$, $E = 0$ within experimental error, and $g = 2.002 \pm 0.003$. Therefore, these sharp lines must be attributed to the hyperfine structure of Mn^{++} ion, the local field around which has axial symmetry about c-axis of the host crystal. The values of A and g show considerably good agreement with those of $MgBr_2$-Mn[2].

From the above results, it would be plausible to consider that Mn^{++} ions occupy the regular sites in host crystal.

The broad line, which overlaps hyperfine lines, seems to have nearly Gaussian shape rather than Lorentzian and the g value of 1.996 ± 0.007, as shown in Fig. 2. The intensity of this broad line did not change when a sample was heated at 450°C for one hour and quenched to room temperature. The ratio of the intensities of a hyperfine line and the broad line changed sample to sample when they were cloven from different parts of an original crystal. Further experiments are necessary to see the relations between the hyperfine lines and the broad line.

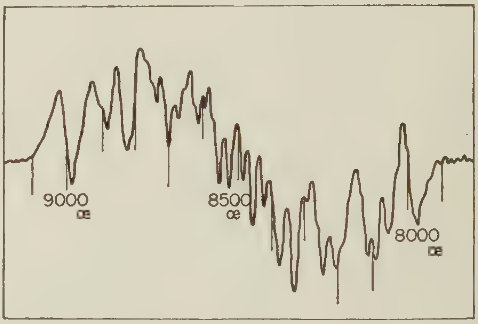

Fig. 2. Electron spin resonance pattern of $MgCl_2$-Mn. Static magnetic field is perpendicular to the c-axis of a sample.

During X-ray irradiation, $MgCl_2$-Mn crystals showed red luminescence (broad band at about 650 mμ) and $MgCl_2$ crystals without manganese weak green luminescence. Electron spin resonance spectra of Mn^{++} ion changed and a few sharp lines (about 10~20 oe.) appeared in the neighbourhood of $g=2$ after X-ray irradiation.

The more detailed investigations of the broad line and the analysis of the new spectra which appeared after X-ray irradiation are now in progress.

The authors wish to express their thanks for the facilities of X-ray diffraction measurements offered by Mr. Tsuneo Seto.

The New Magnetic Phase in Manganese-Aluminium-Nickel System

By Ichiro TSUBOYA and Makoto SUGIHARA

Electrical Communication Laboratory
Nippon Telegraph and Telephone
Public Corporation
Musashino-shi, Tokyo, Japan

(Received March 16, 1961)

The new magnetic phase is observed in Mn-Al-Ni ternary alloy system. The nature of this ferromagnetic phase seems to be the same as κ phase in Mn-Al-Cu¹⁾ and Mn-Al-Fe²⁾ alloy systems reported by the present authors. The composition range of this phase, however, extends more widely than Mn-Al-Cu or Mn-Al-Fe alloys.

For preparation of the specimens, electrolytic Mn (99.9%), electrolytic Ni (99.9%) and pure Al (99.99%) were melted in suitable proportion in air and cast into rods of 10 mm in diameter. The cast specimens were annealed for 1 hour at 900°C in vacuum to remove the segragation, then cooled to room temperature at the rate of 150°C per hour.

The composition range showing ferromagnetism was determined by magnetic examination. The results are shown in Fig. 1 with the results of X-ray analysis.

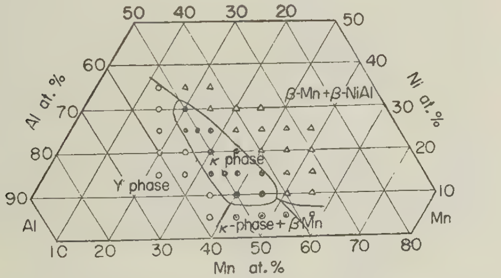

Fig. 1. Results of magnetic examination and X-ray analysis.

- ●: κ phase; magnetic
- ⦿: κ phase and β-Mn phase; weakly magnetic
- ○: orthorhombic Y phase; non magnetic
- △: β-Mn phase and β-NiAl phase; non magnetic
- □: β-Mn phase; non magnetic

According to X-ray analysis, there is a single cubic phase in the composition range of 25 to 50 at.% Mn, 10 to 30 at.% Ni and 40 to 52.5 at.% Al. This composition range nearly coincides with the one which is determined by magnetic examination. It is observed that this cubic phase has the same ordered structure of CsCl type as the κ phase in Mn-Al-Cu and Mn-Al-Fe alloy systems. The lattice parameter of κ phase in this system changes with an increase of Ni content from 2.970 to 2.920Å. The other phases which exist in the composition adjoining to the κ phase are the mixture of β-Mn and β-NiAl phases in the Ni rich region, the orthorhombic Y phase in the Al rich region and the β-Mn phase in the Mn rich and Ni poor region. These phases do not show ferromagnetism.

The magnetic properties such as Curie temperature, $\sigma-T$ curve and temperature dependence of inverse susceptibility are also measured. The Curie temperature and the saturation magnetization show an appreciable composition dependence. The Curie temperature becomes the highest, 550°K, at the Mn rich side and the lowest, 360°K, at the Ni rich side. The saturation magnetization reaches the maximum value 4000 gauss (per mol) near the phase boundary of the Mn and Ni poor side, decreases with an increase of Mn or Ni content, and reaches 1500 gauss at the phase boundary of Ni rich side. The temperature dependence of the saturation magnetization ($\sigma-T$) and of the inverse susceptibility ($1/\chi-T$) are shown Fig. 2 for typical specimens. The $1/\chi-T$ curves almost shows the non-linear relation except for specimens containing nearly 50 at.% Al.

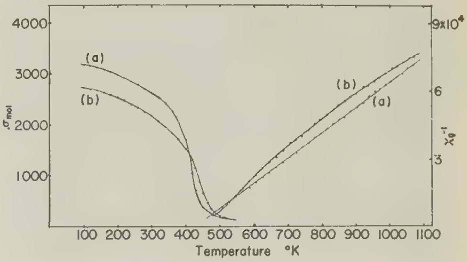

Fig. 2. Temperature dependence of saturation magnetization and inverse susceptibility of a) Mn 35 Ni 15 Al 50 and b) Mn 40 Ni 15 Al 45.

These magnetic properties of the κ phase in Mn-Al-Ni alloy are similar to the κ phase in Mn-Al-Cu alloy¹,³⁾, and can be qualitatively explained by the ferrimagnetism which originates from the antiferromagnetic interactions between Mn atoms occupying two different sublattices of CsCl type structure.

Futher discussion and detailed measurements will be reported later.

Effect of Current Injection on Properties of Cadmium Sulfide Crystals

By Hiroji MITSUHASHI

Technical Research Laboratories, Japan Broadcasting Corporation, Setagayaku, Tokyo

(Received March 30, 1961)

In order to study the effects due to the excitation by Tesla's coil, the specimen was rested in a simple cryostat[1] evacuated at a pressure of about 10^{-2} mm Hg. Green gleams came out from the surface of the crystal when the excitation by the coil was attempted from outside the glass envelope of the cryostat, i.e. a discharging tip of the coil approached the crystal or the wiring connected to the specimen which was kept at the temperature of liquid nitrogen. Immediately after the excitation the conductivity of all the crystals was increased by several orders of magnitude and the photoconductivity became largely overwhelmed by the increased dark conductivity. The higher temperature peaks in the thermally stimulated current curve of the most original crystals disappeared as seen in Figs. 1 and 2, although those of lower temperature kept their shapes. With subsequent gradual heating the increased conductivity began to decrease and approached to the value at its initial state. The stimulated current peaks which once disappeared resumed their shapes. One of the most prominent effects on a few samples was inversion of the quenching spectra (Fig. 3), that is, the crystal got photoconductive at 0.9 and 1.4 microns where the original crystals showed salient quenching[2]. This photoconductivity is quite stable in nature except for the further bombardment and/or heating of the specimen and appears as more exaggerated situation of the enhancement observed by Kitamura[3].

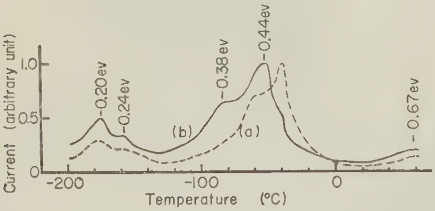

Fig. 1. Thermal stimulation of the unbombarded crystals of (a) No. 3 [0.6 mm×0.15 mm×0.9 mm (|| *c*)] and (b) No. 5 [1.1 mm×0.20 mm×1.5 mm (|| *c*)]. The heating rate was 10 degrees C. per min. The trap depths indicated were calculated on the assumption that attempt to escape frequency was 10^{10} per sec. *c* axis of every specimen was always made parallel to the electric field.

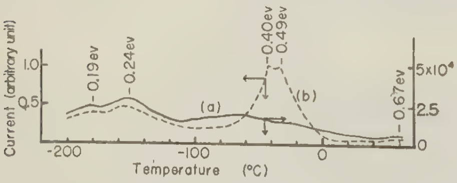

Fig. 2. Variation of thermal stimulation for the crystal No. 3, (a) just after the bombardment and (b) when the crystal came to equilibrium after annealing.

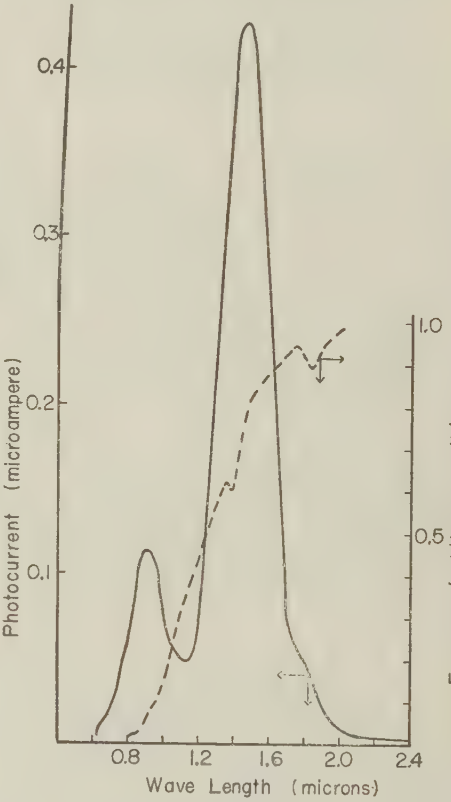

Fig. 3. Inverted photoconductivity for the crystal No. 3 measured at −12°C. with 51 volts applied. The dotted curve shows the incident energy to the sample.

All of these phenomena seem to be closely associated with the change of the lattice imperfections which act as donors and acceptors. The function of the Tesla's coil is understood as providing bombarding ions and electrons of high energy by ionization of the residual gas. The inverted photoconductivity is thought of as occurring from the considerable increase in the imperfections corresponding to the hole trapping centers advanced by Taft[2] and Rose[4].

Absorption and Reflection Spectra of Afterglow Plasma

By Shigetoshi TANAKA

Department of Physics, Faculty of Science
Kyoto University, Kyoto

(Received March 24, 1961)

The plasma resonance, which occurs at $\omega=\omega_p/\sqrt{2}$ (ω_p: plasma frequency) for a circular cylindrical plasma column, has been studied by many workers[1),2)]. It has further been reported that a series of small peaks occur, in addition to the main peak, at lower electron densities, but it was not explained so far, though various mechanisms can be considered[3),4)].

In the present work, both absorption and reflection powers from an afterglow plasma generated by pulsed discharge (pulse width: 15μ sec., peak voltage: 2500 volt, peak current: 2 amp.) were measured at a fixed microwave frequency ($\omega/2\pi=8{,}705$ mc/s), with the plasma column placed across waveguides as shown in Fig. 1. The absorption spectra are shown in Figs. 2 and 3, but the reflection spectra are omitted since they were similar to the former. The plasma resonance did not appear, as seen from Fig. 2 in the case I, where the microwave electric vector E_{rf} was parallel to the tube axis, but did appear in the case II, as shown in Fig. 3, where E_{rf} was perpendicular to the tube axis. Figs. 2 and 3 were photographed in succession by switching over between microwave channels leading to I and II.

Fig. 1. Waveguides and discharge tube (with neon gas filled at 7.55 mm Hg).

The followings are to be noted: The multiple peaks did not appear at electron densities lower than that of $\omega_p/\sqrt{2}=\omega$ in our experiment on afterglow, as seen from Fig. 3, in contrast to the experiment on the active plasma[3),4)], in which a discharge field was kept impressed. The multiple peaks rather appeared at electron densities higher than that of $\omega_p/\sqrt{2}=\omega$ in the case II, as shown in Fig. 3, but they also appeared in the case I, though both are not alike in detail.

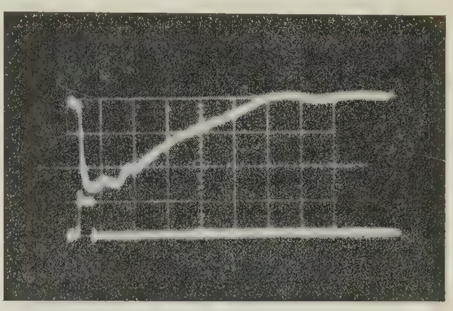

Fig. 2. Absorption spectrum (upper) and tube current (lower, 2 amp/div.) in the case I (swept at 20μ sec/div.).

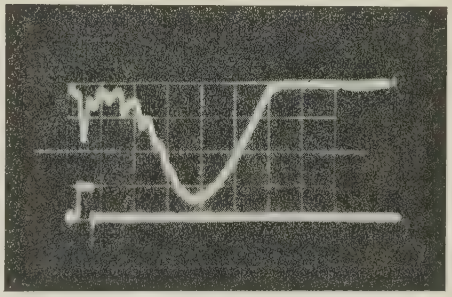

Fig. 3. Absorption spectrum (upper) and tube current (lower, 2 amp/div.) in the case II (swept at $20\,\mu$ sec/div.).

The author wishes to express his thanks to Prof. I. Takahashi for his guidance.

The Base Resistance of the Transistor in the Saturated Region

By Osamu NAKAHARA

Semiconductor Plant, Sanyo Electric Company, Daito City, Osaka Prefecture, Japan

(Received February 6, 1961)

Base resistance of the transistor is heavily modulated by the collector voltage in the saturation region by the conductivity modulation induced by the minority carrier injection from the collector junction. The space charge layer width variation of the junction also take part for it, but it is found that the effect is much smaller than the former effect.

For simplicity of calculation, we consider the external base resistance due to the part shown by the hatched annular part of the *pnp* transistor in Fig. 1. In this case, the external base resistance is given by the well-known formula[1]

$$R_{bN}=\rho_N \ln(r_c/r_e)/2\pi W_N \qquad (1)$$

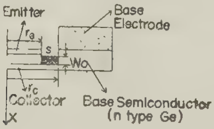

Fig. 1. Transistor geometry for the calculation.

where ρ_N and W_N represent the specific resistivity and the effective width of the hatched part respectively, both functions of the collector voltage. In the operating situation, injected minority carriers from the emitter would affect them, but we neglect the effect here. r_e, r_c denote the emitter and collector radius. We get the approximate expression for ρ_N as a function of V_{bc} (voltage applied between the base and the collector electrodes) as

$$\begin{aligned}\rho_N&=1/q\mu_n\langle n\rangle\\&=1/q\mu_n[p_n\{\exp(qV_{bc}/\lambda kT)-1\}(1+s/2D_P\cdot W_N)\\&\quad/(1+s/D_P\cdot W_N)+n_n]\end{aligned} \qquad (2)$$

where $\langle n\rangle$ means the one dimensional (x-direction) average of the number of the conduction electrons from the emitter side surface to the collector junction in the annular region; q, μ_n, p_n, n_n, k, T and D_P their usual meaning; s, surface recombination velocity for the minority carrier at the emitter side surface. Index λ in the exponential term means the correction factor for the injection relation. We take $\lambda=2$ for $V_{bc}>0$ and $\lambda=1$ for $V_{bc}<0$. In deriving (2), we assume the one dimensional hole distribution from collector junction to emitter side surface in the annular region which induces the same number of free electrons in the conduction band there and take the average for them. It is also assumed $W_N/L_P \ll 1$ where L_P denotes the diffusion length for the hole. In ordinary transistors, $n_n \gg p_n$ is assured to reduce R_{bN} and the effect of V_{bc} on it can not be observed except the case of deep bias. The expression for W_N can be found in the text book.[2]

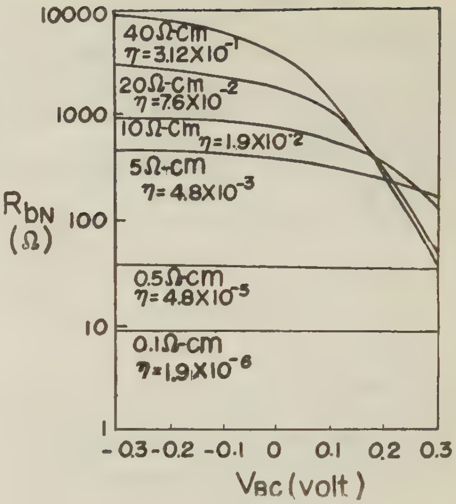

Fig. 2. Variation of R_{bN} with V_{bc} for six different η's. We assume the values W_0 (geometrical width of the annular region)$=10^{-3}$ cm, $s=300$ cm/sec, $T=300$°K, $r_c/r_e=1.5$.

In Fig. 2, the dependence of R_{bN} on V_{bc} is shown graphically with a parameter $\eta=p_n/n_n$ for germanium base. In this example, we take the case for V_{bc} varying from 0.3 to -0.3 volts. This covers the saturation and part of the active region of the grounded-base operation for the transistor with V_{be} (forward bias voltage applied between the emitter and the base electrodes)$=0.3$ volts. It is to be noted that as η approaches unity, R_{bN} varies in a wide range in the saturation region.

Such a rapid charge in R_{bN} results in an interesting phenomenon of negative collector resistance within the saturation region of the transistor of certain types.[3,4] That is, if R_{bN} increases drastically so that the decrease of the minority carriers at the emitter is accompanied by the increase in the d.c. voltage drop (the product of the base current and R_{bN}) in the base circuit with V_{bc}, the collector current in turn decreases, thus the dynatron type negative resistance can be observed in the collector circuit. In the saturation region, the decrease of the minority carriers at the collector junction with V_{bc} is the dominant agent for the internal feedback effect and it is necessary for the negative resistance that the above mentioned external base resistance negative feedback does overcome such internal feedback in the transistor.

The author thanks Dr. S. Iwase, the chief of the plant, for the encouragements given during the work.

On the Secondary Tunnelling Phenomena in a *p-n* Junction of Gallium Arsenide

By Akikazu Shibata
SONY Corporation, Shinagawa, Tokyo, Japan

(Received March 10, 1961)

Several workers have reported the fine structures of the I–V characteristics of a tunnel diode indicating the phonon interaction at low temperature[1),2)] or the presence of intermediate states in the energy gap[3)]. Very recently, an evidence of the possible existence of impurity bands in the energy gap and the tunnelling between the conduction and/or valence bands and impurity band(s) was observed in a *p-n* junction of GaAs. A similar phenomenon was also reported by Holonyak[4)] who observed tunnelling between these impurity bands at 78°K.

The observed I–V characteristics of a typical GaAs *p-n* junction at room and at liquid nitrogen temperatures are shown in Fig. 1. This junction was formed by alloying a Sn-Pb-Te dot to very heavily doped GaAs with Zn ($>10^{19}\,\mathrm{cm}^{-3}$). This junction exhibits very small current peaks of about 50μa at about 0.1 and 0.43 volts at room temperature. (The significance is the appearance of a secondary tunnelling peak even at room temperature.)

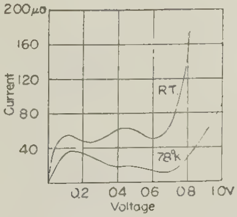

Fig. 1. I–V characteristics of a Zn-doped GaAs *p-n* junction (IP∼50μa at R.T.).

Similar secondary tunnelling current peak was reported in an epitaxially formed P-doped Ge *p-n* junctions at about 0.4 volts at 4.2°K[5)] and a Si tunnel diode in a form of a hump at about 0.8 volts[2)]. Esaki proposed possible existence of a deep impuriy level.

In comparison to the GaAs *p-n* junctions, several P-doped Ge *p-n* junctions were formed and the existence of a hump at about 0.4 volts at 78°K was confirmed. Several As-doped Ge backward diodes having comparable peak currrent were also investigated at 78°K. In this case, however, no evidence of such a hump was observed. In contrast with Zn-doped GaAs *p-n* junctions, a Cd diffused GaAs *p-n* junction showed a clear structure in the current peak at about 0.05 volts at 78°K and did not show a secondary tunnelling hump as illustrated in Fig. 2. This structure may be attributed to the distortion of the energy band edge due to the high impuirty concentration which has been recently investigated by Pankove[6),7)]. A simple calculation of tunnelling current also indicated that such a distorted band edge could produce a structure in the tunnelling current peak.

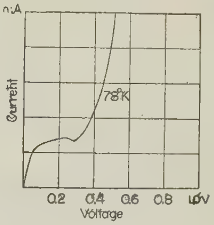

Fig. 2. characteristics of a Cd-diffused GaAs *p-n* junctian at 78°K (IP=0.70 ma).

It could be concluded that these experimental facts, together with those by Holonyak and others, strongly indicate the existence of impurity bands in the energy gap and also the distortion of the energy band edges. However, no such a deep lying impurity band is reported yet. In any case, these secondary tunnelling current peaks are revealed only when specific combinations of impurities and semiconductors are used. It should be a most urget project to elucidate these possible deep lying impurity bands. These phenomena should be observed in all the semiconductors and we are continuing the investigation using other III–V compound semiconductors.

The Optical Absorption of Localized Exciton in KCl-KI Crystal

By Kaizo NAKAMURA, Kuniya FUKUDA, Riso KATO, Atsuo MATSUI and Yoichi UCHIDA

Department of Physics, Faculty of Science, Kyoto University

(Received April 3, 1961)

It has been shown in earlier works[1] that a definite peak is observed at room temperature on longer wavelength side of the fundamental absorption edge of KCl or NaCl crystal containing I^- impurity, and that this peak is ascribed to the localized exciton at I^- ion occupying Cl^- lattice site. Recently, Kobayashi and Tomiki have reported[2] that commercial KCl or NaCl powder contains a considerable amount of Br^- impurity, and that this impurity causes a remarkable shift of the absorption edge to longer wavelength side.

In the present work, the starting material of KCl powder was prepared by the chemical reaction of filtered aqueous solution of potassium bicarbonate and distilled hydrochloric acid. The single crystals of pure KCl and those containing 0.05 mole % of KI in melt were grown by the Kyropoulos method in air with a platinum crucible. The optical absorption spectra of both crystals were measured at low temperature by the vacuum ultraviolet spectrometer[3].

Fig. 1 shows the absorption spectra of KCl single crystals both at room and liquid nitrogen temperatures. The shift of absorption edge due to the presence of Br^- or of other impurities is more than 0.2 ev at room temperature and about 0.4 ev at liquid nitrogen temperature, respectively. The slope from 7 ev to absorption edge which appears in synthetic KCl at liquid nitrogen temperature might be ascribed to the defects such as dislocations.

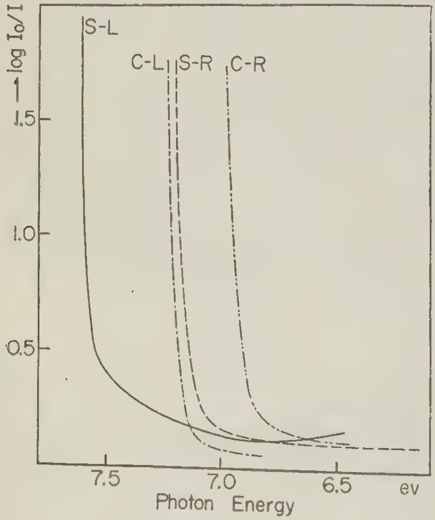

Fig. 1. Absorption spectra of KCl crystals. *C*: crystal from commercial powder, *S*: from synthetic powder, *−R*: measured at room temperature, *−L*: at liquid nitrogen temperature. *C* and *S* are almost the same in thickness.

Fig. 2 (a) shows the absorption spectra of KCl-KI crystals at room temperature. A peak is at 6.58 ev (A) and a hump appears at about 7.1 ev (B) on absorption edge. This hump is masked by the shift of absorption edge in commercial KCl.

Fig. 2 (b) shows the absorption spectra of KCl-KI crystals at liquid nitrogen temperature. The A-band shifts to 6.71 ev and the B-hump appears as a narrow band at 7.2 ev which is observed as a shoulder in commercial KCl. Further, near the absorption edge a shoulder (C) is observed at about 7.5 ev. The half widths of these bands are 0.22 ev for A-band and about 0.1 ev for B-band.

The above three bands may correspond to the "iodine doublet" and the perturbed exciton near I^- ion. Further experiments will be necessary to decide the correspondence. Similar experiments on synthetic NaCl-NaI crystals are now in progress.

Refractive Index Difference of Dilute Aqueous Solution of Polyvinylpyrolidon

By Yasuhiro MIYAKE and Jiro FURUICHI

Department of Physics, Faculty of Science, Hokkaido University, Sapporo, Japan

(Received March 6, 1961)

Recently, the anomalous behavior of the concentration dependence of the reduced viscosity in the very dilute solution of high polymer has been reported and interpreted as either due to (1) the peculiarities of the viscosity, such as the effects of Non-Newtonian or of the adsoption of polymer molecules on the capillary wall of the viscometer or due to (2) the disentanglement and the expansion of polymer molecules occurring below a critical concentration or the nonuniformity of the solution[1]. In order to decide the above interpretations it is desirable to adopt the methods using other than the viscometer and giving a sufficient accuracy in the region of the very dilute concentration. The differential refractometer seems to be the useful one for this purpose. The concentration dependence of the refractive index difference in the dilute aqueous solution of polyvinylalcohol(PVA) has already been investigated by M. Matsumoto and Y. Ohyanagi[2], who have found out the anomaly. On the other hand, the measurement based on the determination of the concentration using the more accurate interferometer for polyvinylacetate in toluene solution by C. A. F. Tuijnman and J. J. Hermans[3], who studied the precision viscometry of this system, suggests that such an anomaly cannot be found out. From these results, one may expect that the anomaly in PVA solution is due to the destruction of the structure of water caused by the strong interaction of the hydroxyl group of every structural unit with water just as the interpretation of M. Matsumoto et al. Therefore the sample which has no such group strongly interacting with a solvent as the hydroxyl group should not show the anomaly. Then, in the present work, the refractive index difference Δn of the dilute aqueous solution of polyvinylpyrolidon(PVP), which is soluble in water like PVA but has not the hydroxyl group, has been precisely measured. Molecular weights of the sample used are 700,000, 40,000 and 20,000 respectively, whicn are obtained from Kyorin medicine manufacture Co. The measurements have been done at 25°C with the cell of the inner angle 125° for the wave length of 436 mμ using Debye-type differential refractometer*. The result is shown in the figure.

It is evident from this that the index difference Δn between the solution and water plotted against the concentration does not show the anomalous behavior. This is likely to confirm the above inference, that is, the disagreement is attributed to the hydroxyl group so that the destruction of the structure of water may be the origin of the anomalous behavior in the static measurement like this as well as in the specific volume one[4] which is not the kinetic method such as the viscometric[5]. It corresponds to the interpretation (2) as the origin of the anomaly. However, the results of the anomalous behavior of polystyrene in various solvents obtained by the authors' viscometric investigation[6] have also to be interpreted as due to the other origin than the interpretation (2). Hence, it is necessary to consider the structure of the polymer and the solvent and also the method of the measurement in the investigation of the polymer solution.

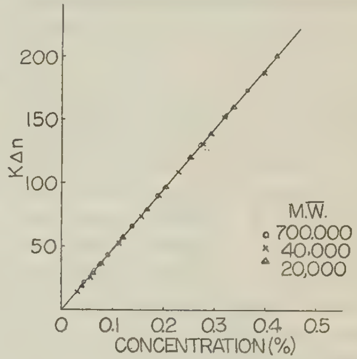

Fig. 1. Refractive index difference between solution and water, Δn, plotted against concentration for aqueous solution of PVP at 25°C. K is constant.

The Electron-Coupled Nuclear Spin Interactions in Ionic Crystals by the Overlap Model

By Tatsuo SHIMIZU

Department of Physics, University of Tokyo

(Received February 16, 1961)

Various properties of the ionic crystal have been investigated by two different approaches. The first is based on the model in which partially covalent bonds are assumed to work, and the second is based on the model in which the overlap between atomic orbitals is explicitly taken into account. The first and the second will be referred to as the covalent and the overlap model, respectively. Yoshida and Moriya[1] calculated nuclear quadrupole relaxations and chemical shifts by the covalent model, and Kondo and Yamashita[2] calculated the same quantities by the overlap model. The results based on the overlap model seem to be more reasonable than those based on the covalent model. Besides these quantities Yoshida-Moriya[1] have calculated the electron-coupled nuclear spin interactions by the covalent model, and Bloembergen and Sorokin[3] have extended them later. The calculation of them on the basis of the overlap model, however, has not yet been carried out. In this note we shall mention the result of such calculation.

The electron-coupled nuclear spin interaction energy is obtained as the second order perturbations of the following interaction operator:

$$\begin{aligned}\mathscr{H}'=\sum_{k,N}&[(16\pi/3)\beta\hbar\gamma_N(\boldsymbol{I}_N\cdot\boldsymbol{S}_k)\delta(\boldsymbol{r}_{kN})\\&+2\beta\hbar\gamma_N\{3(\boldsymbol{I}_N\cdot\boldsymbol{r}_{kN})(\boldsymbol{S}_k\cdot\boldsymbol{r}_{kN})r_{kN}{}^{-5}\\&-(\boldsymbol{I}_N\cdot\boldsymbol{S}_k)r_{kN}{}^{-3}\}]\,.\end{aligned}$$

The notations are those usually used. In calculating the second order perturbations, we approximate the excitation energies by an appropriate average value $\varDelta E$ as is usually done. As the ground state wave function, we take the Slater determinant constructed from the atomic orbitals of the free ions, and we rewrite it with the Löwdin orthogonalized atomic orbitals. We take into account the overlaps S between the orbitals belonging to the nearest neighbor ions only, and retain them up to the order of S^2 in the results. For that sake, we need retain S only in the first order in the Löwdin orbitals. Moreover we retain

$$\int\phi_\mu{}^*(1/r^3)\phi_\nu d\tau$$

only in the case where both atomic orbitals μ and ν belong to the same ion, and neglect the electron densities of the atomic orbitals at the nuclei other than those which they belong to. The results are as follows:

$$\begin{aligned}&(8\beta h/3)^2\gamma_m\gamma_h(1/\varDelta E)[S_{mshs}^2|\phi_{ms}(0)|^2\,|\phi_{hs}(0)|^2\boldsymbol{I}_m\cdot\boldsymbol{I}_h\\&-(3/20\pi)\{S_{hsmp}^2|\phi_{hs}(0)|^2\langle1/r^3\rangle_{mp}\\&+S_{mshp}^2|\phi_{ms}(0)|^2\langle1/r^3\rangle_{hp}\}\\&\times\{\boldsymbol{I}_m\cdot\boldsymbol{I}_h-3(\alpha I_{mx}+\beta I_{my}+\gamma I_{mz})(\alpha I_{hx}+\beta I_{hy}+\gamma I_{hz})\}\\&+(9/400\pi^2)S_{mphp}^2\langle1/r^3\rangle_{mp}\langle1/r^3\rangle_{hp}\\&\times\{\boldsymbol{I}_m\cdot\boldsymbol{I}_h+3(\alpha I_{mx}+\beta I_{my}+\gamma I_{mz})(\alpha I_{hx}+\beta I_{hy}+\gamma I_{hz})\}].\end{aligned}$$

Here m and h designate the metal ions and the halogen ions respectively, and s and p respectively designate the outermost s orbitals and the outermost p orbitals directed to the nearest neighbor ions. α, β, γ are direction cosines of the nearest neighbors. In the above expression, $\varDelta E$ was assumed for simplicity to be common for various terms in braces. The results can also be expressed in the exchange and pseudo-dipolar type coupling, that is:

$$A\boldsymbol{I}_m\cdot\boldsymbol{I}_h+B\{\boldsymbol{I}_m\cdot\boldsymbol{I}_h-3R_{mh}^{-2}(\boldsymbol{I}_m\cdot\boldsymbol{R}_{mh})(\boldsymbol{I}_h\cdot\boldsymbol{R}_{mh})\}\ ;$$

where

$$\begin{aligned}A=&(8\beta h/3)^2\gamma_m\gamma_h(1/\varDelta E)(S_{mshs}^2|\phi_{ms}(0)|^2|\phi_{hs}(0)|^2\\&+(9/200\pi^2)S_{mphp}^2\langle1/r^3\rangle_{mp}\langle1/r^3\rangle_{hp})\,,\\B=&-(8\beta h/3)^2\gamma_m\gamma_h(1/\varDelta E)\{(3/20\pi)\\&\times(S_{hsmp}^2|\phi_{hs}(0)|^2\langle1/r^3\rangle_{mp}+S_{mshp}^2|\phi_{ms}(0)|^2\langle1/r^3\rangle_{hp})\\&+(9/400\pi^2)S_{mphp}^2\langle1/r^3\rangle_{mp}\langle1/r^3\rangle_{hp}\}\,.\end{aligned}$$

Here $\boldsymbol{R}_{mh}$ is a vector connecting the metal ion and the nearest neighbor halogen ion. The above expressions for A, B have the same form as those obtained using covalent model, if we replace $2S_{mshp}^2$ etc. by $\lambda|a_{ms}|^2|a_{hp}|^2$ etc. respectively. This correspondence is similar to that in the case of the chemical shift[2].

Only experimental results on A and B in ionic crystals, which have been published, are those of CsBr, and the results are $Ah^{-1}=55$ cps, $Bh^{-1}=+15$ cps or -89 cps[3]. The theoretical prediction shows that B is always negative, so that we must take -89 cps as the experimental value of Bh^{-1}. Since there are many unknown parameters in the theoretical expressions, we can not obtain convincing theoretical values of A and B. However, we may make a rough estimate of them in order to see whether our model gives a reasonable result. We assume the following values: $\varDelta E=10$ eV, $S_{mphp}=0.080$, which has been obtained by Kondo-Yamashita from the experimental value of the chemical shift[2], $\langle1/r^3\rangle_{mp}=29$ A.U. and $\langle1/r^3\rangle_{hp}=13.6$ A.U. which have been obtained by Barnes and Smith semiempirically[4], and $|\phi_{ms}(0)|^2=65$ A.U. which is calculated by the Hartree-Fock wave function[5]. Furthermore if we assume $1/9S_{mphp}=1/3S_{hsmp}=1/3S_{mshp}=S_{mshs}$, we obtain the experimental value of A for $|\phi_{hs}(0)|^2\sim40$ A.U. which seems reasonable. From these parameter values, we find $Bh^{-1}\sim-20$ cps. If we assume $1/4\ S_{mphp}=1/2\ S_{hsmp}=1/2\ S_{mshp}=S_{mshs}$, we obtain the experimental value of A for $|\phi_{ks}(0)| \sim 8$ A.U., and Bh^{-1} again becomes ~ -20 cps. The discrepancy between -20 cps and -89 cps does not seem to be serious in view of the rough nature of our estimation.

Finally, we note that if we take into account the overlaps between the next nearest neighbor ions, the interactions between metal ions or halogen ions will be obtained in the form exactly the same as the expressions obtained above. Therefore the unpublished experimental results on the coupling between Tl ions cited in Yoshida-Moriya's paper[1] may be explained by our model, although it is apparently very difficult to explain it by the covalent model.

Magnetic Properties of B8 Type Compounds in Manganese-Tin System

By Mitsuru ASANUMA

Department of Physics, Faculty of Science, Hokkaido University

(Received January 21, 1961)

In previous report[1], it has been pointed out that $Fe_{1.3}Sn$ has a B8 type structure and shows ferromagnetism with the Curie temperature at 676°K. In this system, the composition range of B8 phase is so narrow that it was not possible to observe the variation of the magnetic moments of the compounds as a function of the composition.

However, in manganese-tin system, as the homogeneous range of B8 structure is considerablly wide, being estimated to be 35~40 atomic per cent tin by Nial[2], it has been possible to observe the variation of the magnetic moments of the system in this range of composition. This fact is important, since, from this result, it is possible to estimate the magnetic moments of manganese atoms in each lattice site theoretically.

The specimens were prepared as follows; after melting the mixture of each component in argon atmosphere, it was crushed, baked at 600°C for a week in evacuated silica tube, and quenched in water.

The obtained specimens were examined by X-ray Debye-Scherrer method with Fe-Kα, and it was recognized that $Mn_{1.5}Sn$, $Mn_{1.6}Sn$, $Mn_{1.7}Sn$ and $Mn_{1.8}Sn$ have all B8 type structure.

The dependence of saturation magnetization at absolute zero temperature on manganese content is shown in Fig. 1 and Table I, together with the lattice parameters and the Curie temperature in the latter. The value of saturation magnetization at 0°K decreases as manganese content increases.

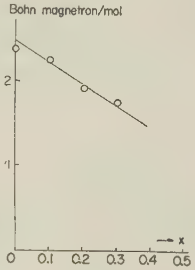

Fig. 1. The dependence of saturation magnetization at 0°K on manganese contents in $Mn_{1+x}Sn$.

Table I.

	$\sigma(\mu_B)$/mol	Curie Temp. (°K)	a (Å)	c (Å)	c/a
$Mn_{1.5}Sn$	2.38	269	4.37_2	5.50_8	1.26_0
$Mn_{1.6}Sn$	2.27	263	4.37_7	5.51_7	1.26_0
$Mn_{1.7}Sn$	1.92	258	4.39_1	5.52_4	1.25_8
$Mn_{1.8}Sn$	1.76	256	4.39_4	5.51_8	1.25_6

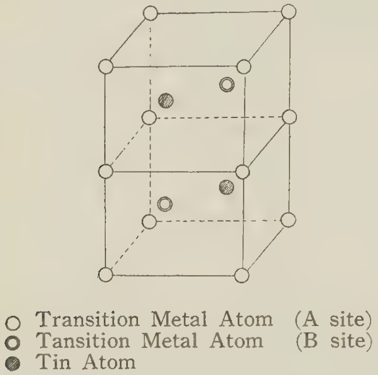
The fact that the magnetic moment per mol decreases as the manganese content increases suggests that the phase is probably ferrimagnetic.

When one assumes the variation in population of the manganese atoms takes place mainly on the B sites in Fig. 2, the magnetic moment of manganese atom on B sites is calculated to be $2.2\,\mu_B$.

The same assumption leads to the value of $3.5\,\mu_B$ as the magnetic moment on A sites.

B8 type structure extends from $B8_1$ type to $B8_2$ type for certain kinds of metalloid element. Here, $B8_1$ type structure corresponds to a filling of octahedral interspaces with transition metal atoms, in a hexagonal close packed structure of metalloid elements, and $B8_2$ type structure corresponds to a filling of both octahedral and trigonal interspaces with transition metal atoms, in a hexagonal close packed lattice. Since the volume of octahedral interspace is larger than that of trigonal interspace, it is reasonable to assume that the octahedral interspaces, i.e. A sites are always filled up and the variation in population takes place only on the trigonal interspace, i.e. B site.

Guillaud[3] has suggested that the critical distance of ferromagntic and antiferromagnetic interaction between manganese atom may be 2.81 Å as deduced from the analysis of the variation of the Curie temperature in MnAs, MnSb and MnBi. In a specimen $Mn_{1.8}Sn$, Mn–Mn distance in A site is 2.75_9 Å and the distance between A and B sites is 2.88_7 Å.



○ Transition Metal Atom (A site)
○ Tansition Metal Atom (B site)
● Tin Atom

Fig. 2. The crystal structure of $B8_2$ type structure.

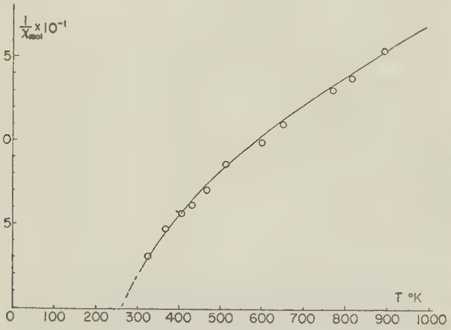


Fig. 3. The curve of the inverse of magnetic susceptibility *vs* temperature.

Therefore, according to Guilland, it is expected that J_{AA} is negative, while J_{AB}, J_{BB} are positive, and present result is inconsistent with Guillaud's criterion. The behavior is also same in $Mn_{1.5}Sn$.

The dependence of the inverse of magnetic susceptibility above the Curie temperature in $Mn_{1.7}Sn$ is slightly concave against temperature axis as shown in Fig. 3. This result also suggest the B8 phase in manganese-tin system is ferrimagnetic. The details will be published in this Journal.

On the Decomposition of the Ferromagnetic Phase of the Heusler Alloy, Cu_2MnAl

By Ren'iti Kimura, Tetuo Ohoyama
and Keizo Endo
Department of Physics, Faculty of Science,
Tokyo Metropolitan University

(Received March 6, 1961)

Through our recent study of isothermal change in the electrical resistance, the decomposition of the metastable β-phase of a Cu-Mn-Al alloy has been found to be complicated by the cooperation of two mechanisms of different kinds. These processes consist of the precipitation of more stable phases, but the different values of the activation energy seem to suggest that different processes predominate in higher and lower temperature regions.

The specimen for this study had the composition of Cu_2MnAl and was prepared as follows: Mother alloys with composition of Cu_3Mn and Al_3Mn were first prepared from electrolytic copper (99.9%), electrolytic manganese (99.9%), and pure aluminum (99.99%). The metals of desired proportion were charged in an alumina crucible, melted in an induction furnace, and cast into an iron mold. Then the mixture of the mother alloys in an optimum proportion to obtain the composition of Cu_2MnAl was melted in an atmosphere of argon, and a rod of ca. 1.5 mm in diameter was drawn up into a quarz pipe. The specimen thus obtained was attached with appropriate electrical lead wires and placed in an electrical furnace. On heating and cooling as well as at definite temperatures, the potential drop in the specimen on passing a stationary current was recorded, as a function of time, on an electromagnetic oscillograph paper by means of a feed back device[1].

In Fig. 1, the electrical resistance of the specimen which was quenched into water from 800°C and was ascertained to be of the β-phase by the X-ray diffraction is shown as a function of temperature. The resistance observed on heating at a rate of ca. 250°C per hour is shown by the full curve. It increases first as though it is the disordering process, and at 350°C, with the beginning of the precipitation, becomes to increase more slowly, and after a sudden fall at about 500°C, increases again toward the knick point at 700°C, after which it remains constant or rather decreases slightly*.

---

* Further investigations will be necessary to ascertain whether the temperature coefficient is realy negative at these temperatures, and to discuss the origin of it, if it is the case.

Then the change in the resistance when the temperature was held constant after having been raised up to that point at the same rate as before were also recorded and plotted in the same figure. The points corresponding to the equal time duration held at each temperature are connected by dotted curves. It is clearly seen in the figure that the rate of change in the resistance becomes much greater at the temperatures above 410°C. The logarithm of the time necessary for 50% of the total isothermal change to take place is plotted against the reciprocal of absolute temperature in Fig. 2. It forms a knick point at about 410°C and the activation energies can be calculated from the slope of the straight lines to be 0.42 and 1.5 eV for the lower and the higher temperature ranges, respectively.

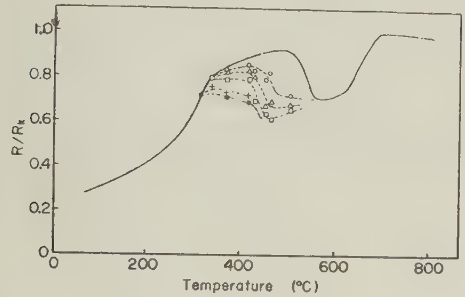

Fig. 1. Full curve: The change in electrical resistance of β-Cu_2MnAl when heated at a rate of 250°C per hour. R_k is the value at the knick point 700°C. Dotted curves: The resistance after held at constant temperatures for 9 min. (○), 18 min. (△), 36 min. (□), 90 min. (+), and 135 min. (●).

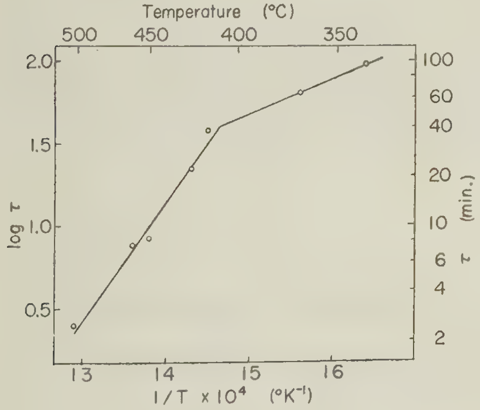

Fig. 2.

To obtain more informations about the difference of the two processes, microscopical observations and Debye-Scherrer X-ray analysis have been undertaken. More dispersed fine precipitations were observed under a microscope in the specimen held at lower temperature range, but unfortunately, the Debye photographs taken at room temperature for the powdered specimen quenched at each stage of the resistance change could not offer any clue to this problem, presumably owing to the instability of the phases in the quenched specimen. Thus the high-temperature X-ray technique seems to be essential to proceed further. As it is in preparation, we hope the result will be reported in future.

The authors wish to express their hearty thanks to Profs. E. Fukushima and T. Sato for their kindness to afford them facilities to achieve the work, and are also grateful to Mr. T. Kuwajima for the design of the feed-back device for the automatic recording.

Microwave Measurement of Fast Time varying plasmas

By Susumu Takeda

Nagoya University, Nagoya, Japan

(Received April 21, 1961)

The electron density ($5\times11^{11}\sim2\times10^{13}\,\mathrm{cm}^{-3}$) and the collision frequency in a decaying plasma are deduced from the simultaneous recording of two X-band microwave detector siginals displayed on the dual trace oscilloscope. The electron temperature, except in its very early period, decreases more slowly than expected on the basis of the simple assumption of energy equipartition between electrons and ions. The collision frequency measured here is compared with other results.

The principle of the measurement is a modification of the method previously described[1]. This method can yield the instantaneous value of both the electron density and the collision frequency of a time varying plasma.

In order to confirm the applicability and the validity of this measurement, it was tested to a typical recurrent decaying plasma. Since the two detector signals are photographically recorded, this tecenique can be especially adapted to plasmas produced by non repeated discharges.

The electron density n and the collision frequency ν are related to the plasma impedance $r+jx$, as follows[2]

$$n=\frac{A}{x-B}\,,\qquad \frac{\nu}{n}=\frac{\omega r}{A}\,.$$

where A and B depend on the dimension of the wave guide and the glass tube which contains the plasma and penetrates through the wide side of that waveguide.

Figure 1. shows ν_{ei}/n (here electron-ion collision frequency ν_{ei} predominates and is almost equal to total ν) and the electron temperature T_e calculated from $\nu_{ei}/n \sim (T_e/300)^{-3/2}$ versus time. The characteristic time for equipartition of the temperature between electrons and ions, τ_{ei}, is difined $\tau_{ei}=1/\nu_{ei}\,M_i/2m$ where M_i is the ion mass. And the theoitical value[3] of τ_{ei} in this experimental condition is of the order of a few μ sec; that is much shorter than the measured one. One reason which can possibly explain the measured long decay time of the electron temperature would be the presence of metastable atoms, heating the electron gas by the intermediary of the ion gas.

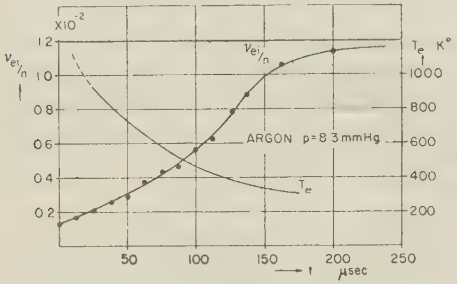

Fig. 1. Ratio of the electron-ion collision frequency ν_{ei} to the electron density n, and the electron temperature T_e versus time.

It was usually assumed that the maximum light intensity originating from the afterglow close to the beginning of a pulsed discharge occured at the time when the electron temperature reached 300°K. The photomultiplier datas of these experiments, especialy in Neon afterglow, contradict this assumption, since the light intensity maximum appears in less than 20 μ sec, whereas the electron temperature reaches 300°K after more than 100 μ sec.

The value of ν_{ei}/n in the late time in Fig. 1 approaches the value 1.2×10^{-2} cm^3/sec, which is compared to the theoretical and experimental values derived by other authors and listed in Table 1.

Table I. Theoretical and experimental values of ν_{ei}/n (cm^{-3}/sec) at room temperature.

Hot Electron Behavior at High Pressures

By Louis GOLD

Radiation Laboratory and Department of Nuclear Engineering, University of Michigan, Ann Arbor, Michigan

(Received March 17, 1961)

Changes produced in the hot electron behavior of many-valley semiconductors by high (hydrostatic) pressures afford a means for securing information on the energy gap pressure coefficient. This brief communication discloses how a newly developed phenomenological theory[1] for the nonequilibrium carrier distribution in such multivalued band minima structures characterizes hot electron departure from Ohm's law, to the extent where the role of high pressure may be appraised.

It has been demonstrated that the angular deviation ε from collinear current and voltage directions relates to the all important total carrier density via

$$\tan\varepsilon \propto e^{\varepsilon/kT}\,, \tag{1}$$

where ε was identified as an appropriate activation energy[1]. Now interpreting ε as essentially an energy gap E_g for the intrinsic range, the relation (1) may be reexpressed as

$$\tan\varepsilon \propto e^{E_g/2kT} \cdot e^{\pm\alpha P/2kT}\,, \tag{2}$$

where α is the pressure coefficient for the increase or decrease ($\pm$) of E_g with hydrostatic pressure P. Hence, provided the mounting pressure does not expend itself in merely redistributing carriers over the various band minima, a state should exist where the dominant effect contributing to $\tan\varepsilon$ is the gap change per se.

Now the high pressure-hot electron researches by Koenig et al.[2] do indeed manifest findings along the lines of indicated expectations. Thus in the neighborhood of electric fields near 3000 v/cm small increases of ε in N-germanium were detected at 77°K when pressures up to $\sim 10^9$ dynes/cm^2 were impressed; according to Eq. (2), perceptible pressure effect becomes favorable for $\alpha P \gtrsim kT$. Numerically then, with $\alpha = +5\times10^{-12}$ ev/dyne/cm^2 and $P_{\max} = 5.2\times10^9$ dynes/cm^2, $\alpha P \sim 0.025$ ev which exceeds $kT \sim 0\text{-}0066$ ev ($T = 77°$K). Hence the theory appears in sensible agreement with these experimental observations.

Future studies of high pressure-hot electron interaction may be judiciously guided by the foregoing considerations. For example, in view of the negative coefficient for N-silicon $\alpha = -1.3\times10^{-2}$ ev, higher pressures and lower temperatures are called for to detect the anticipated decrease of ε. More generally, with recognition of the crucial role played by the free carrier density, it becomes of interest to explore the influence of impurity concentration, optical excitation, etc. It is conceivable that the presently advocated scheme for determining energy gap changes with hydrostatic pressure may lend itself to band structure exploration in less familiar semiconductors.
